CHAPTER
27

Endourology for Stone Disease

Janelle A. Fox and Michael C. Ost

EPIDEMIOLOGY

Over the past three decades, pediatric urologists have noticed a change in the epidemiology of pediatric urolithiasis, with transition from lower to upper tract stones, along with a rise in the incidence.[1] Both hospital admissions and population-based records seem to support this trend, although the etiology for the rise in stone incidence is not well defined.[2–4] Prior to 1990, urolithiasis was responsible for 1 in 1000 to 1 in 7600 hospital admissions annually throughout the United States.[5] Newer data derived from the Pediatric Health Information System (PHIS) database indicate that pediatric stone disease accounts for 57 per 100,000 (1 in 1,754) children seen annually at representative children's hospitals.[4] The public health impact of pediatric stones can no longer be ignored as a contributing factor to the $2.1 billion annual cost of urolithiasis.[6] Bush and colleagues found that pediatric stone disease accounted for 1 in 685 hospital admissions annually,[3] with regional variation among hospitals. Additionally, retrospective series from industrialized countries, including the United States, the United Kingdom, and Iceland, have echoed concern for a higher than expected incidence of pediatric stone disease.[7–9] The Icelandic series estimates an incidence of 5.6 per 100,000 children, most of which had metabolic abnormalities.[8] Studies from the United States also report frequently finding metabolic abnormalities during stone workup.[10] A 2003 study from the United Kingdom compared 5-year periods from the late 1960s to the late 1990s, noting a decline in infectious stones offset by a rise in metabolic-induced stones in children (Figure 27.1). Finally, a 40-year review from Japan revealed a rising incidence of urolithiasis in children and adults of all ages.[11]

ETIOLOGY

There appears to have been a stage migration from bladder stones to upper tract stones[12] of predominantly calcium content,[12–14] with concern that this is occurring as more countries adopt a Western diet high in salt and processed foods, with less water drinking. Endemic areas, such as Pakistan and Turkey, have previously estimated the prevalence of pediatric stones, including bladder stones, at 15% of children.[15] For such countries with endemic stone disease, the consequences are severe, accounting for 8% of cases of end-stage renal disease.[16] North American data suggest that predialysis urolithiasis is a more frequent occurrence than in age-, race-, and gender-matched adults, with an 8.3% prevalence compared with 2.6% in the general population.[17]

The incidence and prevalence of pediatric stone disease is consistently different by country. It seems unlikely that this rising incidence is secondary to poor diet or better detection, although both are certainly regional factors. Different cultures will have different stone types and patient demographics as an underlying pattern,[18] and many countries have reported that these patterns are changing over time. Adolescent females form a particularly at-risk subset for upper tract stone disease, whereas males often present in the first decade of life[19–22] (Figure 27.2). Studies evaluating differing hormone profiles by age and gender are not available in children, so the etiology for this difference is unclear. A few reports have attempted to link body mass index to risk of stone formation in children,[9,23] as obesity has tripled among U.S. children since the 1980s.[24] Analysis of urinary metabolites has shown higher rates of hyperoxaluria, hypocitraturia, and hyperuricosuria in obese children.[23,25] However, recent data refute a positive association of stone disease with obesity.[19,26,27] Further metabolic data exist to suggest that the rise in pediatric urolithiasis is due to factors other than obesity. Citrate levels and urine pH appear to be fairly constant when stratifying pediatric weight by adult BMI cutoffs,[28] and many researchers agree that calcium excretion appears more closely linked to dietary sodium and protein than obesity.[25,28] Hydration, fluid status, and consumption of sweetened beverages may contribute to rising stone disease in children, as beverage consumption transitions away from water and milk to soft drink consumption.[29–31] Dietary and lifestyle evolution likely play large roles, although environmental factors may contribute to rising stone disease. Brikowski and colleagues have offered mathematical models suggesting that stone prevalence will increase in the United States as annual temperatures rise due to cyclical variation or global warming, although this theory remains as yet unsubstantiated with clinical data.[32] Finally, one cannot discount the potential that stone diagnoses are more commonly made incidentally with the widespread availability of highly sensitive radiographic imaging, namely, noncontrast computed tomography (CT) scans. For example, the performance of CT scans for nephrolithiasis evaluation has increased almost 20% between 1999 and 2008.[4]

Certain cultures or geographic regions are known to have characteristic stone types, which may alter the selection of radiographic imaging, threshold for imaging,

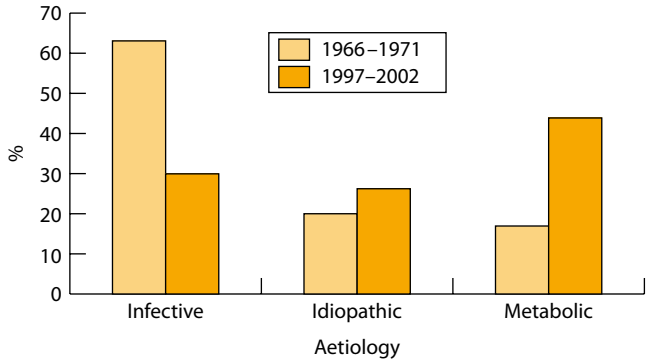

FIGURE 27.1 Data from the United Kingdom demonstrating a shift in the type of pediatric stone disease for the modern era, including a decline in infectious stones with a rise in idiopathic and especially metabolic-related calculi. (Reproduced from Coward R et al. *Arch Dis Child* 2003;88:962–5. With permission.)

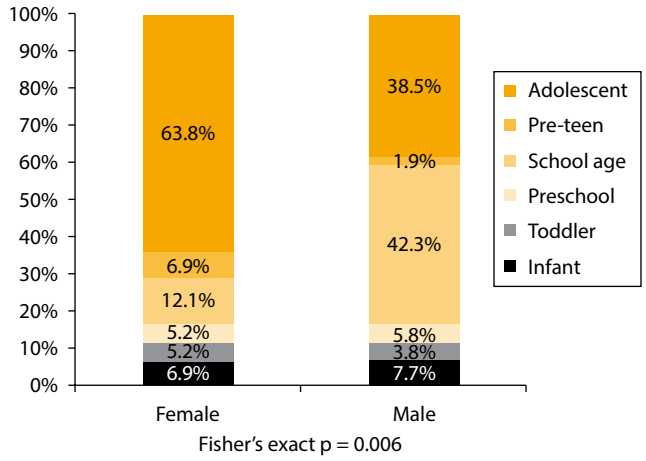

FIGURE 27.2 Data from the Children's Hospital of Philadelphia insurance records indicate a significant difference in the age of presentation for male vs. female children. Male children overall have a younger age at presentation, compared with female children, who often present during adolescence. (Reprinted from Kim S et al. *J Urol* 2011;186:1734–9. With permission.)

and treatment patterns. In Laos, bladder stones are a more frequent occurrence due to diarrhea and the early introduction of white rice, even in the neonatal period. Aboriginal children in Australia are predisposed to urate stones, often without underlying anatomic abnormalities. In such regions, chronic diarrhea can contribute to chronic metabolic acidosis, risking stone formation; one cause in young children is carbohydrate intolerance with enteric bacterial breakdown of sugars.[18] Regional variables may influence stone incidence. For example, in 2008 an outbreak of melamine-induced nephrolithiasis from contaminated infant formula occurred in China, affecting very young children. Melamine stones are thought to occur due to formation of a mesh network, which traps smaller acidic molecules in the urine and becomes trapped in renal tubules.[33]

EVOLVING TECHNIQUES

The management of upper urinary tract calculi has evolved dramatically in both adults and children in the last two decades. Smaller, more durable endoscopes and more effective lithotripsy technology have historically been adopted in adults prior to their acceptance in children. For both, minimally invasive techniques have revolutionized treatment and improved morbidity.

Since its introduction in the 1980s, extracorporeal shock wave lithotripsy (ESWL) transformed the management of pediatric upper tract calculus disease and remains very useful today. Other modalities of treatment, including ureteroscopy, percutaneous nephrolithotomy (PCNL), and combination treatment protocols, allow for flexibility in management. However, a consensus has not been reached as to the most effective and safe technique for upper tract urolithiasis, especially between ESWL and ureteroscopy. Despite the lack of compelling scientific data comparing these treatment methods in children, ureteroscopy has emerged in many centers as the first line of treatment. Given increased presentation of both simple and complex upper tract stones, the pediatric urologist must maintain a vast endourologic skill set and become familiar with constantly evolving minimally invasive technologies.

EVALUATION

Metabolic Workup

A metabolic stone evaluation is recommended for all pediatric first-time stone formers,[1] even in the context of underlying anatomic abnormality, such as ureteropelvic junction (UPJ) obstruction.[34] A complete metabolic blood profile and a 24-hour urine collection is obtained at least 1 month following stone treatment or upon stone diagnosis, depending on the urologist's preference. Unfortunately, there are no accepted standard reference ranges for 24-hour urine chemistries in the stone-forming pediatric population. Indeed, many pediatric urologists use adult standards to direct medical treatment because specific reference ranges are not readily available or require additional complicated calculations. Regrettably, there are significant differences between the normal ranges of urine chemistries in children and adults.[35,36] In addition, conflicting reports exist as to the commonality of metabolic disturbances in the presence of calcium-based stones.[13]

In the preliminary evaluation of pediatric stone disease, it is common to obtain 24-hour urine values for creatinine, sodium, calcium, oxalate, uric acid, and citrate. The very cumbersome nature of a 24-hour urine collection and the toilet training status of the child often limit accuracy and feasibility in the pediatric population. In light of this, random urine spot sample ratios have been used. Urine calcium–urine creatine ratios (Uca/Ucr), for example, have been used with sensitivities and specificities up to 90% and 84%, respectively, in the evaluation of hypercalciuria, a known risk factor for urolithiasis.[37] However, such a test is limited to one urinary metabolite and cannot be relied

on to monitor response to medical therapy. Furthermore, it is unreasonable to solely rely on urinary calcium excretion values as a proxy for overall metabolic disturbances.

It has been suggested that measurement of urinary supersaturation products (calcium oxalate and urate) may help to improve identifying those children at risk for stone formation. DeFoor et al. most recently determined that supersaturation levels of calcium oxalate, as well as calcium-to-creatinine levels, were significantly higher in children with stones than in controls.[38] However, this may have been reflective of differences found in urinary volumes. Lande et al. have demonstrated that low urine volumes in children often negate the benefit of pursuing urine supersaturation products in a stone workup.[39] Such conflicting data often confuse clinicians as to what urinary evaluation to pursue in the workup and management of pediatric stone disease.

Stone disease in the pediatric population has genetic, anatomic, metabolic, and dietary causes. There are numerous genetic causes of hypercalciuric nephrolithiasis alone that contribute to pediatric stone disease.[40] In this regard, the medical treatment always accompanies the endourologic management. *In order to fully treat the pediatric stone patient, there must be a focus on prevention through diet and medication monitoring. For this reason, the pediatric nephrologist is a critical player in the management and surveillance of these children*. Details regarding the metabolic workup and medical treatment of pediatric stone disease are beyond the scope of this chapter. Numerous pediatric nephrology resources are available. Alon provides an excellent pediatric nephrology review, including medication dosing by weight.[41] Litholink (www.litholink.com) is a commercially available 24-hour urine analysis, which stratifies risk profile for stone formation based on pH, volume, supersaturation profile, and concentration of lithogenic substances. However, 24-hour urine studies can be adequately performed through one's hospital with appropriate urologic or nephrologic counseling.

Imaging

Radiographic assessment of the child with calculus disease must be accurate, economic, and safe. *The goals of radiographic assessment include determination of stone location, size, density, and urinary tract anatomy*. Indications for assessment include acutely symptomatic children with a suspected calculus, or children with known calculus disease requiring follow-up evaluation to determine either stone burden or recurrence. Radiographic evaluation is also important in children with abnormal urinary tract anatomy that may predispose to calculus formation requiring eventual surgical management.

Radiographic imaging in children is unique in that a conscious effort is made to reduce the radiation burden during diagnostic workup. While older reports suggest that children present with classic renal colic only 50% of the time,[42] more recent reports suggest that abdominal and flank pain actually occur in the majority of children with stones. As no consensus exists on the optimal imaging regimen for a suspected urinary tract stone in a child, diagnostic imaging is typically the choice of the provider, with substantial provider variation.[4] *Initial screening with renal ultrasound or abdominal plain film alone, renal ultrasound plus abdominal film, or stone protocol CT is currently practiced*, with intravenous pyelography (IVP) having fallen out of favor. Brenner and colleagues penned a well-publicized 2007 review of the long-term radiation risks of CT in children in the *New England Journal of Medicine*, and since that time, the public has motivated clinical providers to reduce unnecessary CT exposure.[189] A contemporary large-scale retrospective review of more than 1 million pediatric emergency room records between 2003 and 2010 was the first to demonstrate a recent change toward decreasing CT utilization for commonly imaged areas of the body where alternative imaging, such as ultrasound, is available. Such was the authors' experience with reduced abdominal CTs for abdominal pain,[43] although this trend has not been specifically demonstrated for pediatric stone disease.

Unenhanced helical CT of the abdomen and pelvis to evaluate urinary tract calculi was first described in 1995 as the mainstay for calculus imaging in adolescents and adults.[44] Many, if not most, children with renal colic present to an emergency room, and *unenhanced helical CT is often performed as initial imaging for its efficiency and accuracy*. Typically, a thin-slice helical protocol is defined by narrow collimation ($\leq$5 mm). While calculi smaller than 5 mm can be missed between cuts, this is rare, with a reported sensitivity of 94%–99%.[45–48] In addition, CT also has the potential to rule out alternative diagnoses. *CT is also helpful in demonstrating secondary signs of acute obstruction, such as hydroureteronephrosis, renal enlargement, and perinephric or periureteric stranding; however, the latter findings may be less obvious or absent in pediatric patients due to comparably less retroperitoneal fat*.[49–51]

Passerotti et al. prospectively evaluated 50 children with both renal ultrasound and stone protocol CT scan, with blinded radiologic interpretation. Interestingly, although renal ultrasound was clearly less sensitive than CT at 76%, the majority of missed stones were 1–2 mm and within the kidney. The authors routinely recommend renal ultrasound, with the option of combined abdominal film and kidney, ureter, and bladder (KUB), as opposed to CT, as the first-line imaging modality. However, unenhanced stone protocol CT is recommended in cases where renal ultrasound quality is limited or diagnosis is uncertain, or for surgical planning of complex stone disease.[52] The cumulative effect of radiation exposure, the rising cost of healthcare, and the likelihood for stone recurrence in a young patient's lifetime must now be factored in, giving the pediatric urologist pause to consider how likely a CT is to change management decisions. Because children are at significant lifetime risk for recurrence of urolithiasis, the authors' reported 10 mGy unenhanced CT radiation dose can eventually multiply, potentially increasing the risk of future malignancy. Unfortunately, risk of radiation-induced malignancy is not a perfect mathematical model, and *there is no known threshold dose below which radiation exposure is safe*. The Biological Effects of Ionizing Radiation Panel VII (BEIR VII) report provides the existing data on the risks of ionizing radiation, based on available outcomes from Hiroshima and Nagasaki atomic

bomb survivors exposed to low-dose ionizing radiation of <100 mSv. Estimation of radiation-induced cancer risk is inherently flawed, however, given that no prospective, controlled epidemiologic studies exist to show adverse effects at radiation doses of <100 mSv.[53] Ultimately, close cooperation with our radiology colleagues can help to minimize radiation delivery to our pediatric patients when warranted.

Progress has been made in developing unenhanced CT protocols that minimize the radiation dosage while not compromising diagnostic information.[48,54,55] Experimental protocols utilizing anthropomorphic pediatric phantoms have been used in a number of studies to determine specific organ doses, calculate effective dose, and determine the lifetime attributable risk (LAR) for cancer incidence, and relative risk of cancer induction from a single scan under both standard- and low-dose modes.[56,57] Computer-simulated dose reduction has been useful in determining diagnostic thresholds in children with preserved accuracy of the CT scan.[58,59] *Perhaps most importantly, radiation exposure can also be reduced by limiting the number of CT examinations performed for weak clinical indications, scanning only the anatomic region of interest, and not performing both unenhanced and contrast-enhanced scanning unless absolutely necessary.*[60] For example, in a recent epidemiologic study by Routh and colleagues, 79% of children undergoing CT scanning as part of the workup for a stone episode had two or more studies performed. CT use was associated with older patient age, nonwhite race, and public insurance, but the treating hospital was the most important driver for CT use in children. Variability among hospitals for pediatric CT use was marked, ranging from 47% to 84%.[4]

Ultrasound is less accurate in the assessment of urolithiasis than CT, but it has the distinct advantage of no associated ionizing radiation. Therefore, ultrasound should be considered a screening tool in the workup of pediatric abdominal or flank pain. In the *acute setting*, when the child initially becomes symptomatic, ultrasound may miss migrating ureteral stones; however, it is very sensitive once hydronephrosis develops. The sensitivity of pediatric ultrasound for stone detection is 59%–78%, with up to 100% specificity.[47,52,61] Similar results have been reported in adults.[62,63] Many ultrasound proponents agree that ultrasound should be used in conjunction with KUB, given its added sensitivity for radiopaque stone detection. Symptomatic children with a known history of renal urolithiasis, or children on observation protocols, should typically be reevaluated with ultrasound and KUB to minimize cumulative radiation exposure.

Fluoroscopy has an important role in the real-time detection and management of urolithiasis in children, and the same important safety concerns exist with respect to radiation exposure as for CT. C-arm fluoroscopy is utilized in the surgical setting to assist in antegrade percutaneous access of the upper urinary tract and retrograde access of the lower urinary tract. Manipulation of endoscopic instruments in vivo often requires fluoroscopic monitoring. Fluoroscopy is also used during ESWL to assist in stone localization and monitor the effectiveness of treatment. Urologists must have a working understanding of the principles of fluoroscopy and be aware of the intraprocedure fluoroscopy time and energy settings to limit radiation exposure to both the pediatric patient and operative staff. Important variables, which will impact the dose of patient radiation when using fluoroscopy tables or C-arms, are the distance from the patient to the radiation source, gating down to the area of interest, pulsed instead of continuous dosing, and lead shielding of sensitive organs (gonads, thyroid, and breast tissue). In a recent prospective study from the Children's Hospital of Boston, dose rate settings were higher than recommended in 43% of cases and better C-arm positioning had the potential to reduce ionizing radiation exposure by 14%–49%.[64] Pediatric urologists should be cognizant of fluoroscopy time used and radiation source settings from the beginning of each case, especially since maintenance protocols and default settings are often not governed by the surgeon. Excellent reviews exist for the urologist and should be studied for both patient and personal safety when using fluoroscopy.[65,66]

CONSERVATIVE MANAGEMENT

Conservative management of pediatric nephrolithiasis is considered first-line treatment provided there is no evidence that an obstructing stone is harboring an infection or a child is failing to thrive as the result of his or her stone disease. Clinical scenarios, including fever, anorexia greater than 24 hours, persistent nausea and vomiting, and/or pain refractory to conservative measures, prompt endourological intervention. In the instance of a stone in a solitary kidney, early intervention over conservative treatment is favored. The same data are not available in children as in adults to determine the average time and likelihood of stone passage stratified by size. Small retrospective series suggest stones 4–6 mm or larger are likely to require endourologic treatment.[67,68] Interestingly, younger patients tend to present with renal stones, as opposed to older children, who present with ureteral stones,[13,42,47,69] often with larger stone burden. Larger, more proximal stone burden can negatively impact the likelihood for passage in young patients,[68] although studies of a similar stone burden using age 10 years as a cutoff failed to find a difference in spontaneous passage rates for younger versus older children.[69] The pediatric ureter is remarkably elastic for its small size, perhaps even more than the adult ureter.[70]

There have been many studies in adults evaluating the efficacy of medical expulsive therapy to facilitate distal stone passage. Use of alpha-antagonists, calcium channel blockers, and steroids has been shown to be effective. Based on the efficacy demonstrated in the adult population,[71] alpha-receptor antagonists, such as tamsulosin, may be offered on an individualized basis as adjunctive therapy to facilitate ureteral expulsion in children. A randomized prospective clinical trial recently completed in Egypt compared tamsulosin (0.4 mg for children 4 years and above, 0.2 mg if less than 4 years) to analgesic alone, finding enhanced stone-free rates of 87% versus 64% by 4 weeks for stones up to 1.2 cm.[72] Safety data concerning adult dose tamsulosin in children are only starting to become available, with this study demonstrating no increased rate of side effects.[72] Prior studies

of tamsulosin in pediatric nonneurogenic dysfunctional voiding also failed to demonstrate any adverse effect on blood pressure.[73] Some argue against the utility of medical expulsive therapy in children. For example, a Turkish study administering 0.03 mg/kg of the alpha-antagonist doxazosin versus analgesic alone did not demonstrate superior expulsive results with regard to distal ureteral stones up to 10 mm in children 2–14 years of age; this study was limited by the small number of overall patients who passed stones.[74] If a child fails a trial of spontaneous passage and definitive endourologic therapy cannot be accomplished immediately, a stent is placed and lithotripsy is delayed 2–4 weeks to allow for passive ureteral dilation, resolution of edema, and clearance of any infection, if present.

MANAGEMENT OF UPPER URINARY TRACT CALCULI

Pediatric Considerations

Special considerations in the endourologic management of stone disease in children include preservation of renal development and function, prevention of radiation exposure, and minimizing the need for retreatment. Despite advances in endourologic equipment and technique, controversy remains regarding the causality of diabetes or hypertension from ESWL, and whether ureteral orifice dilation during ureteroscopy leads to ureteral stricture formation or development of vesicoureteral reflux. International consensus is lacking as to the most effective surgical management of pediatric stone disease due to the lack of prospective randomized trials comparing treatment modalities and disparity in the access to emerging technologies.

Studies on stone fragment clearance suggest enhanced early stone fragment passage following ESWL for children with renal stones ranging from 1 to 2 cm in size (but not more than 2 cm), when compared with adult counterparts.[70] In contrast, Afshar et al. have demonstrated that residual stone fragments (RFs) of <5 mm in size are associated with adverse clinical outcomes in 69% of 26 affected renal units (stone growth, symptoms, or stone recurrence).[75] *Therefore, the surgeon's goal with pediatric urolithiasis is stone-free status*. Surgeon experience is paramount to facilitate complete stone clearance and minimize retreatment rates. The decision regarding the most efficacious primary treatment modality must be individualized per child based on age, anatomy, location, and composition of stone burden.

Antibiotic Use

In line with the 2008 American Urologic Association best-practice statement on antibiotic prophylaxis, ≤24 hours of perioperative antibiotics is indicated in all patients undergoing upper tract instrumentation.[76] In children, appropriate agents include trimethoprim-sulfamethoxazole, first- and second-generation cephalosporins, and ampicillin in combination with an aminoglycoside. A urine culture is mandatory before all upper tract procedures to determine if the urine is sterile, and culture results are used to guide preoperative antibiotic therapy, particularly for percutaneous procedures, patients with high-grade obstruction, or patients with an indwelling stent.[77] In our practice, children with a negative urine culture undergoing uncomplicated ureteroscopy (URS) procedures receive perioperative cefazolin, and all children undergoing a percutaneous procedure or who have a preexisting ureteral stent or nephrostomy tube receive a fluoroquinolone or ampicillin or gentamicin. Use of postoperative antibiotics is controversial and is determined on an individual child basis, especially with recent data demonstrating an increased risk of developing resistant bacterial strains with prolonged use of prophylactic antibiotic therapy.[78] Fluoroquinolones are often safely used in children, but the side effect profile can be serious due to the proposed destructive effect on collagen and connective tissue fibers in weight-bearing joints.[79] Cartilage abnormalities have been identified in juvenile animals after quinolone use, as well as increased rates of arthralgia in children compared with controls 1 year following quinolone administration (3.4% vs. 1.8%, respectively).[80] Currently, fluoroquinolones are routinely used for pediatric indications of *Pseudomonas aeruginosa* infections, beta-lactam and macrolide-resistant otitis media, resistant gram-negative infections, and bacterial meningitis.[81] Fluoroquinolones are not contraindicated in children, but parents should be counseled on theoretical cartilage damage and arthralgia if electing their use.

SHOCK WAVE LITHOTRIPSY

The emergence of shock wave lithotripsy (SWL) revolutionized the minimally invasive treatment of adult urolithiasis during the early 1980s. Since the initial report of successful SWL use in children in 1986,[82] large series have reported complication, safety, and stone-free rates comparable to those of adult cohorts[15,83–89] (Table 27.1). When used as a primary treatment option for upper tract calculi, SWL efficacy ranges from 68% to 84%.[15,35,83] SWL has been a preferred treatment modality for uncomplicated renal and proximal calculi of ≤15 mm in the pediatric population. In a contemporary series of 216 children (mean age 6.6 years) with a mean stone size of 14.9 mm undergoing SWL with the Dornier HM3 lithotriptor, Landau et al. reported a 3-month stone-free rate of 80%, demonstrating that efficacious stone-free rates can be achieved in appropriate candidates.[94] *Although retreatment rates are high, complications are typically low, with severity ranging from hematuria and ecchymosis to obstruction with sepsis*.[95]

Although well tolerated in children, current stone-free rates with SWL are difficult to interpret from the existing body of data due to discrepancies between studies with regard to type of lithotriptor, number of shocks administered, and retreatment rates. *Recent data suggest that stone-free rates in children with a history of urologic condition or urinary tract reconstruction are quite low (12.5%) and with alternative surgical techniques available, these children may be better served with URS or PCNL*.[91] Despite encouraging results, SWL has not been

approved by the Food and Drug Administration for use in children, although it is a widely accepted treatment modality.

SWL Technique in Children

General anesthesia is administered in a majority of smaller children to avoid both patient and stone motion, and the need for repeated repositioning. With modern lithotriptors, intravenous sedation has been successfully employed in select older children.[96] Bowel preparation is seldom utilized to avoid dehydration and electrolyte imbalance postoperatively. The number of shocks delivered and the kilovoltage used vary per lithotriptor, but the current consensus is that low-power settings (17–22 kV) be used to prevent stone migration during the procedure, with 3000 shock waves per session (<2000 in very young children).[95] A recent report assessed and compared the

number and intensity of shock waves required for stone fragmentation in 44 children (mean age 5.9 years) and 562 adults (mean age 40.9 years). With an equivalent number of sessions (1.1 vs. 1.1), the mean number of shock waves (950 vs. 1262, $p < 0.001$) and the kilovolts required (11.8 vs. 12.4, $p < 0.001$) were significantly reduced in the pediatric cohort.[97]

Whether or not to place a ureteral stent prior to ESWL in children remains a controversy and a matter of personal preference. A meta-analysis of eight adult SWL trials suggests ureteral stenting may reduce the rate of Steinstrasse, although overall stone-free rates were not improved and lower urinary tract symptoms were worse.[98] Data are inconclusive in children, but the pediatric ureter is believed to better expel stone fragments after SWL, and in children, well-tolerated Steinstrasse fragments may be conservatively managed. Although prestenting rates are not consistent across series, *current relative indications include cases of solitary kidneys, staghorn calculi, large ureteral calculi, obstruction, or abnormal anatomy and are not based on total stone burden*. Ureteral catheters that can be used for retrograde opacification are occasionally placed immediately prior to SWL to aid in the localization of radiolucent calculi.

Stone Size, Location, Composition, and Patient Age

While early series focused primarily on the feasibility, safety, and efficacy of SWL in children, recent efforts have centered on identifying demographic, anatomic, and stone-related prognostic factors for treatment success. Onal and colleagues have recently constructed a nomogram based on Turkish children to assist pediatric urologists in predicting stone clearance following SWL, although this has not been externally validated. Multivariate analysis revealed younger age, female gender, lower stone burden, and lack of prior ipsilateral stone treatment to be positively associated with stone clearance.[99] SWL is currently considered the primary treatment modality of choice for upper tract calculi of ≤15 mm in children,[95] but evidence supporting this stone size cutoff is lacking. Ather and Noor, for example, analyzed the correlation between stone size and clearance in 105 children younger than 14 years of age. They reported an overall stone-free rate of 95% after a mean of 1.7 SWL treatments; 5% of patients required additional procedures as adjuncts to SWL. In this cohort, the mean stone size in the treatment success group was 14 mm, compared with 16 mm in the treatment failure group.[86] In a larger series of 150 children, Habib and colleagues recently found that larger stone size was significantly associated with SWL failure and retreatment; stones of >3 cm failed 66.7% of the time, and stones of >1.35 cm accounted for 80% of the failures.[90] In contrast, Elsobky et al. reported a 91% stone-free rate versus 75% stone-free rate for mean stone diameters of less than and greater than 10 mm, respectively.[84] Recently, Shouman et al. reported on a series of 24 children with a mean stone size of 31 mm undergoing SWL with the Dornier DoLi S device. In 53 sessions requiring a mean number of 3489 shock waves per session, stone-free and complication rates were 83.3% and 25%, respectively.[100] *While it is possible to treat very large stone burdens with SWL, concerns include the necessity of more shock treatments, more frequent retreatment sessions, and an increased risk of postoperative obstruction*. Further study delineating a clear size cutoff for uncomplicated upper tract stone burden is required to effectively counsel parents regarding the most effective first-line therapy for renal calculi between 1 and 1.5 cm.

Renal anatomy and stone location has been the subject of recent interest. Badawy and colleagues have suggested that prior urologic surgery and ureteral stones of >1 cm are associated with lower SWL success rates, potentially benefitting from other forms of surgical management.[101] Previously operated urinary tracts (for UPJ obstruction and ureterovesical junction [UVJ] surgery) were found in 16 of the 19 (84%) renal stones failing SWL in this series, which is echoed in other reports.[91] The subject of frequent debate in the adult population, the most effective management of lower-pole calculi in children has yet to be determined. Stone-free rates from initial small retrospective SWL series range from 56% to 61%,[102,103] with retreatment rates as high as 40%.[103] *SWL failure and the need for retreatment were associated with increased mean stone burden,*[103] *increased infundibular length,*[102] *and an infundibulopelvic angle of greater than 45°.*[102]

Staghorn calculi are uncommon in children and represent a management challenge. Although monotherapy success rates are low in adults, acceptable stone-free rates in children have been achieved with SWL. In 23 children stratified by age with a mean stone burden of 1.6 cm, Lottmann et al. reported an overall stone-free rate of 82.6%, with only one case of symptomatic obstruction. A ureteral stent was placed in 22% of children, and these authors reported an 88% stone-free rate in children less than 2 years of age compared with 71% in children aged 6–11 years.[104] In 42 children with a mean stone burden of 3.2 cm stratified by ureteral stent placement, Al-Busaidy et al. reported an overall stone-free rate of 79%. While stent placement did not affect stone-free rates, they found that stent placement significantly reduced the major complication rate.[105] *The superior success rates with SWL monotherapy in children compared with adults have been attributed to softer stone composition, smaller relative stone volume, increased ureteral compliance to accommodate stone fragments, and smaller body volume to facilitate shock transmission.*

SWL safety and efficacy have been demonstrated even in very young children. McLorie et al. treated 34 children younger than 3.5 years old (mean age 23 months) and reported an 86% overall stone-free rate (66% after one treatment) without major complications.[106] Some authors suggest that proximal ureteral stones have success rates similar to those for renal stones in pediatric series,[83,91,107] although others report reduced treatment success for all levels of ureteral stones.[101] Treatment of mid- to distal ureteral calculi had been historically avoided in children due to difficulties with localization over the sacroiliac joint and concern regarding possible injury to developing reproductive systems. The greater and lesser sciatic foramina have been utilized as a blast path to treat distal stones in children with success rates of 77% and 100% at 2 weeks and 3 months, respectively, in 22 children, with a mean distal stone burden of 6.8 mm.[108]

SWL success by stone composition is similar between the adult and pediatric populations. Cystine stones are uniquely challenging due to their durability and high recurrence rates; however, calcium oxalate monohydrate, brushite, and matrix stones also have less favorable response rates to SWL.[109] While SWL monotherapy has demonstrated variable results in adults, there are few reports in the pediatric population. In a small recent series, Slavkovic et al. reported a 50% stone-free rate in six children with cystine stone burden ranging from 2 to 2.5 cm. Although stone-free rates were low, fragmentation was achieved in 100% of patients and the stone dissolution was achieved with medical therapy in the remaining children following SWL.[110] Cystine stones formed within 2 years of therapy may be more easily fragmented with SWL, and stone number, rather than diameter, may better predict success.[95]

Additional factors to optimize the success of stone clearance with SWL include reducing the shock wave rate, improving acoustic coupling, power ramping (gradual increases in kilovolts), and utilizing dual-energy CT for stone composition.[109,111,112] Lingeman et al.[112] reported on several methods currently under investigation to improve the efficiency of SWL, including improvements in lithotriptor technology and lithotripsy technique. The former includes acoustic tracking for stone targeting, feedback to ensure adequate acoustic coupling, assessment of stone breakage, transcutaneous focused ultrasound to help clear RFs, and employing wider focal zones. *Regarding technique, it seems that minimizing both the total shock wave dose and rate is prudent to limit renal injury, especially in children*. To enhance efficacy, the pediatric urologist should optimize acoustic coupling by eliminating air pockets between the patient and treatment head, which can reflect 99% of shock waves. Historically, a water bath was used for the Dornier HM3, and a partial water bath is still used for the Storz SLX (Storz Medical, Tägerwilen, Switzerland); gel is the most common interface of other devices.[112]

Limitations and Concerns

In children, there is currently no consensus regarding the maximum size of RFs that are considered clinically significant,[77,95] and as a result, there is no clear definition as to what constitutes "stone-free" status. While children have been shown to have a greater capacity to clear fragments than adults,[70] the presence of RFs has been correlated with adverse clinical outcome.[75] Afshar et al. followed 26 renal units with RFs of $\leq$5 mm and reported that while 31% were asymptomatic with no fragment growth, 69% had adverse clinical outcomes, including RF growth or clinical symptoms. Patients with RFs had a significant increase in adverse clinical outcome compared with stone-free subjects, and the presence of metabolic disorders was associated with RF growth.[75] For these reasons, metabolic evaluations are now routinely being performed in children with a history of calculi, and every attempt should be made to achieve stone-free status.

Although SWL is well tolerated in children with few complications, stone-free rates following single-session monotherapy can remain as low as 44%.[85] As a result, children are subjected to multiple treatments requiring general anesthesia.[96] *The need for multiple treatment sessions is concerning since the long-term effects of shock waves on renal tissue are unclear*. In adults, shock waves may result in renal vasoconstriction with renal tubular injury and subcapsular hematoma from cavitation and shear forces, which are dependent on the kilovoltage applied.[113] In 2006, a large retrospective series of 340 adult patients with a mean follow-up of 19 years post-SWL raised initial concern regarding increased risk of hypertension and diabetes mellitus due to incidental shocks to the pancreas.[114] However, since that time investigators from the same group at the Mayo Clinic reevaluated both questions of increased diabetes and hypertension risk with a population-based cohort study via the Rochester Epidemiology Project. This more recent study found no association between SWL and subsequent development of either disease.[115] Janetschek et al. found that development of hypertension in their retrospective series was highly correlated with disturbances in renal perfusion, as measured by elevated resistive indices, and this risk was purely age dependent, essentially confined to patients over 60 years old.[116] Additionally, rat and rabbit ovaries have been evaluated following shock wave therapy, finding no histopathologic, apoptotic, or reproductive impairment.[117,118] Animal testes exposed to shock waves do appear to undergo early histologic changes with vascular congestion and focal hemorrhage; however, these changes appeared reversible with time and did not impact function as assessed by hormone levels and fertility.[119] Adult male rabbits exposed to 2000 shock waves were found to have vacuolization of Sertoli cells, but no changes in sperm morphology up to 1 week postintervention.[120] Long-term disease evaluation following SWL is extremely limited in children, but thus far adult studies do not associate SWL with long-term renal, gonadal, or pancreatic impairment.

Existing data have failed to demonstrate significant renal scarring or functional impairment in pediatric kidneys post-SWL. Retrospective evaluation of 14 children following SWL and PCNL did not find renal morphologic or functional impairment when measuring glomerular filtration rate (GFR) and serial radionuclide (dimercaptosuccinic acid [DMSA]) scans at 3 and 6 months postintervention. While three children had preexisting renal scars, importantly, no new renal scars occurred.[121] A larger Spanish study of 18 children undergoing exclusively SWL demonstrated a majority of children did not experience long-term renal scarring, as measured by radionuclide scintigraphy (DMSA); 1 child had impaired ipsilateral renal growth and reduced tubular function after a three-staged procedure.[122] Recent prospective, controlled evaluation by Fayad and colleagues compared renal growth with renal ultrasound–measured bipolar length during the first year after SWL. No difference was found between children undergoing SWL and those who had no renal procedure at both 6 months and 1 year follow-up; further analysis revealed that neither age, number of SWL sessions, or number of stones altered that outcome.[123] In addition, Sarica et al. followed 35 children with blood pressure checks every 6 months, finding no adverse impact on pediatric hypertension or renal parenchyma as measured by renal ultrasound.[124] Finally, an animal model,

which utilized immature, 7-week-old rabbits undergoing SWL, failed to demonstrate renal growth impairment, although mean arterial pressure and histologic changes were found in adulthood.[125]

URETEROSCOPIC MANAGEMENT OF UPPER URINARY TRACT CALCULI

The indications for primary ureteroscopic management of upper tract calculi in children have significantly expanded. Increasingly smaller versions of endourologic instrumentation and the holmium:YAG laser make treatment of calculus disease throughout the entire pediatric urinary tract safe and effective in the acute setting. Adoption of ureteroscopy in the treatment of pediatric upper tract calculus disease lagged behind the adult experience because of concerns regarding large ureteroscope caliber causing greater complications in children. However, evolving experience with pediatric ureteroscopy and recent large retrospective series have reported enhanced stone-free rates and similarly low complication rates when compared with SWL, validating it as a staple in children.

Indications

Since the mid-1980s, with the acceptance of SWL as the primary therapy for upper tract calculi of <1.5 cm, ureteroscopy has been historically utilized for calculi below the iliac crests, and for upper tract calculi after SWL failure.[77] Ureteroscopy was not considered primary therapy for upper tract stones in children due to complications from ureteral ischemia, perforation, stricture formation, and development of vesicoureteral reflux as a result of dilation of small-caliber ureteral orifices.

With significant improvements in both the miniaturization and durability of endoscopic equipment and the acceptance of the holmium laser, ureteroscopy has become a more attractive option in young children. Early series using rigid ureteroscopy for distal stones reported stone-free rates ranging from 86% to 100% with minimal complications (Table 27.3).[15,67,126–131] Children randomized to either ureteroscopy or SWL as primary therapy for distal ureteral stones were reported to have a significantly higher stone-free rate after one treatment (94% vs. 43%) for those treated with ureteroscopy.[128] Another group reported experience using 4.5, 6, and 8 Fr rigid ureteroscopy in treating proximal ureteral stones, with a mean age of 10.7 years. Ureteral dilation was not performed in any of the cases, and 100% of children were rendered stone-free.[132] *The results of these retrospective studies have begun to refute the notion that dilation of the pediatric ureter will result in vesicoureteral reflux or the development of ureteral strictures.* In a systematic review of the literature encompassing 221 pediatric ureteroscopies, Schuster et al. noted only two ureteral strictures and a low incidence of vesicoureteral reflux.[127] Newer 4.5 Fr semirigid ureteroscopes, with working ports that accommodate 2.4 Fr endosurgical instrumentation, extend the versatility of managing distal ureteral calculi in most pediatric patients without predilation.

Standardization in the treatment of distal calculi in children has led a number of centers to expand ureteroscopy to the treatment of upper tract calculi (Table 27.2). Comparable stone-free rates approaching 100%, with complication rates similar to those of the adult population, have recently been reported.[130,132,136–138] Smaldone et al. reported a 91% stone-free rate with a mean follow-up of 10 months in a series of 100 children with a mean stone diameter of 8.3 mm, 52% of which had upper tract calculi. Nine percent of these children underwent staged procedures. They reported a 4.2% perforation rate managed with ureteral stenting and one distal ureteral stricture requiring open neocystostomy.[136] Corcoran et al. reviewed a cohort of 47 children (mean age 9.4 years) with upper tract calculi managed with flexible ureteroscopy and holmium laser lithotripsy. An 88% stone-free rate with a mean stone burden of 10.2 mm was reported, with 26% requiring staged procedures.[138] *These authors concluded that because of improved ureteroscopic access to the pediatric upper tract, calculi up to 15 mm were safely and as effectively treated in children as adults.* Even with outstanding pediatric ureteroscopic technology, pediatric ureters may require a period of stenting prior to embarking on endoscopic treatment. For example, a smaller-caliber ureter, resistant to instrumentation, may be passively dilated with an indwelling stent over 2–8 weeks (Figure 27.3).

Adoption of techniques utilized in the adult population, most notably sequential coaxial and balloon dilation of the ureteral orifice and use of ureteral access sheaths, has further facilitated access to the pediatric urinary tract. Initially described in eight children by Singh et al.,[139] ureteral access sheaths have been shown to facilitate repetitive upper tract access, reduce intrarenal pressures, decrease operative time, and improve stone-free rates in adults. Access for the treatment of lower-pole calculi is possible with the use of ureteral access sheaths and a 6.9 Fr flexible ureteroscope, a stone location that would have previously required SWL or PCNL. Cannon et al. reported a 76% stone-free rate in 21 children with lower-pole calculi and a mean stone diameter of 12.2 mm. After a mean of 11.4 months, no major complications were observed.[137] *Therefore, many centers are transitioning from SWL to ureteroscopy for both safety and lower retreatment rates. Current relative contraindications to ureteroscopic management include staghorn stones in recurrent stone formers, anatomic anomalies making retrograde access difficult, and previous endoscopic failure.*

Equipment

Having an updated and well-stocked system that is familiar to the operative staff is vital to efficient management. It usually falls on the nursing staff to care for the delicate instruments and keep up on repairs so that the instruments are operational when needed; maintenance is often needed after 20–30 uses. A "basic" ureteroscopic kit is listed below; however, variation exists based on manufacturers. Various arrays of semirigid and flexible pediatric ureteroscopes, in addition to ureteral access sheaths, are available from numerous companies.[140] In general, semirigid ureteroscopes usually have a 2.4–3.5 Fr working port (Figure 27.4), and flexible ureteroscopes a 1.8–3.5

Abbreviations: EHL, electrohydraulic lithotripsy; R, renal; U, ureteral; LP, lower pole.

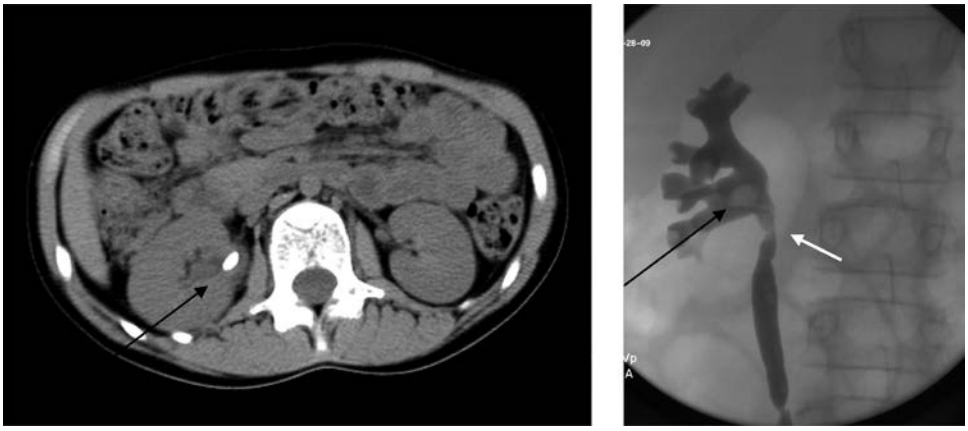

FIGURE 27.3 CT scan and retrograde pyelogram in a 10-year-old female with glucose transport deficiency demonstrating a 9 mm renal pelvic stone (black arrows). A metabolic defect was identified: hypocitraturic hypercalciuria. Primary ureteroscopy could not be accomplished due to a narrowed segment of the proximal ureter (white arrow) from stone-induced edema, but was successful after 8 weeks of ureteral accommodation with an indwelling stent.

Fr working port (Figure 27.5). With flexible ureteroscopes, deflection of the distal tip up to 270° can facilitate access to most lower-pole stones. Deflection can be limited with instruments placed in the working channel; therefore, use of smaller baskets (1.9 Fr nitinol) and laser fibers (200 μm) will improve lower-pole renal access.

Ureteroscopes
- 6.9 Fr flexible ureteroscope
- 4.5 and 6.5 Fr semirigid ureteroscopes

Endourologic equipment
- Guidewire array: 0.035 sensor, 0.018–0.025 straight or angled glidewire

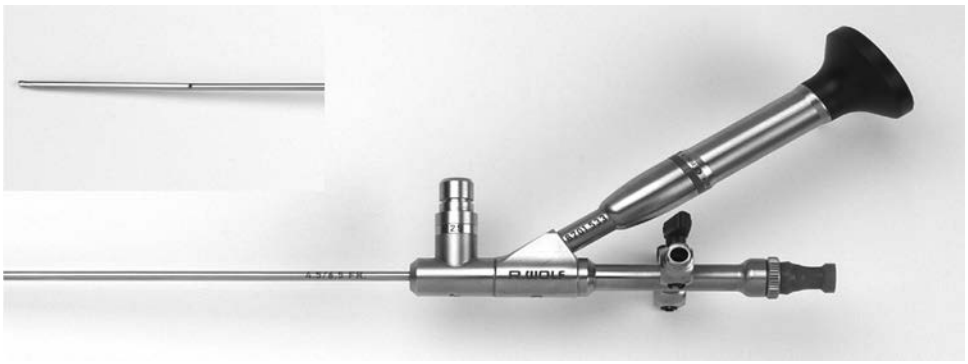

FIGURE 27.4 Pediatric semirigid self-dilating ureteroscopes may be used for rigid ureteroscopy in toddlers. A 4.5 F distal beak (inset) allows easier passage to facilitate dilation with the 6.5 F proximal component. (Picture provided by Richard Wolf. Copyright © 2012, all rights reserved.)

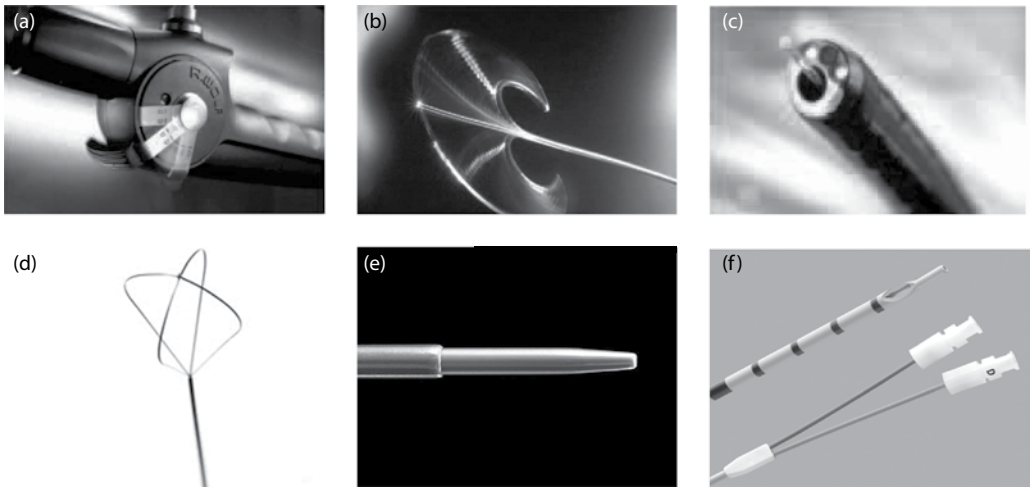

FIGURE 27.5 (a and b) Flexible ureteroscopes are capable of thumb-controlled, biplanar 270° deflection. (c) Working channels from 1.8 to 3.6 Fr can accommodate working elements, such as a Ho:YAG laser fiber. (d) Nitinol zero-tip baskets ranging from 1.9 to 3.2 Fr impair deflection of flexible ureteroscopes the least, with minimal risk of mucosal injury. (e) Coaxial 8 Fr inner/10 Fr outer dilator set (tip shown) passively dilates, and also calibrates, the ureter to facilitate ureteroscopic sheath placement. (f) A dual-lumen catheter allows safe passage of two wires (working and safety wires) into the renal pelvis with passive ureteral dilation to 10 Fr. (Picture provided by Richard Wolf. Ureteroscopic Technique in Children

All ureteroscopic procedures are performed under general anesthesia with paralysis to prevent patient movement and minimize the risk of ureteral perforation. Occasionally, expeditious stone extractions for predilated patients or distal ureteral stones require deep anesthesia but not paralysis. Close communication with anesthesia regarding the expected duration of the procedure is essential. When clinically appropriate, a urine culture should be confirmed prior to surgery. First- or second-generation cephalosporin antibiotic prophylaxis is administered within 30 minutes of procedure start, although an oral fluoroquinolone or sulfamethoxazole-trimethoprim is acceptable. Patients are placed in the lithotomy position, and rigid cystoscopy is performed with a 7.5, 11, or 18 Fr cystoscope for infant, school, or adolescent ages. This allows the surgeon to inspect the bladder for stone passage and anatomic variant, and to perform a retrograde pyelogram. A safety wire (typically 0.035 sensor) is placed under fluoroscopic guidance. Wires of 0.018- to 0.038-inch diameters exist, with either polytetrafluoroethylene (PTFE) or nitinol coating. Nitinol is a nickel-titanium alloy exhibiting excellent shape memory and elasticity at body temperatures, making it safe in the delicate pediatric ureter. Nitinol's hydrophilic properties are what allow the tip of sensor wires or glidewires to access tortuous ureters. Glidewires have so much "slip" that they require handling with a moist sponge to prevent loss of the wire and are not recommended as safety wires for this reason; safety wires typically have an inner

stainless steel core for stability and outer PTFE coating to reduce friction of instrument passage. Infants typically require passive dilation over a number of weeks with a 3.7 Fr ureteral stent, placed using the supplied 0.018 guidewire, prior to any ureteral manipulation. Initial ureteral orifice dilation is performed under C-arm fluoroscopic guidance with a 8 Fr inner/10 Fr outer diameter (8/10 Fr) coaxial dilator, ureteral dilator set (6–14 Fr), or 10 Fr dual-lumen catheter if the patient has not had a period of prestenting. Balloon dilation of the orifice is reported but remains controversial, due to anecdotal cases of ureteral strictures or de novo vesicoureteral reflux, and is based on surgeon preference.[130] It is the authors' preference to avoid balloon dilation anywhere along the ureter, and if encountering difficulty with passage of an 8/10 Fr coaxial dilator, our preference is then to place a stent and return for ureteroscopic completion. In our practice, as has been established by others, stent length (cm) is typically determined by "Age + 10" until adolescence, at which point cross-sectional imaging (if available) is helpful in measuring radiographic length from the renal pelvis to the bladder trigone. Data on stent tolerance in children are extremely limited. Although Hubert and Palmer reported no bladder spasms in their retrospective cohort of 26 children (age 14 or less),[141] Wang and colleagues indicate that 32% of their 96 children had stent-related symptoms sufficient enough to call the surgeon's office after ureteroscopic treatment.[142] In the authors' experience, stent-related symptoms worsen with increasing age, most notably in adolescence.

The decision to use a flexible (6.9 Fr) or semirigid (7.5 Fr) ureteroscope is made based on size and location of the stone, anatomic factors, and individual surgeon preference. Rigid or semirigid ureteroscopy for ureteral calculi is routinely performed with a safety wire in place, while flexible ureteroscopy is performed with both a safety and a working wire in place. Ureteral access sheaths (internal diameter of 9.5, 11, or 12 Fr; outer diameter of 11, 13, or 14 Fr) are routinely utilized to facilitate flexible ureteroscopy, especially in cases of large proximal ureteral stones and heavy renal pelvis stone burdens. *Access sheaths may also serve to facilitate flexible ureteroscopy when altered anatomy or tortuous ureters are encountered* (Figure 27.6). Advances in flexible ureteroscope have resulted in improved image quality to ensure better stone clearance, especially with the transition from fiber-optic to digital imaging in 2007 with the Gyrus ACMI®. Since that time, Olympus has produced the URF-V and Storz the Flex-X. The Storz Flex-X flexible ureteroscope has a maximum diameter of 8.5 Fr, is the smallest flexible ureteroscope available at this time, and passes easily through the smallest ureteral access sheath (9.5/11 Fr). This makes flexible ureteroscopy through even infant ureters feasible (Figure 27.7).

Irrigating fluid, which may be used under pressure, should be isotonic and kept at body temperature to avoid hyponatremia and hypothermia. Flow will be limited through the 11 Fr access sheath. Calculi are basket extracted when feasible or fragmented using the holmium:YAG laser to facilitate removal. *The decision to place a ureteral stent postoperatively is made based on the duration of the procedure, number of passes with the ureteroscope, and degree of visible ureteral trauma or edema at the conclusion of the procedure.* If the child can tolerate leaving a urethral string in place for 3 days to 1 week, the patient's parents are asked to remove the stent at home. If left in place for greater than 1–2 weeks, the dangle is removed from the stent (due to theoretical risk of pyelonephritis and possible stent dislodgement) and the stent is subsequently removed with a brief anesthetic.

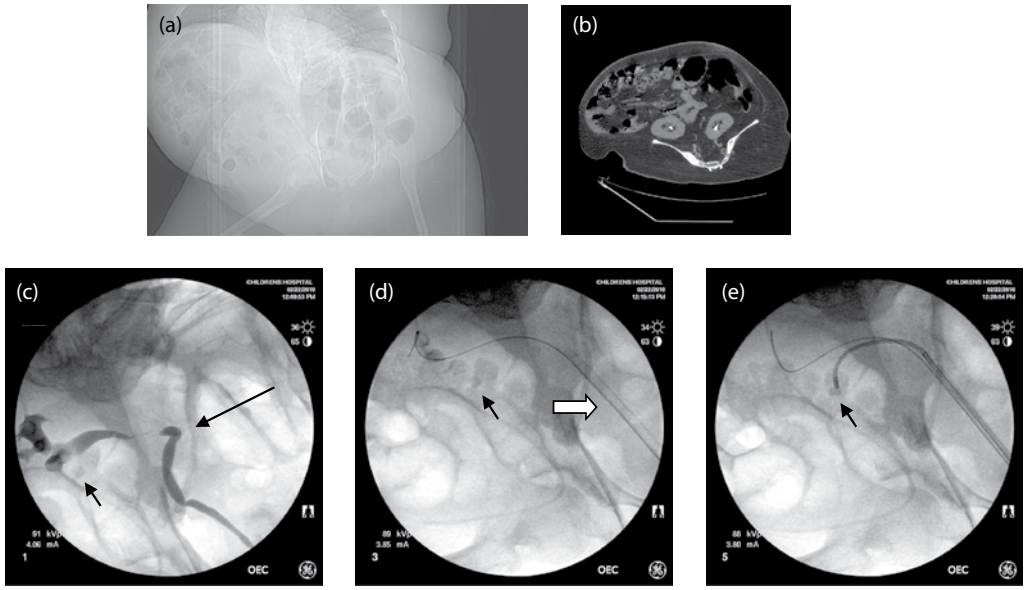

FIGURE 27.6 Altered anatomy in a 17-year-old male spina bifida patient who underwent a high thoracic myelomeningocele closure at birth (a). A CT scan performed for a gross hematuria workup revealed bilateral nephrolithiasis in pelvic kidneys (b). The right retrograde pyelogram (c) demonstrated the lower pole stone (short arrows) and a tortuous ureter almost taking a perpendicular course (long arrow). Placement of a ureteral access sheath (d) straightened the ureter (white arrow), allowing easier access to address the stone with a flexible ureteroscope (e).

FIGURE 27.7 One-year-old female successfully managed with flexible ureteroscopy for a 1.5 cm stone with prestenting, given the large stone burden. A 9.5/11 Fr ureteral access sheath and 200 μm Ho:YAG laser fiber were used to clear this symptomatic, furosemide-induced stone.

Limitations and Complications

As ureteroscopy is becoming more prominent in the pediatric endourologist's armamentarium, complications need to be anticipated and unanswered questions addressed. *The most common complications involve unrecognized ureteral injury, including mucosal flaps and tears, perforation, false passage, and partial to complete avulsion.* Mitigating the damage by early recognition and temporizing with immediate discontinuation of the procedure and passage of a ureteral stent may avoid complications related to shear force injury on the ureter, ischemic damage, and extravasation of irrigant or urine. Injury can occur during introduction of the ureteroscope, or passage either antegrade or retrograde of instrumentation (guidewires, baskets, and dilators), especially in the area of an impacted ureteral calculus. Attempting to withdraw a basket-entrapped calculus too large for the ureter to accommodate can result in any of the above-mentioned injuries. In postpubertal children with an adult body mass, ureteroscopic access is technically similar to the adult population. However, in the prepubertal child, whether to attempt primary treatment without ureteral orifice dilation, perform dilation at the time of definitive therapy, or place a stent and allow the ureter to passively dilate prior to definitive therapy remains. Herndon et al. performed semirigid ureteroscopy (4.5 and 6.5 Fr) in 29 children with a mean age of 11 years for distal ureteral calculi. With no ureter actively dilated and only 14% of children prestented, the ureter was accessed in 100% of cases for a stone-free rate of 96%.[143] We can further validate this report with our own institutional experience utilizing 6.9 Fr flexible and 4.5 and 6.5 Fr semirigid ureteroscopy; however, it is our preference to sequentially dilate with the 8/10 coaxial dilator even in very young children. If we encounter difficulty, a stent is placed rather than dilated more aggressively. This approach appears to minimize the immediate risks and potential long-term complications, particularly in the management of upper tract calculi; however, it increases the number of children that require a second anesthetic and procedure to achieve stone-free status. Recent reports suggesting that up to 40% of pediatric patients will require at least two procedures to treat upper tract calculi imply that the likelihood of achieving a stone-free status after one ureteroscopic procedure may not be significantly better than with SWL.[138] Additional procedures were reported in more than half of the stones 6 mm or larger.[144]

The necessity of placing a stent postureteroscopy in all children is also debated. While the tendency in large series has been to leave a stent in place after ureteroscopic manipulation in a majority of children,[136] several authors have reported no acute or long-term sequelae despite leaving a postoperative stent in less than 20% of cases.[143] In our experience, the decision to place a postprocedural stent is made on an individual patient basis and is dependent on surgeon experience and degree of visible ureteral trauma at the conclusion of the procedure.

PERCUTANEOUS NEPHROLITHOTOMY

The safety and efficacy of PCNL for large stone burdens have been well established in adults. Initially, urologists were reluctant to perform PCNL in children due to concerns regarding the use of large instruments in pediatric kidneys, parenchymal damage and the associated effects on renal function, radiation exposure with fluoroscopy, and the risks of major complications, including sepsis and bleeding. Also a deterrent to performing PCNL in children was the potential resultant sequelae of hypothermia (i.e., coagulopathy) from prolonged exposure to irrigation. *With significantly accumulated experience, however, PCNL is currently being utilized as monotherapy and in combination with SWL (sandwich therapy) in children, achieving stone-free rates ranging from 68% to 100%*[15,145] (Table 27.3). *Although there is no current international consensus, relative indications for PCNL as the primary treatment modality in children include large upper tract stone burden (>1.5 cm), lower-pole calculi of >1 cm, concurrent anatomic abnormality impairing urinary drainage and stone clearance, and known cystine or struvite composition.*[77,95]

The earliest pediatric PCNL series were performed using standard adult-sized instruments. In 1985, Woodside et al. first reported on a series of seven patients (age range 5–18 years old) who were rendered stone-free without complications using adult percutaneous techniques and equipment.[166] Years later (1997), Mor et al.[167] reported on their pediatric PCNL series utilizing adult-sized instruments as well. These early series avoided performing PCNL in very small children (<5 years of age) due to concerns regarding parenchymal damage. *In contrast to these concerns, multiple series subsequently utilized adult-sized instruments and reported high efficacy rates with acceptable complication rates even when dilating a tract size as high as 30 Fr.*[164–168] *In fact, recent data have suggested that PCNL is possible in very young children using adult-sized*

equipment.[152] Investigations regarding the risk of renal damage in pediatric patients treated with PCNL have revealed that there is no significant risk of renal functional loss. Mor et al. performed radioisotope scans on 10 children before and after PCNL and found no change in differential function and no evidence of significant scarring.[167]

Despite early successes employing adult equipment, early efforts focused on developing technology to minimize percutaneous tract size without affecting PCNL efficacy. Jackman and Docimo developed a novel percutaneous access technique ("mini-perc") using an 11 Fr peel-away vascular access sheath and reported an 85% stone-free rate for 11 procedures in seven children with a mean age of 3.4 years and an average stone burden of 1.2 cm^2.[149] With a shortened tip of the inner vascular sheath to prevent renal pelvic perforation, mini-PCNL could now be safely performed in *preschool-aged children*. Mini-perc kits are now commercially available, ranging in size from a plastic disposable 11 Fr sheath (Figure 27.8) to a 16 Fr rigid metal sheath (Figure 27.9). *The benefits of minimal tract dilation include increased maneuverability, decreased blood loss, reduced complication rate, and shorter hospital stay. However, disadvantages including prolonged operative times, impaired visualization, and small nephroscope working channels limit this technique for very large stone burdens.*

Recent advancements in instrumentation, such as smaller nephroscopes (15–18 Fr) and less morbid renal access techniques, are reducing complications, hospital stays, and pain. As a result, PCNL has now replaced open surgery as the treatment of choice for a large stone burden of >2 cm in children of all ages. Recent reports comparing mini-PCNL with retrograde intrarenal surgery, however, are showing promise for ureteroscopy as an effective alternative to mini-PCNL for stone burdens between 1 and 3 cm.[148]

Four energy sources exist for intracorporeal lithotripsy, including electrohydraulic, pneumatic, ultrasonic, and laser probes. Electrohydraulic lithotripsy (EHL) sends current across a rigid probe (ranging from 1.9 to 9 Fr), creating a spark, which vaporizes irrigant into a cavitation bubble. Collapse of the bubble generates a shock wave to fragment the stone (Figure 27.10). Pneumatic ("ballistic") probes require direct contact with the stone and fragment via mechanical energy transmission with minimal risk to the surrounding urothelium. There are both rigid (0.8–2.5 mm) and flexible probes, with larger probes having greater efficacy. The Swiss Lithoclast has been the best studied. The Lithovac is a pneumatic probe that adds suction of stone fragments. Ultrasonic probes use high-frequency vibrations, come directly in contact with the stone to cause fragmentation, and with a central hollow core, allow for simultaneous suction of the fragments. Significant heat is generated by the ultrasonic probe, so care must be taken to avoid thermal injury to both the surgeon and patient. Pneumatic and ultrasonic probes run the least risk of urothelial and local tissue injury. Finally, the holmium:YAG laser is the most widely utilized laser in endourology, and is the only laser capable of fragmenting all stone types, yet it is relatively safe when kept at least 1 mm from urothelium. Photothermal energy

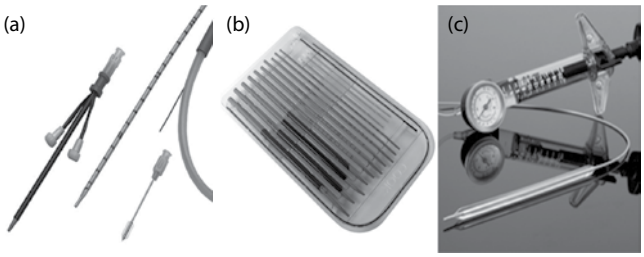

FIGURE 27.8 (a) Docimo Mini-Perc percutaneous nephrostomy set containing 11 Fr inner (removable) and 13 Fr outer sheath through which nephroscopy is performed via a flexible ureteroscope or pediatric cystoscope. (b) An Amplatz renal dilator set allows dilation up to 30 Fr for use of an adult rigid nephroscope. (c) A nephrostomy balloon dilator set contains 6, 8, and 10 × 15 mm balloons for dilation of the nephrostomy tract to 30 Fr and admission of adult nephroscopes. (From Cook Medical Inc., Bloomington, IN. With permission.)

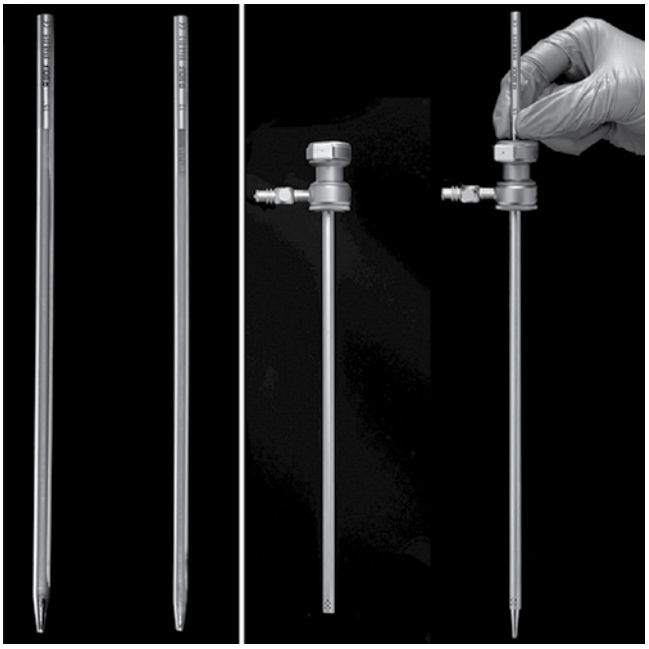

FIGURE 27.9 Smaller-caliber nephroscopes (15–18 Fr) advanced through reusable metal mini-sheaths help to minimize access tract size and reduce blood transfusion rates in pediatric patients. (Picture provided by Richard Wolf. Copyright © 2012, all rights reserved.)

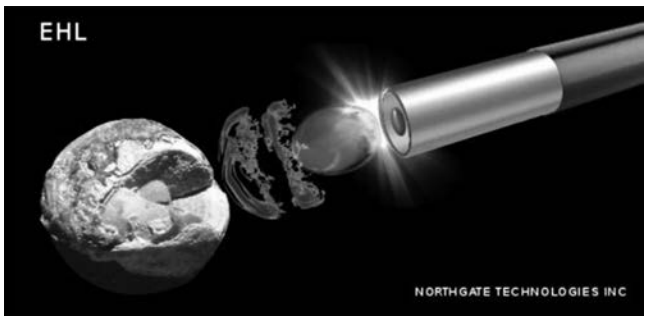

FIGURE 27.10 Four different energy sources are available for intracorporeal lithotripsy in children: laser, ultrasonic, pneumatic or ballistic, and electrohydraulic. EHL, depicted here, forms a cavitation bubble, which generates shock waves upon collapse of the bubble. Direct contact is not made with the probe, as the most effective lithotripsy occurs at a 1 mm distance. (From Northgate Technologies Inc., Elgin, IL. Reprinted with permission.)

is generated at a wavelength of 2100 nm, via laser fibers ranging in size from 200 to 1000 μm. Only 200 and 365 μm fibers can fit through a ureteroscope. Stones then require either complete dusting or basket extraction of fragments.[169]

Planning for PCNL in Children

Careful planning is required prior to embarking on PCNL in children. Films must first be reviewed scrupulously to determine if the stone is amenable to a percutaneous procedure. *Nephrocalcinosis in children, for example, may be confused with staghorn calculi, and the etiology and treatment are very different* (Figure 27.11). Infection is the most common causative agent in the formation of a staghorn calculus, and PCNL is a first-line therapy. The most frequent causes of nephrocalcinosis are hereditary tubulopathies and vitamin D intoxication. *Medullary sponge kidney is a renal malformation characterized by cystic anomalies of precalyceal ducts, which is frequently associated with nephrocalcinosis and stone formation.*[170] Nephrocalcinosis is most often not amenable to successful endourologic treatment because calculi are intraparenchymal, and thus outside the collecting system. Management is often medical and aimed at prevention of further nephrocalculi, a cause of worsening renal function. Medical prophylaxis for calcium-based stones, not necessarily associated with nephrocalcinosis, may also be very helpful in preventing stone recurrence and enhancing stone-free rates in children following surgical treatment, as has been demonstrated after pediatric PCNL.[171]

The risks of the PCNL must be reviewed with the consenting parent or guardian. *It must be understood that a percutaneous procedure carries risks that include, but are not limited to, bleeding requiring transfusion, delayed renal hemorrhage requiring angioablation, sepsis, pneumothorax, hemothorax, urothorax, incomplete stone treatment, and injuries to organs adjacent to each respective kidney.*

Every attempt should be made to treat a urinary tract infection and/or minimize bacteriuria prior to the procedure. A urine culture, with antibiotic sensitivities, should be checked 3 weeks prior to the procedure. Any positive culture requires a full course of antibiotics and repeat culture to confirm sterility. Three to five days of prophylactic antibiotics is recommended prior to the procedure, even with a negative preoperative culture. Broad-spectrum IV antibiotics (i.e., ampicillin and gentamicin) should be given at the time of the procedure.

All percutaneous procedures are performed using general anesthesia. *A warm operating room, warmed isotonic irrigation solution, short operative times (not to exceed 1.5 hours), proper draping, and monitoring of body temperature should decrease the incidence of hypothermia and hyponatremia.* After induction of anesthesia with the patient in the lithotomy position, a retrograde pyelogram is performed to outline the collecting system and an occlusive balloon or a 5 Fr open-ended ureteral catheter is left in situ to opacify the collecting system during percutaneous access. The patient is then repositioned in the prone position with the torso elevated at 30° from the table surface with a towel or gel roll.[95]

Circumstances that require special consideration involve children with spinal cord injuries and congenital anomalies, such as spina bifida. In these patients, positioning can be a challenge due to existing spinal hardware and limb contracture.[172] Patients who have had prior spinal surgery consisting of vertebral fusion or Harrington rod placement will have restricted spinal mobility, spinal curvature, and/or atrophic or contracted extremities. *As the result of scoliosis, lordosis, and or kyphosis, renal anatomy is altered. As a consequence, the risk of injuries to adjacent organs (i.e., pneumothorax) during percutaneous procedures increases.* Assessing the degree of mobility in the trunk and extremities is crucial in planning for

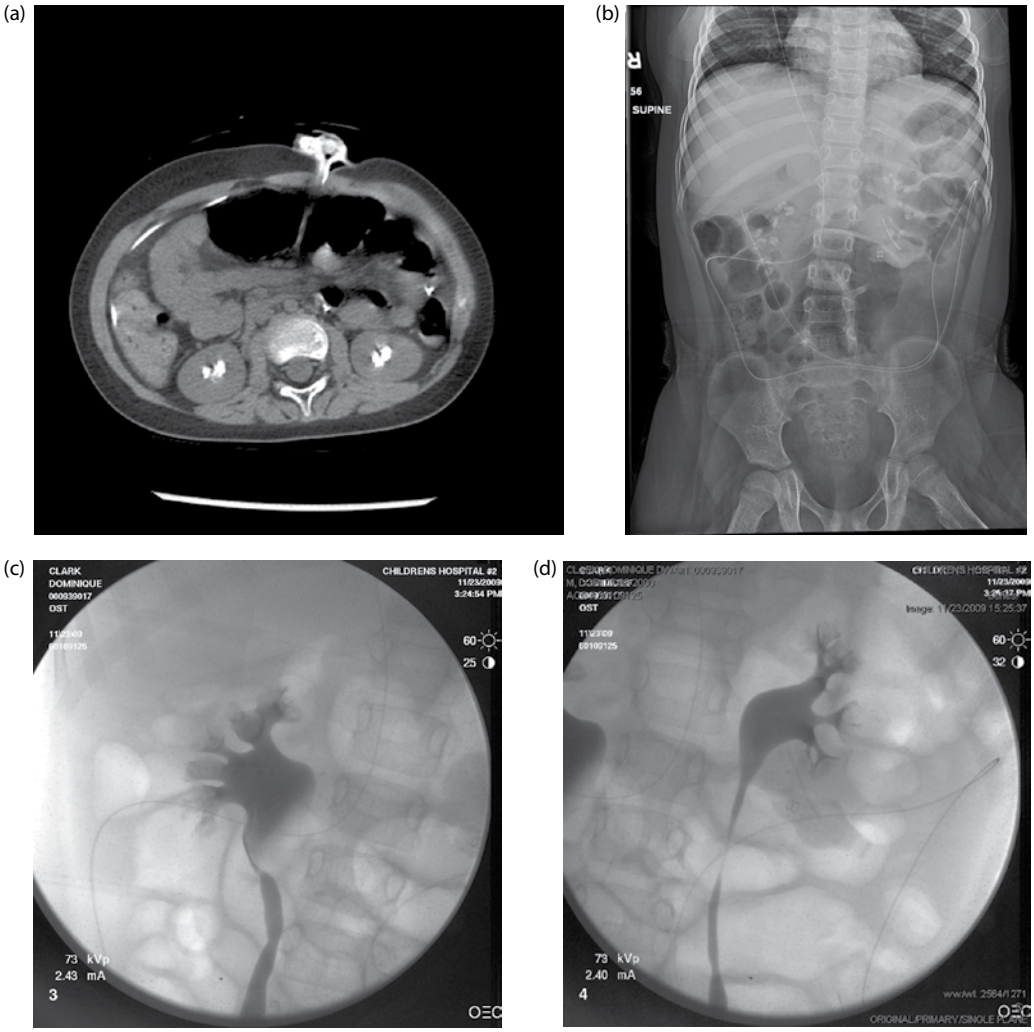

FIGURE 27.11 Nine-year-old boy with cerebral palsy and gross hematuria. CT scan demonstrated bilateral nephrolithiasis (a), thought to be staghorn calculi. Plain x-ray (b) and bilateral retrograde pyelograms (c and d) demonstrate nephrocalcinosis (white circles and black arrows) reflective of medullary sponge kidney. Subsequent metabolic workup revealed renal tubular acidosis with hypercalciuria.

PCNL in these patients. These patients must be placed in the most comfortable position possible without excessive contortion or flexion of the joints. Special attention must be paid to latex precautions in the myelomeningocele and bladder exstrophy populations, and as in all cases, proper padding of pressure points is mandatory.

Percutaneous Nephrolithotomy Technique in Children

After selection of the desired calyx, a 16- or 18-gauge spinal needle is placed with the assistance of fluoroscopy in the 30° position (Figure 27.12). When fluoroscopy is used, the collecting system is opacified through an open-ended ureteral catheter that has been inserted cystoscopically prior to positioning in the prone position (Figure 27.13). Alternatively, ultrasound guidance can be used to puncture the calyx of choice. The ideal tract is one that provides the shortest and most direct access to the stone (Figure 27.14). For complex calculi occupying multiple calices including the lower pole, supracostal posterior access is preferred to provide visualization of the superior calyx and pelvis, access to the pelvis and ureter, and straight access to the inferior calices, allowing easier manipulation of the working instruments and minimizing torque on the collecting system.[173] Following initial puncture, no attempt should be made to redirect the needle while it is located within the cortex of the kidney to avoid trauma. With the C-arm in the 90° plane, the depth and medial extension of the needle are checked. After access is confirmed with urine or irrigation return, a flexible guidewire is placed into the collecting system through the needle and directed down the ureter into the bladder. A small skin incision is made with a No. 11 scalpel, and 8 and 10 Fr coaxial dilators are passed over the guidewire into the collecting system. Once in place, an Amplatz Super Stiff™ guidewire is placed as a working wire.

Tract dilation can be performed by several techniques. Serial dilation with Amplatz dilators over working wires and subsequent sheath placement under fluoroscopic guidance is the most common technique employed. For

FIGURE 27.12 An initial mark can be placed on the back, using a metallic pointer under fluoroscopy to localize the desired posterior calyx. The desired calyx is localized with the C-arm at 0° and 30°, for AP and oblique orientation. The collecting system is visualized via retrograde contrast injection via ureteral catheter. Alternately, injection of air will localize the posterior-most calyx, as air bubbles will rise.

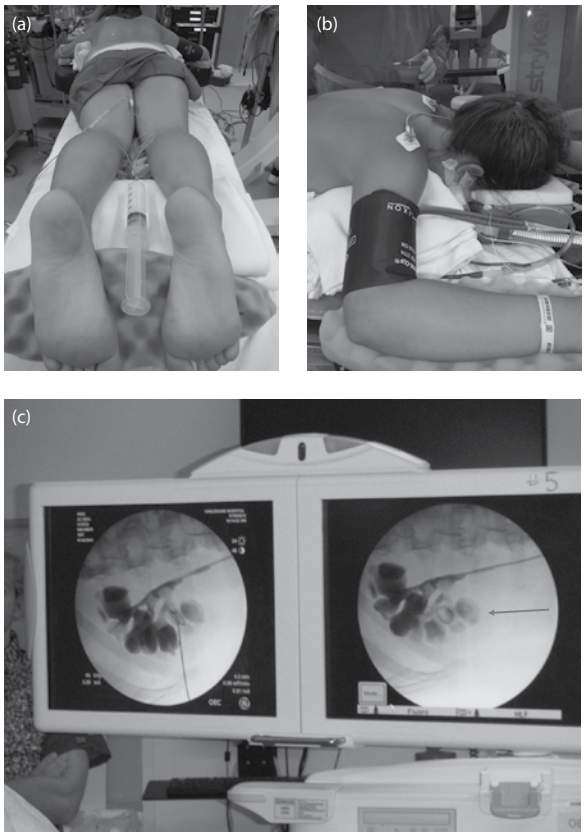

FIGURE 27.13 Fluoroscopic or ultrasound-guided renal access is performed at surgeon discretion. Patient positioning using the C-arm requires a sliding operative table. Flank and prone positioning are both adequate positioning options. Cystoscopy has been performed prior to prone positioning (authors' preference) for retrograde placement of a ureteral access catheter, for retrograde contrast injection (a). (b) Bilateral gel rolls are placed at the anterior axillary lines when prone. An axillary roll is used for older children in flank positioning. Careful axillary and ulnar padding (seen here) prevent brachial plexus and ulnar neuropathies. (c) A reference image is horizontally oriented and saved (on the right), demonstrating stone location throughout the procedure (arrow). The working fluoroscopic image is seen on the left, with wire coiling around the lower-pole stone.

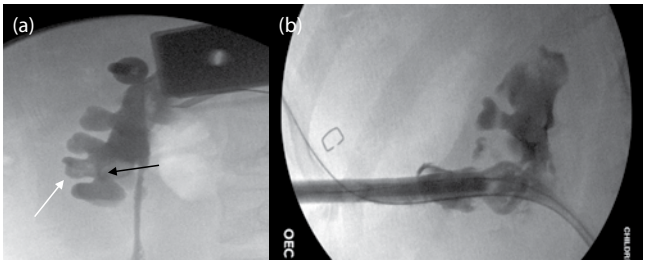

FIGURE 27.14 (a) Seven-year-old boy with two separate 7–9 mm stones within a lower-pole calyx (white arrow). Flexible ureteroscopy was attempted, but impossible due to a lower-pole infundibular-UPJ angle of >270° (black arrow). (b) PCNL was subsequently successful for complete stone clearance.

preschool-aged children and lower stone burdens, an 11 Fr peel-away sheath (Docimo Mini-Perc, Cook Urological Inc., Spencer, Indiana) and trocar are passed over the wire and through the calyx under fluoroscopic guidance. For balloon dilation, either the Bard X-Force or NephroMax™ High Pressure Nephrostomy Balloon Catheter (Boston Scientific, Natick, Massachusetts) may be used. Either will facilitate dilation of a 30 Fr tract at a pressure of 17 atmospheres. This technique permits dilation and sheath placement in a single step, thereby minimizing potential parenchymal trauma and bleeding from sequential dilation with rigid dilators. While the decision to proceed with mini-perc or dilation to a slightly larger (16 Fr) or standard (30 Fr) access sheath is individualized based on child's age, anatomy, and stone burden, familiarity with all the above techniques facilitates complete access with minimal morbidity.

Once access is obtained, nephroscopy and nephrolithotomy can be performed with a variety of energy sources for stone fragmentation. The outer diameter of nephroscopes ranges from 15 to 26 Fr, and a 15 Fr flexible nephroscope with a 6 Fr working channel has also been developed. In addition, 7 and 8 Fr offset cystoscopes with 5 Fr working ports and 7–9 Fr flexible ureteroscopes can be used through an 11 Fr access sheath with enough clearance to allow low-pressure irrigation.[77] Only the EHL probe or holmium laser fiber can fit through the narrow

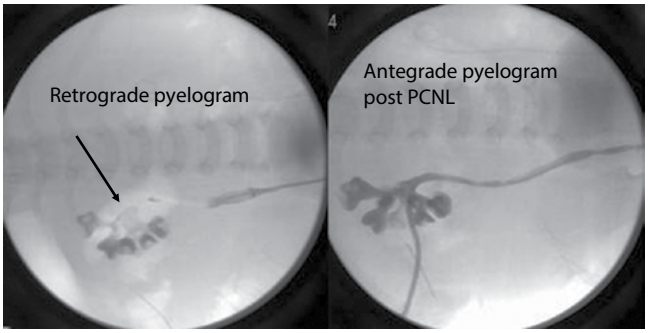

FIGURE 27.15 A retrograde pyelogram determines stone burden prior to renal access and can help localize the desired calyx for renal puncture. An antegrade pyelogram is routine to confirm nephrostomy tube placement and clearance of large stones after PCNL; if complete stone clearance is uncertain, second-look nephroscopy, delayed nephrostogram, and a low-dose CT stone protocol are acceptable options.

working channel in a pediatric cystoscope or ureteroscope during mini-perc. However, ultrasonic, pneumatic EHL, and the holmium laser are both accommodated through the adult nephroscope with a standard renal access tract. Individual preference is determined by availability and surgeon experience. Postoperative stenting and/or placement of a nephrostomy tube is both patient and surgeon dependent and varies between series. An immediate postoperative nephrostogram can be useful in determining renal drainage at the conclusion of PCNL (Figure 27.15). Similar to adult procedures, tubeless PCNL has theoretical advantages, including decreased postoperative pain and a short hospital stay, but currently data are limited in the pediatric population.[174]

Percutaneous Nephrolithotomy Outcomes

Recent large retrospective series of PCNL monotherapy have demonstrated high efficacy rates approaching 90%[161,164,168] (Table 27.3). In 56 children (mean age 9.1 years) with a mean stone burden of 337.5 mm^2, Desai et al. reported a stone-free rate of 89.8% utilizing EHL through a 14 Fr nephroscope and a 20–24 Fr sheath. Of these, 61% required multiple tracts and 45% were staged procedures. Findings demonstrated that the number and size of tracts were significantly associated with postoperative hemoglobin decrease (mean 1.9 g/dL) and overall transfusion rate (14%).[161] In 52 children with a mean age of 7.9 years and a mean stone burden of 282 mm^2, Zeren et al. reported an 87% stone-free rate using ultrasound and EHL for fragmentation and tract dilation from 18 to 30 Fr. Complications included postoperative fever (30%) and need for transfusion (24%). *Transfusion was associated with operative time, sheath size, and stone burden.*[164] In 135 children aged 8.9 years with a mean stone burden of 507 mm^2, Salah et al. reported a 98.5% stone-free rate utilizing ultrasound through a 26 Fr nephroscope. Complications were low (8% urine leak rate and 0.7% transfusion rate), with only one patient requiring a second procedure.[162] In a recent series of 46 children with a mean stone burden of 332 mm^2, Bilen et al. reported an 88% stone-free rate using EHL, ultrasound, and the holmium laser. When stratified by tract size (14, 20, and 24 Fr), efficacy rates were similar in all groups, but there were no complications or transfusions in the 14 Fr tract group.[168]

In an effort to reduce the number of tracts and associated morbidity, some centers have chosen to follow primary PCNL with adjunctive SWL therapy to clear RFs. In a small series of 29 children with a mean age of 3.8 years and a mean stone burden of 2.4 cm, Mahmud and Zaidi reported a 60% stone-free rate after PCNL monotherapy using EHL through a 17 Fr angled nephroscope. Only one tract was used in all patients, and after SWL sandwich therapy, the stone-free rate increased to 100%.[145] In a larger series of 169 children with a mean stone burden of 3.1 cm, Samad et al. reported a 59% monotherapy stone-free rate with 96% of cases performed through a single tract. Approximately one-third (34.5%) of primary failures were treated with SWL; the cumulative stone-free rate in all patients was 93.8%, with a 3.6% transfusion rate.[156] When stratified by age, anatomy, bilaterality, and renal function, stone-free outcomes were equivalent in all groups. The decision to follow PCNL with SWL is related to operator experience with percutaneous technique and available technology. *It is our preference to perform a second-look nephroscopy through the original tract to ensure stone-free status during the initial hospital admission rather than progress to SWL sandwich therapy.* Endoscopic surveillance during the initial procedure can determine the need for second-look nephroscopy without relying on additional imaging and the associated risks of radiation exposure.[175] With continued improvement in technology and technique, the indications for PCNL in children will continue to increase. Technically challenging in nature, surgeon experience with PCNL is paramount in developing individualized treatment plans to optimize efficacy with minimal morbidity.

LAPAROSCOPIC AND ROBOTIC-ASSISTED PYELOLITHOTOMY

Treatment of large stone burdens in children is technically challenging, often requiring multiple procedures. Laparoscopy and robotic-assisted laparoscopy has been utilized successfully in adults for the treatment of calculi during the concomitant treatment of UPJ obstruction and in the primary treatment of staghorn calculi. Small series utilizing these techniques in children have only recently been described. In eight children (mean age 4 years) with a mean stone burden of 2.9 cm undergoing transperitoneal laparoscopic pyelolithotomy, Casale et al. reported a 100% intraoperative success rate, a mean hospital stay of 2.15 days, and a mean operative time of 1.6 hours, with no major complications.[176] In the first report of robotic-assisted laparoscopic pyelolithotomy, Lee et al. described their experience in five patients, four with cystine staghorn calculi refractory to PCNL and SWL and one with calcium oxalate calculi and concurrent UPJ obstruction. Of these cases, four were completed robotically, with one patient having a residual 6 mm lower-pole stone and one patient requiring conversion to an open procedure. The mean operative time in this series was 315 minutes, the

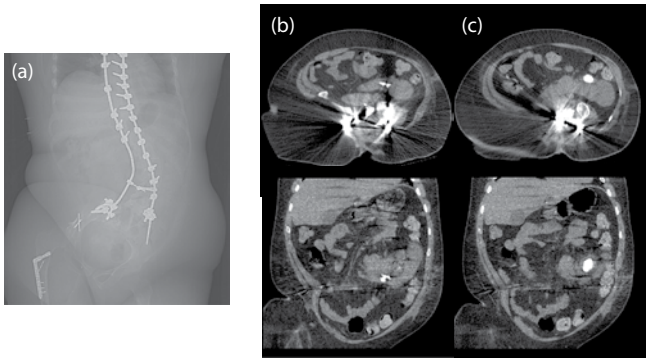

FIGURE 27.16 (a) Stones overlying spine not seen on x-ray due to body habitus: 1.8 cm in left lower pole near isthmus and 3.1 cm in left renal pelvis in horseshoe kidney. (b and c) When faced with the inability to access stones percutaneously (for example, overlying spinal hardware in a horseshoe kidney) and high stone burden, minimally invasive or open pelviolithotomy is an efficient option to multiply staged SWL or ureteroscopy.

mean estimated blood loss was <20 cc, and the mean hospital length of stay was 3.8 days.[177] These early experiences demonstrate that laparoscopic pyelolithotomy is feasible, safe, and efficacious as an alternative to open pyelolithotomy in children and warrants further study. However, due to their demanding technical nature, these procedures will likely be limited to endourologic management failures or renal anatomy, which prohibits ureteroscopic and percutaneous intervention. For example, vertebral abnormalities, such as severe scoliosis or spinal hardware, may obstruct access to a horseshoe kidney with a large amount of stone burden, as seen in Figure 27.16.

PERCUTANEOUS CYSTOLITHOTRIPSY FOR BLADDER STONES

Bladder stones are more often found in children from developing countries and are thought to be related to malnutrition in the absence of anatomic abnormality. It is thought that diets low in animal protein and phosphorous (breast milk as opposed to cow's milk), in addition to vitamin A deficiency, are contributory.[178] *Bladder stones from children in these developing countries are most often composed of ammonium acid urate*. In contrast, among children from industrialized nations, bladder stones are most often found in those with spinal cord injuries or congenital abnormalities, such as spina bifida. Very often, these children have undergone augmentation cystoplasty and/or manage their bladders by clean intermittent catheterization. *It has been reported that up to 50% of those children with reconstructed bladders will develop a bladder stone in their lifetime.*[179] *Urinary stasis, bacterial colonization or infection with urea-splitting organisms, retained mucous, and foreign bodies can all contribute to the formation of bladder stones, the majority of which are struvite. Recently, dextranomer/hyaluronic acid (Deflux®) has been demonstrated in a trigonal and distal ureter distribution following endoscopic treatment of vesicoureteral reflux*. While uncommon, this is now in the differential diagnosis of bladder and distal ureteral stones for patients providing a history of Deflux injection, who have lower-density lesions (median 193 Hounsfield units) on CT than is expected of calculi[180] (Figure 27.17).

Open cystolithotomy has been the traditional modality to treat bladder stones. Transurethral cystolithotripsy is an alternative, although not ideal in the pediatric population. In children, a smaller-caliber urethra limits effective treatment of large bladder stone burdens. Percutaneous cystolithotripsy, however, is now utilized worldwide with the advantage of shorter hospital stays, smaller scars, and less indwelling catheter time postoperatively.[181] Presently, percutaneous cystolithotripsy is the preferred method to treat bladder stones that have formed in reconstructed bladders.[182] In developing countries as well, percutaneous lithotripsy has become the first-line treatment modality to address bladder stones in bladders that have not been augmented. Salah et al. reported on their experience with cystolithotripsy in 155 children from Pakistan and Yemen with a mean age of 4.5 years and average bladder stone burden of 2.3 cm (range 0.7–4 cm). All children were treated safely and successfully using a 26 F nephroscope through a 30 F sheath placed through a 1 cm suprapubic incision.[183]

Percutaneous cystolithotripsy has also been used effectively in infants of less than 1 year of age to clear bladder stones. Gan et al. reported on their experience using a 16 F peel-away sheath with a ureteroscope to treat bladder stones with an average size of 1.4 cm in 15 boys with a mean age of 8.2 months.[184]

Percutaneous cystolithotripsy in children may be performed under ultrasound or fluoroscopic guidance and is most often an outpatient procedure. With either modality, the bladder is first filled to capacity with water or contrast, respectively. The child is placed in the Trendelenburg position to minimize the risk of bowel injury during access and tract dilation or formation. An 18-gauge needle is

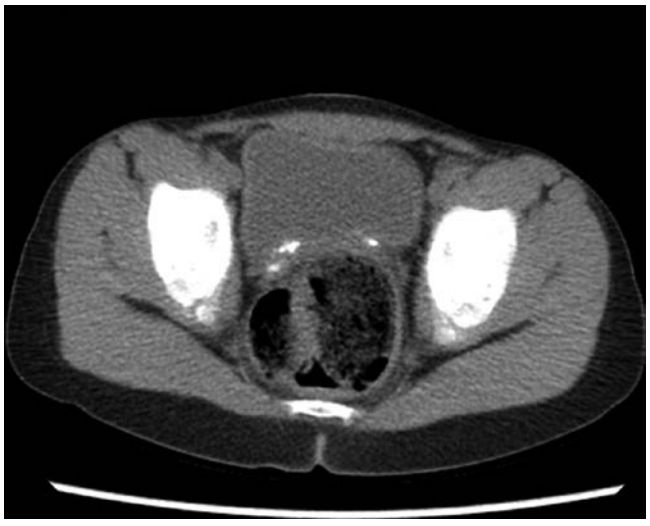

FIGURE 27.17 False-positive CT scan for distal ureterolithiasis in a 7-year-old patient with a history of bilateral subureteric Deflux injections. Median densities up to 193 Hounsfield units are reported for Deflux implants on noncontrast CT. Abdominal x-ray does not visualize these implants. Patient history and lower-density appearance are keys to an accurate diagnosis.

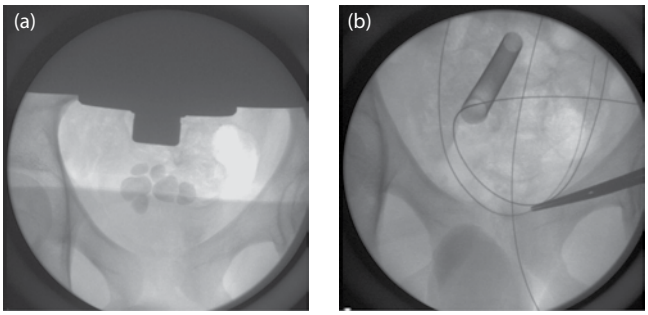

FIGURE 27.18 (a) Bladder stones in a spina bifida patient post-ileocystoplasty. (b) An Amplatz 30 Fr sheath and rigid nephroscope (seen here) or 10 mm laparoscopic trocar can be placed into the bladder, facilitating percutaneous ultrasonic lithotripsy or basketing. Referring to recent cross-sectional imaging is important if the patient has had prior bladder or bowel surgery. Loops of the bowel may overlie the bladder and be injured with percutaneous access. Catheter placement per Mitofanoff or Monti is critical to prevent injury to a continent catheterizable channel.

placed into the distended bladder midline, one to two finger breadths above the pubic bone. Once proper placement is confirmed with return of fluid, a wire is passed through the needle into the bladder. A tract may then be established reflective of stone diameter and child size. Most often, a tract is established with a balloon dilator to accompany a 30 F sheath. Amplatz dilators may also be used. A 26 F nephroscope is used to extract stones of <1 cm with a rigid stone forceps, or an ultrasonic lithotriptor may be used to fragment stones of >1 cm. At the conclusion of the percutaneous cystolithotripsy procedure, a Foley is left per urethra or per continent catheterizable stoma for 1 week. The rectus fascia defect is closed with a 2-0 vicryl suture (Figure 27.18).

SILENT OBSTRUCTION AND OTHER CONSIDERATIONS

Silent ureteral obstruction, evaluated in 506 adult patients, was associated with reduced renal function at the time of stone diagnosis and no further deterioration after stone clearance.[185] While similar pediatric data are not available, *silent obstruction is a relative indication for surgical intervention in children in order to preserve renal function and prevent further deterioration.*

DETERMINATION OF STONE-FREE STATUS

To date, there is no standardized method of defining stone-free status following definitive therapy. Similar to adults, the presence of RFs in children has been associated with inferior outcomes and increased stone recurrence.[75,186] Dincel and colleagues recently evaluated 49 children retrospectively following ureteroscopy to determine an efficient imaging regimen for the identification of clinically significant stone fragments.[190] At initial follow-up, three stone fragments were found to have migrated to the kidney, requiring further surgery, and six kidneys were found to be hydronephrotic, although five of six responded favorably to medical expulsive therapy or observation. Unfortunately, renal ultrasound alone was only useful for the detection of postoperative hydronephrosis with 85.7% and 97.7% sensitivity and specificity. In this series, the authors found the combination of renal ultrasound and abdominal plain film to be adequate for postoperative surveillance of hydronephrosis and stone fragments, respectively. Weizer and colleagues recommend a regimen of IVP, spiral CT, or renal ultrasound within 3 months of surgery to survey for silent obstruction, which occurred in 2.9% of their adult series.[187] However, proponents of earlier surveillance recommend imaging within 6 weeks of surgery due to the risk of silent obstruction with incipient renal damage. *To limit the risk of chronic damage in the pediatric kidney, surveillance renal ultrasound within 6 weeks of surgery is recommended.*

Balancing the risks of radiation exposure for post-treatment stone detection and the risks of anesthesia for secondary procedures is a challenging dilemma for contemporary pediatric endourologists. Ultimately, if stone fragments are seen on plain film, CT does not provide additional useful information.[188] In addition, maximizing intraoperative fragment detection by direct visualization in URS and PCNL and continued development of high-resolution real-time fluoroscopy may result in less reliance on postoperative imaging. Advancements in flexible ureteroscopes and nephroscopes, transitioning from fiber-optic to digital technology and with "chip on the tip" technology, should maximize image quality and decrease the need for second-look surgery or sandwich therapy.[172] Since ionizing radiation use in children is still subject to the as low as reasonably achievable (ALARA) principle, use of stone protocol CT scans for postoperative surveillance is not routine and should be based on suspicion for RFs. Surveillance CT should be individualized by age, anatomy, stone burden, and underlying metabolic abnormalities.

CONCLUSIONS

Evolution of technique and miniaturization of instruments have changed the management of pediatric stone disease. However, despite encouraging results, concern remains regarding the safety of the endourologic treatment in smaller patients and its subsequent effects on the developing kidney. While SWL is still considered first-line therapy for upper tract calculi of <1.5 cm, evidence is accumulating that ureteroscopy with laser lithotripsy and stone basketing may be more efficacious and reduce retreatment rates for upper tract stone disease in children. Ureteroscopic stone extraction is also becoming recognized as similarly efficacious compared with mini-PCNL, with potentially fewer side effects. While PCNL remains the most effective technique for large upper tract stone burdens, there are now reports of laparoscopic and robotic-assisted laparoscopic pyelolithotomy in major pediatric academic centers with extensive laparoscopic and robotic experience. Prospective studies designed to determine "the preferred" endourological approach to upper tract calculi would provide useful information.

In this regard, individual surgeon experience and comfort level will weigh heavily in choosing a treatment modality. In addition, standardized protocols for diagnostic imaging, renal monitoring with conservative therapy, and postoperative surveillance are needed. Pediatric urologists will have to monitor the advances in minimally invasive lithotripsy techniques, as we aim to minimize morbidity and preserve renal function in children at high risk of stone formation into adulthood.

CHAPTER
28

Renal Parenchymal Imaging in Children

Daniel B. Herz

INTRODUCTION

Traditionally, imaging of the renal parenchyma is useful to determine if there is acute urinary tract infection (UTI) that involves the parenchyma, the presence of renal cortical scarring and differential function, the presence and character of a mass or cyst, the presence of congenital dysplasia, the presence and burden of nephrocalcinosis, and the extent of renal trauma, as well as to evaluate gross or microhematuria. In addition, more recently, parenchymal imaging is useful in the *top-down approach* to determine the true overall renal risk of a child with UTI. This has gained resurgent interest after several studies have shown that this can be pivotal in determining the clinical significance of vesicoureteral reflux (VUR).[1–3] Ultrasound (US), in general, is the primary initial imaging modality of the renal parenchyma in infants and children. It has essentially replaced intravenous pyelography (IVP), and is found to be more cost-effective and safer than computed tomography (CT) and magnetic resonance imaging (MRI). Renal scintigraphy, however, has maintained its usefulness because it is used to determine differential function, excretory function, and parenchymal integrity.

US uses sound waves that are above the audible range of normal human hearing of 20 kHz. Medical US probes typically operate at frequencies of 2–18 MHz. The choice of frequency to use to image different parts of the body is based on a trade-off between image resolution and depth of penetration into the body. Lower-frequency sound waves penetrate deeper into the body. Higher-frequency sound waves have lower wavelengths and higher attenuation coefficients; thus, they are absorbed more readily by tissues and do not penetrate as deep, but the images have better resolution. Imaging the kidney will typically use lower frequencies, unless imaging an infant, where higher-frequency probes will be used because deeper penetration is not needed. Higher-frequency sound waves can also detect and reflect sound off smaller structures and, for this reason, are also better suited for the pediatric application. The sound wave is typically produced by a piezoelectric transducer that is made of ceramic that vibrates or "rings" when contacted by short electrical pulses produced by the machine itself. The sound is then focused in an array that is based on the shape of the transducer, which is then transmitted through a water-based gel on the child's skin. Sound is then deflected and reflected based on the density of tissues it contacts. The reflected sound wave or "echo" is picked up and then vibrates the transducer, which is converted to an electrical pulse. This pulse is then processed into a digital image. To create the two-dimensional (2D) image, the US machine must also determine how long it took for the echo to be received after it was transmitted (the greater the time, the deeper the image), how strongly the echo was reflected back (the stronger the reflection, the brighter the image), and the focal length of the object reflecting the sound wave back. Based on these three determinations, the machine creates pixels of different intensities and positions. This "sonogram" image is the digital construct of the pixels created by sound wave reflected back to the transducer by that particular body organ or structure. Solids and gases have the greatest acoustic impedance, and therefore will be almost 100% reflected back and show up as a bright white image.

For the vast majority of medical imaging, US images are 2D. Commonly, a specialized probe that mechanically scans a conventional 2D image transducer is used. Doppler US is used to study blood flow and muscle motion. The different detected speeds are represented in color for ease of interpretation. The *Doppler effect* assesses whether fluid, usually blood, is moving toward or away from the probe. By calculating the frequency shift of a particular sample volume, its velocity and direction can be determined and visualized. This is particularly useful in urology to determine the absence of obstruction in a ureter, or vascular flow in a kidney. The Doppler information is often displayed graphically using a spectral Doppler, or as an image using a color Doppler (directional Doppler) or power Doppler (nondirectional Doppler). Most modern US machines used in medical technology use the color red to indicate flow toward the transducer and blue away from the transducer. Because at any one angle the kidney has arterial and venous blood flow that can be both toward and away from the transducer, the sonographer and urologist must understand the underlying acoustic physics of color Doppler and the physiology of normal and abnormal blood flow in the human body.[4–6]

The strengths of US lie in its ability to image muscle, soft tissue, and bone surfaces, as well as show the structure of organs. It is also particularly useful for delineating the interfaces between solid and fluid-filled spaces. It can also render "live" images, where the operator can readily and dynamically select the most useful section for diagnosis and documenting changes over time. Live images also allow for US-guided biopsies or injections, which can be cumbersome with other imaging modalities. US has no

known long-term side effects and rarely causes any discomfort to the patient. US equipment is widely available, relatively inexpensive, and comparatively flexible, and easily carried scanners are available so that examinations can be performed at the bedside. US is generally considered to be the safest imaging modality.[7–15]

The weakness of US devices is that they have trouble penetrating bone and gas, and they perform very poorly when there is a gas or bone between the transducer and the organ of interest. Overlying rib and/or gas in the gastrointestinal tract often makes US scanning of portions of the kidney difficult, especially in obese children, even at low frequency. Furthermore, using a lower-frequency transducer to compensate for body habitus and increased thickness of the subcutaneous fat often yields lower-resolution poorly diagnostic images. US is also very operator dependent. A high level of skill and experience is needed to acquire good-quality images and make accurate diagnoses, especially in pediatric and prenatal fetal applications. One further limitation is that there is no scout image, as there is with CT and MRI, and so there is no comparison of tissues to baseline.

Normal Kidney Ultrasound

There are normal differences in the imaging characteristics of the kidneys between newborns, infants, and younger children and older children. In newborns and infants, the renal cortex is much thinner, with larger, more hypoechoic-appearing medullary pyramids, which can be attributed mostly to dilute or poorly concentrated urine in the distal tubules and collecting ducts. This appearance of the medullary pyramids can be misinterpreted as hydronephrosis or caliceal dilation to the inexperienced clinician. In the neonate, a transient increase in the echogenicity of the medullary pyramids can also be seen, and results from precipitation or protein deposits in the tubules, known as Tamm–Horsfall proteinuria. Dehydration and administration of hyperosmolar contrast agents can make this phenomenon worse. However, this is considered to be benign and self-limited.[16–19]

In the first 2–3 months of life, the cortex is thinner and can appear hyperechoic or echogenic compared with the adjacent liver or spleen. It has been suggested that this is due to the increased number of glomeruli in the renal cortex, as well as a larger number of the loops of Henle (~20%) being situated in the cortex compared with in the older child.[20] This phenomenon can be normal and persist up to 6 months of age.[21–24] However, if the echogenicity of the renal cortex after 2–3 months is much brighter than the liver or spleen, this is a sensitive marker for underlying parenchyma medicorenal disease. Two other phenomena occur in the newborn kidney that might be misinterpreted or mimic pathology. The first results in a fusion line between two areas of primitive blastemal, which results in an echogenic stripe of nonparenchymal extrarenal fatty tissue that often courses obliquely through the upper pole of the kidney. This is called the interrenicular line or Odonno's sulcus.[25,26] This should not be misinterpreted as a parenchymal scar. Due to the relative thin newborn cortex, a column of Bertin hypertrophied segment of parenchyma can be easily misinterpreted as a renal mass. This can easily be cleared up by CT or MRI; however, these studies in newborns and young infants are quite sensitive to motion artifact and require anesthesia sedation and intravenous injection of potentially nephrotoxic contrast agents.

Any process that disrupts the normal parenchymal architecture is likely to change the acoustic characteristics of the tissue. Alterations in renal perfusion, cellular infiltration, and interstitial fluid level are common in acute pathology and will likely change the acoustic interfaces and the echogenicity of the kidney without disrupting overall architecture (Figure 28.1). However, interstitial fibrosis and histologic disruption and nephron disorganization are common in chronic pathology and are very likely to alter normal architecture and cause changes in the acoustic interfaces between the renal cortex and medulla. This change results in poor corticomedullary differentiation, the hallmark of what is broadly referred to in pediatric renal imaging as *medicorenal disease* (Figure 28.2).[27–31] Renal size or linear measurement may also change with disease states in the child. A large echogenic kidney usually suggests acute cellular infiltration and edema. Smaller highly echogenic kidneys usually indicate a chronic condition with renal atrophy or loss of nephron function. Surveillance of renal growth by serial renal size measurement is a valuable way to establish the health of the kidneys over time.[21,27,32,33] Measuring the

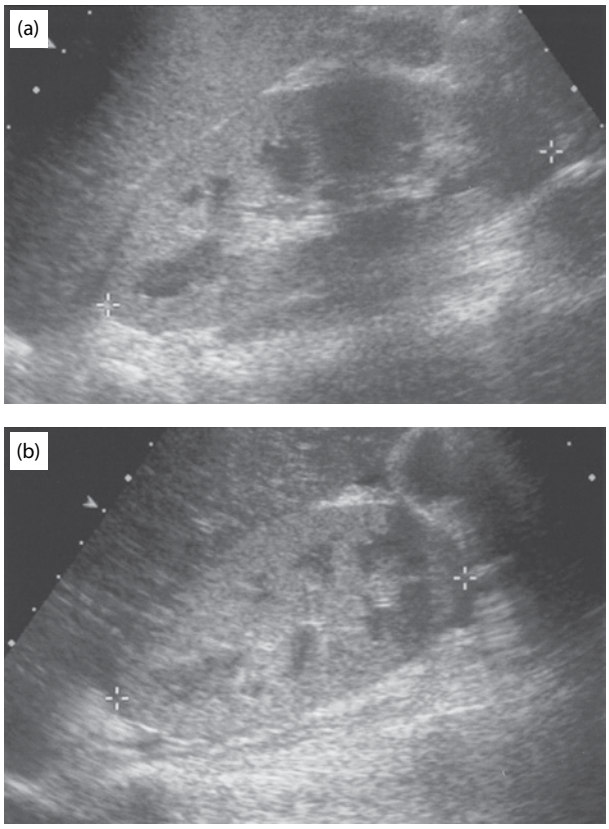

FIGURE 28.1 A 7-year-old boy with toxic shock syndrome presenting with scalded skin syndrome and acute oliguric renal failure. Ultrasound shows both kidneys are markedly enlarged with diffusely echogenic cortex. However, the pyramids remain hypoechoic and are easily identified. (a) Ultrasound: longitudinal view of the right kidney (length 9.3 cm). (b) Ultrasound: longitudinal view of the left kidney (length 9.3 cm).

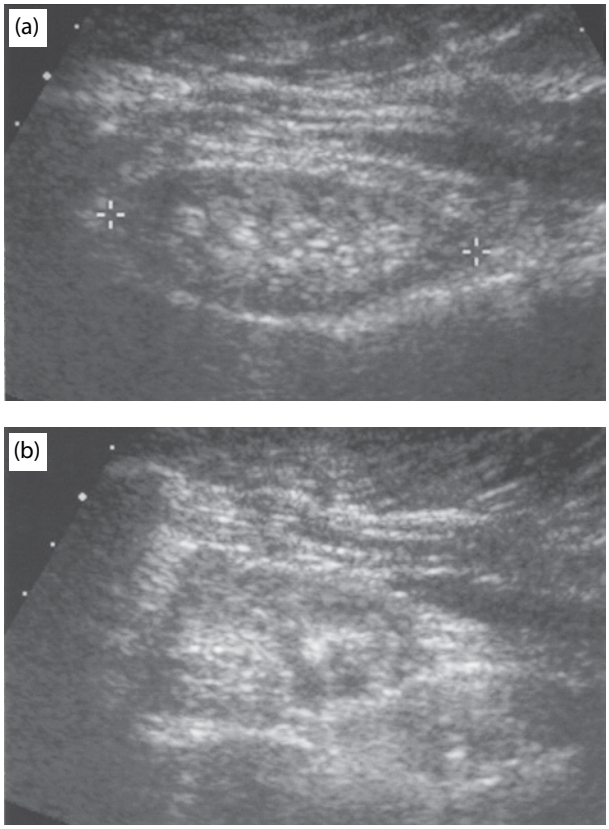

FIGURE 28.2 A 16-year-old boy with chronic medical renal disease and renal insufficiency on hemodialysis. Ultrasound of the kidneys shows that both kidneys are small with diffusely echogenic parenchyma and no visible corticomedullary differentiation. (a) Ultrasound: longitudinal view of the right kidney (length 6.7 cm). (b) Ultrasound: longitudinal view of the left kidney (length 6.8 cm).

resistive indices of the kidney in a young child is not often performed, and some question its value. However, in general, processes that cause obstruction of the collecting system, interstitial fibrosis, or obstruction of venous outflow will cause a rise in the resistive index. Both acute and chronic pathology that cause a reduction in the arterial inflow will be associated with a reduced resistive index.[21,27,31,34]

RENAL INFECTION

Acute Pyelonephritis

Currently, the initial study of a child with a febrile UTI suspected of having acute pyelonephritis (APN) is a renal US. Findings of acute infection are localized or generalized enlargement of the kidney due to acute cellular infiltration and interstitial edema (Figure 28.3a). There is usually thickening of the lining of the collecting system, and the renal parenchyma initially appears hyperechoic with loss of normal corticomedullary differentiation. Depending on the stage of infection and the presence of tissue ischemia, the parenchyma may appear hypoechoic.[35–45] Doppler or power Doppler examination of the kidney in the early stage would reveal hypervascular flow. As inflammation becomes worse and necrosis begins, the renal perfusion in affected areas would then change and appear hypovascular. Proponents of early US argue that pelviectasis that results from endotoxin in the urinary system or blood, desquamated cellular and crystalline debris, or frank purulent material in the collecting system will alert the clinician to those that are at risk for having underlying obstruction or VUR. Recently, however, some have begun to question the utility of US after the onset of febrile UTI. In 2003, Hoberman et al.[46] found that US was of limited value in children with their first acute febrile UTI because the abnormalities found in the 12% of 309 children did not change the immediate management. He attributed this to the assumption that in the modern era of prenatal US, almost all clinically significant renal abnormalities due to obstruction or VUR would be diagnosed before the onset of infection during the postnatal workup for prenatally detected abnormalities. However, despite this report, in 2010, the American Academy of Pediatrics (AAP) came out with new guidelines that recommended an US in children even after the first febrile UTI.[47]

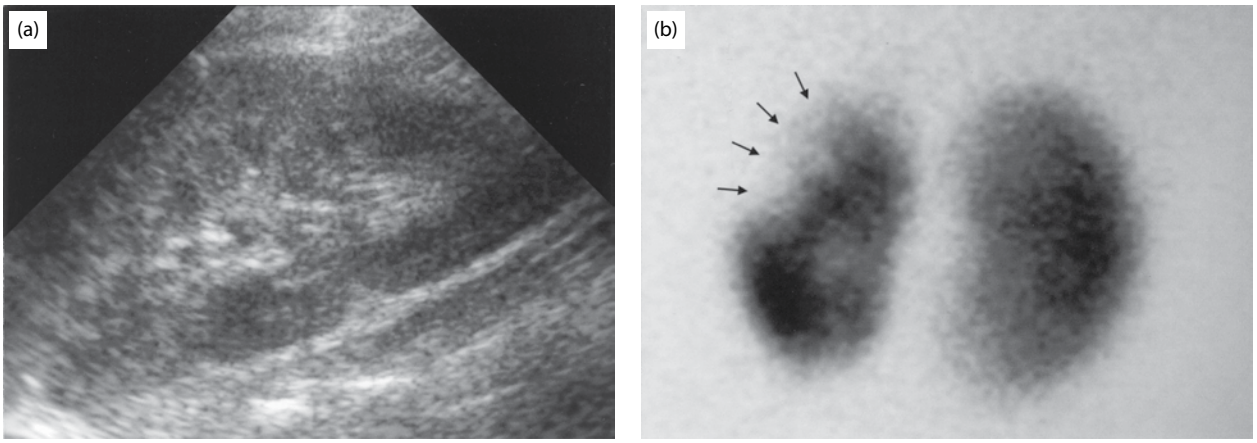

FIGURE 28.3 A 7-year-old girl with fever and left flank pain due to acute left pyelonephritis. (a) Ultrasound: longitudinal view of the left kidney (length 10.3 cm) shows that the upper half of the left kidney is enlarged and echogenic and appears somewhat bulbous compared with the lower pole. (b) ^{99m}Tc DMSA renal cortical scintigraphy (posterior view) confirms the presence of a large perfusion defect in the upper half of the left kidney (arrows).

Since US findings are neither sensitive nor specific, and changes in renal size and contour, as well as changes in parenchymal echogenicity, are often too subtle to detect prospectively during acute infection,[38,41,48,49] some have advocated the use of dimercaptosuccinic acid (DMSA) renal scintigraphy in the early stages of infection to diagnose APN. This so-called top-down approach relies on the sensitivity and specificity of a triangular wedge-shaped area of reduced cortical uptake of radiotracer (Figure 28.3b) that is characteristic during acute infection, as opposed to no cortical uptake in the area of a chronic previous renal scar.[41,48,50–53] The postulate behind the top-down approach is that a more reliable diagnosis of APN would establish a more accurate renal risk over time and, by doing so, identify those with clinically significant VUR. Then, voiding cystourethrography (VCUG) could be utilized exclusively in those with a positive scan who are at the highest renal risk. In the past, when a DMSA scan was performed after 3–6 months, when the majority of children at high renal risk have a normal scan, many children with clinically significant VUR and other nonrefluxing children at higher renal risk were "missed" because VCUG was not performed and measures to prevent further APN were not embarked on. Because of this, some have argued for a DMSA scan in the acute setting to determine who is at highest renal risk because they have radiographic evidence of renal inflammation. Indeed, when put to the test in recent years, it has been shown that a DMSA renal scan in the early phases of acute infection can identify almost all children with clinically significant VUR, identify children with and without VUR who have the greatest potential for renal scarring, and identify a cohort of children at greater risk for recurrent pyelonephritis and renal scarring based on comorbid bladder and bowel dysfunction.[1–3]

The practical role of CT and MRI in APN is less clear. Prior studies have shown a sensitivity similar to that of the gold standard DMSA.[50,52,53] On contrast-enhanced CT scan, APN appears as segmental areas of decreased or uneven parenchymal enhancement, with patchy areas of edematous margins that are most common in the poles of the kidney (Figure 28.4).[41,45,53–56] On postgadolinium contrast MRI T1-weighted images, areas of acute inflammation show reduced contrast enhancement; however, with T2 and inversion sequences, areas of acute inflammation remain bright, while healthy enhancing parenchyma has reduced signal intensity.[35,52,53,56–59] In several recent comparisons of diffusion-weighted (DW) versus the traditional gadolinium contrast-enhanced MRI, DW confirms the presence of APN with comparable sensitivity and specificity. The authors note that DW is a rapid, comprehensive, less expensive alternative magnetic resonance modality to traditional contrast-enhanced MRI that could obviate the need for contrast for the diagnosis of APN. Figure 28.5 shows that only the nonspecific finding of renal enlargement can alert the clinician to the presence of APN.

From the studies that have been published comparing the different diagnostic imaging modalities in APN, renal US, even with power Doppler imaging, seems to be the easiest and least expensive initial study to obtain in children suspected of having APN; however, it is the least sensitive. DMSA, contrast-enhanced abdominal CT scan, and contrast-enhanced abdominal MRI, on the other hand, all have comparable sensitivities (>90%). Since the kidneys are relatively radioresistant compared with other solid organs and gonads, and the kidneys take up the entire dose of the ^{99}mTc-DMSA, DMSA has an advantage over CT scan, where the entire abdomen receives the dose of radiation. MRI has the advantage of no radiation exposure but is very expensive. All three modalities are motion artifact sensitive, so all three require sedation in the younger child. DW MRI seems to have the most promise for the future because it offers multiplanar sensitive imaging without radiation exposure, and since it is a rapid study, sedation risks, as well as the associated prohibitive costs, are mitigated.[60–63]

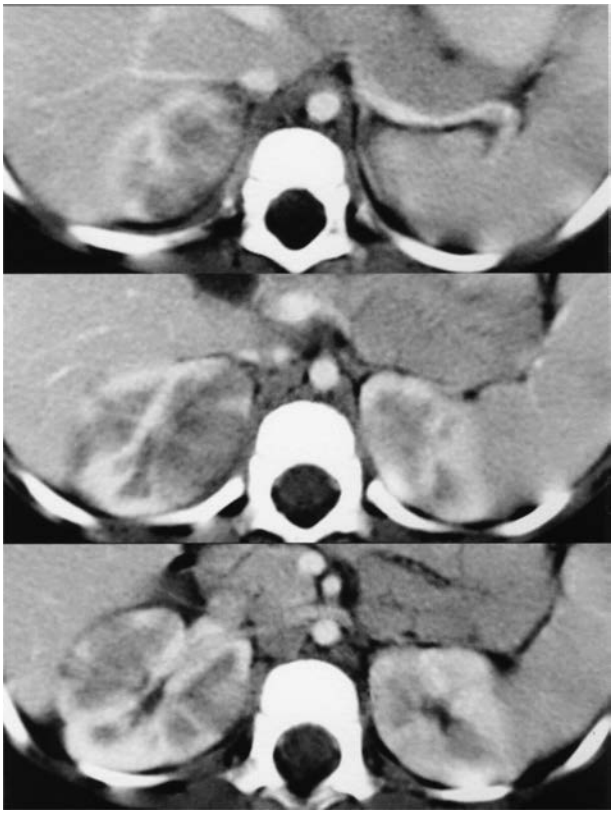

FIGURE 28.4 An 18-month-old girl with bilateral acute multifocal pyelonephritis, presenting with high fever and febrile seizure. Contrast-enhanced CT shows multiple wedge-shaped, low-attenuation, non-enhancing lesions in both kidneys.

Fungal Pyelonephritis

This form of pyelonephritis is usually associated with sepsis and is common in newborns and older children with indwelling urinary catheters, as well as immunocompromised children. Fungal septicemia from urinary fungal infection has an associated 50% mortality in children. Early diagnosis and aggressive treatment are essential. US is usually diagnostic since fungus balls are hyperechoic and do *not* shadow. On CT scan, focal areas of fungal pyelonephritis and fungal abscesses appear similar to bacterial pyelonephritis and abscess with heterogeneous areas of low attenuation (Figure 28.6). *Candida albicans* is the most common organism.[58,64–67]

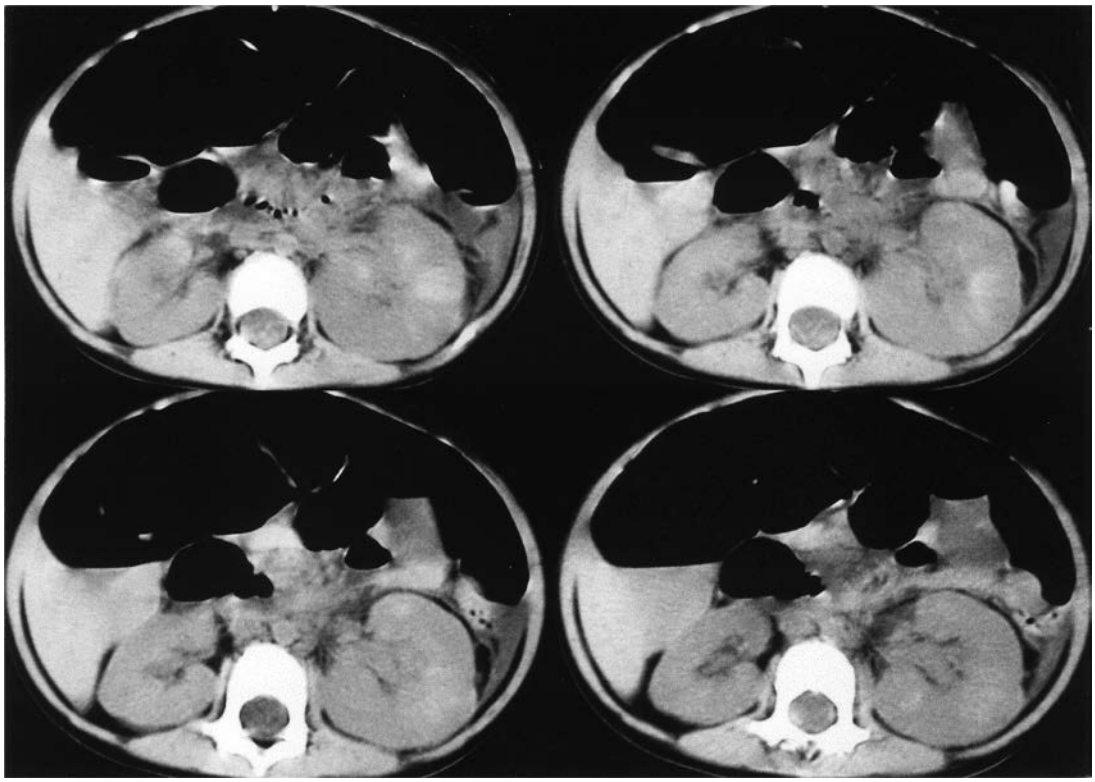

FIGURE 28.5 A 3-year-old girl with acute hemorrhagic pyelonephritis presenting with fever, gross hematuria, and *E. coli* bacteremia. Intravenous contrast material was not given for CT because of acute renal insufficiency requiring peritoneal dialysis. Non-enhanced CT shows that her left kidney is enlarged, with multiple slightly higher attenuation areas scattered throughout the parenchyma. Several similar, more subtle lesions are also present in the right kidney.

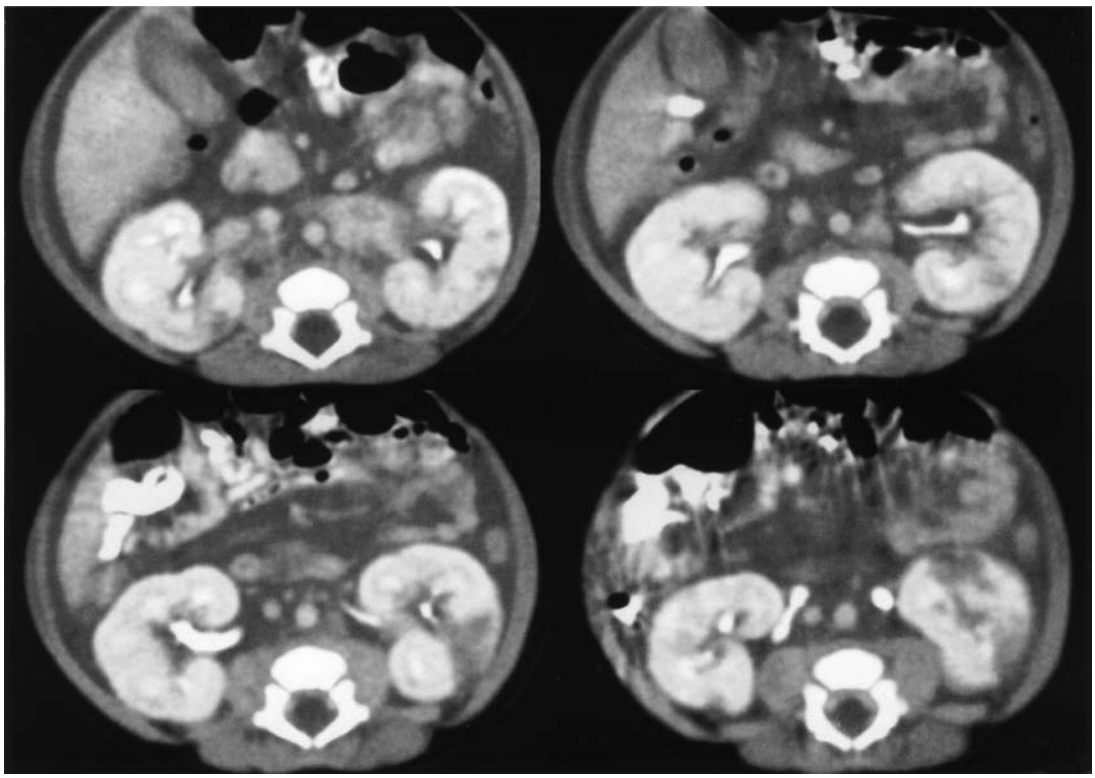

FIGURE 28.6 A 2-week-old boy with *Candida albicans* sepsis and bilateral fungal pyelonephritis. Contrast-enhanced CT shows both kidneys are enlarged and contain multiple scattered, peripheral, low-attenuation, non-enhancing parenchymal lesions.

Complications of Acute Pyelonephritis

Renal Abscess

Because of the nonspecific and often nondiagnostic images on US of a renal abscess, CT scan and MRI are often performed initially when renal abscess is suspected. For the most part, CT is the gold standard for imaging a renal abscess (Figure 28.7); however, the as low as reasonably achievable (ALARA) principle has caused a more modern trend toward the use of MRI. In addition, CT diagnosis is optimized by the use of iodinated contrasts, and these should not be used in children with renal failure or insufficiency, who seem to be the highest risk for renal abscess.[68] Most recently, some have prospectively evaluated the accuracy of the quantitative apparent diffusion coefficient (ADC) value obtained on DW MRI to differentiate nephritis from renal abscesses in patients with pyelonephritis.[69] They found that for the diagnosis of pyelonephritis, DW MRI had a higher sensitivity (95.3%) than non-contrast-enhanced CT (66.7%) and contrast-enhanced CT (88.1%). Areas of nephritis had significantly lower ADC values ($p < 0.001$) than the normal renal cortical parenchyma. In addition, renal abscesses had significantly lower ADC values ($p < 0.001$) than areas of nephritis. However, CT was more useful for the diagnosis of nephrocalcinosis and emphysematous pyelonephritis. Xanthogranulomatous pyelonephritis (XGP), perhaps the worst of all the complications of acute and chronic pyelonephritis, is characterized by granulomatous infiltration of the kidney by lipid-laden macrophages that leads to extensive parenchymal destruction.[41,58,70–73] It is usually caused by chronic *Escherichia coli* or *Proteus* sp. infection. There are nephrolithiasis and chronic obstruction in almost all cases. US appearance is nonspecific with a markedly enlarged echogenic kidney with abnormal architecture and almost no corticomedullary differentiation. In most cases, these findings, along with diffuse or focal hyperechoic calcifications or frank calculi, will alert the clinician, and further confirmation is usually obtained by contrast-enhanced CT scan. Because of the signature presence of calculi, MRI is of less value than CT in the imaging of XGP. On contrast-enhanced CT scan, the affected kidney is usually nonfunctioning and the parenchyma appears low in attenuation secondary to necrosis and extensive cellular infiltration of macrophages. Although rare, focal XGP is characterized by a large inflammatory irregular renal mass, often with extrarenal extension and a calcification or stone within the mass itself.

Pyonephrosis is an acute bacterial infection in an obstructed dilated collecting system that is best and most easily imaged by grayscale 2D US, and is characterized by usually severe hydroureteronephrosis filled with purulent urine. The debris is echogenic and layers dependently, as opposed to air bubbles, which if present will appear as similar brightly echogenic shadowing debris that will rise or float on top of the urine. Areas of focal or diffuse pyelonephritis often accompany pyonephrosis as well. If further imaging is needed, CT again has the advantage over MRI because it is often better at characterizing the presence of an obstructing calculus. Isolated debris in the collecting

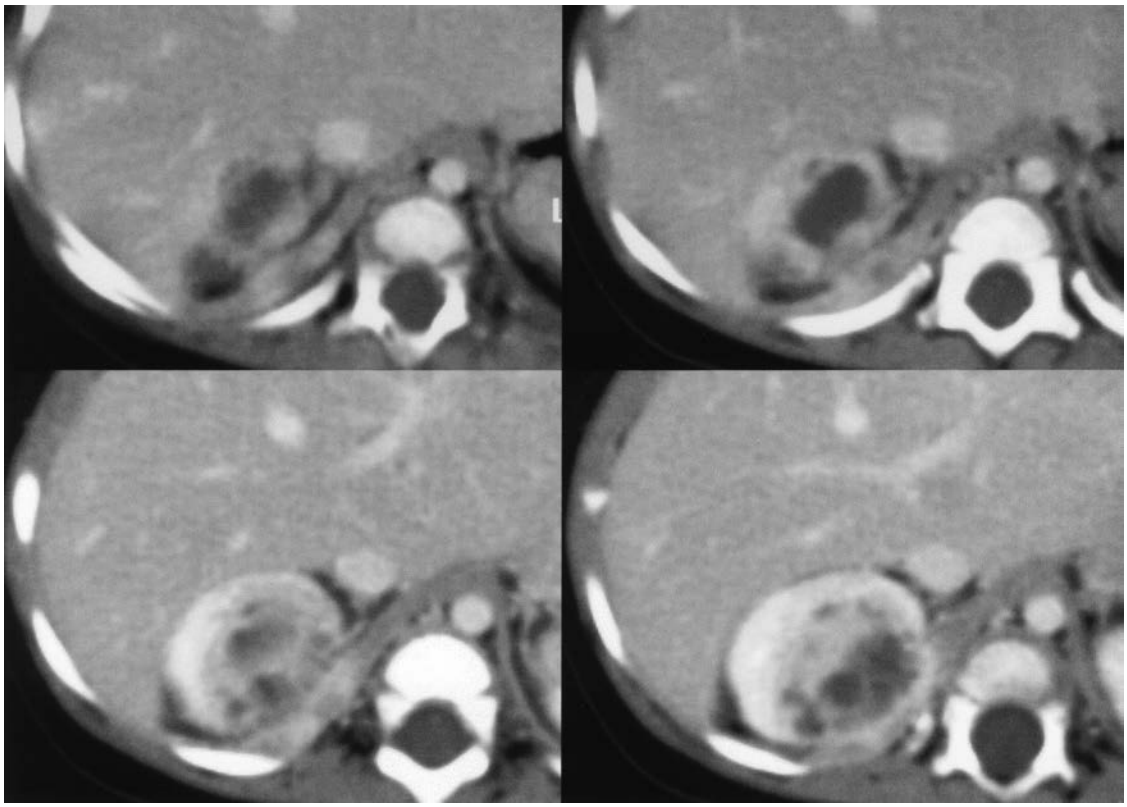

FIGURE 28.7 A 9-month-old boy with right acute pyelonephritis and intrarenal abscess. Contrast-enhanced CT shows a complex large-area abnormal enhancement with necrosis in the upper pole of the right kidney.

system is often seen with concentrated urine or can be seen early on with the endotoxin-induced atony of the collecting system in uncomplicated pyelonephritis. Similarly, air bubbles can be introduced into the bladder during routine or intermittent catheterization and, when present in the bladder, can get into the upper tract in children with VUR. These findings in isolation should not be mistaken for pyonephrosis.[41,58,65,74–76]

Renal scarring, or *chronic pyelonephritis*, otherwise known as reflux nephropathy, results from recurrent episodes of APN. Imaging of renal scars is largely performed in children by US. This modality has completely replaced IVP.[35–37,39,43,77] The US appearance of cortical scarring is heralded by cortical thinning or loss. Because of contraction and fibrosis, the adjacent calices are blunted. Cortical scars are more common at the poles due to the composite calices that allow for reflux into the medullary pyramids—so-called "intrarenal reflux"—and usually become more evident at least 3–6 months after acute infection, but can take up to 3 years to develop. Therefore, serial USs over time are important to follow linear measurements and document an acquired renal scar. Global scarring of the renal parenchyma is easily seen on US. The kidney is small with echogenic thin parenchyma. Focal scarring is likely more common, and much harder to see on US. The kidney may be normal size with imperceptible parenchymal volume loss. Cortical scars of this type are also more common in the polar regions of the kidneys. These should not be mistaken for fetal lobulations, which are uniformly spaced between pyramids and have no adjacent parenchymal thinning or blunting of calices. Chronic pyelonephritis is best seen by ^{99}mTc-DMSA renal cortical scintigraphy. Although DMSA is not good at differentiating a mature scar from congenital scars (i.e., dysplasia), there is a difference between an area of APN, an immature scar, and a mature scar. Mature scars are sharply defined wedge-shaped defects in the renal cortex, whereas a more acute or immature scar that has not had complete necrosis and fibrosis of the involved parenchyma will appear as a more irregular photopenic defect. Mature scars have renal volume loss with flattened renal contour due to complete fibrosis, whereas an immature or an acute defect will be more enlarged with an irregular, less defined renal outline.[43,45,51,78]

The role of MRI in the evaluation of renal abnormalities is increasing. MRI is useful in cases of compromised renal function and severe contrast allergy, and in children, with an emphasis on minimizing radiation exposure. Furthermore, MRI can be used as a problem-solving modality when the US findings are not diagnostic. Combined static–dynamic magnetic resonance urography (MRU) provides high-quality depiction of the urinary tract in infants and children, while allowing accurate determination of single-kidney function and reliable evaluation of urinary excretion.[63] In a comparison of MRU to DMSA scan for the identification of renal parenchyma defects in children with VUR, Cerwinka et al.[79] found that although DMSA scan and MRU were similar in their ability to diagnose parenchymal defects, MRU was considered to represent the true diagnosis in 11 of the 12 discordant cases in consensus review by four pediatric radiologists. MRU showed a much higher interobserver agreement with a weighted kappa of 0.96 for both kidneys. Based on their findings, they concluded that MRU was superior to DMSA scan in the identification of renal parenchyma defects. Likewise, in another study that used DMSA as the gold standard, Chan et al.[80] found that MRI with fat-saturated T1-weighted and after gadolinium, short tau inversion recovery (STIR) sequences was comparable to planar ^{99}mTc-DMSA. Static renal MRI using a fat-saturated T1-weighted sequence is a rapid, accurate, and minimally invasive technique for the detection of renal scarring that does not employ contrast enhancement or ionizing radiation.[60] By comparing the diagnostic performance of MRU in renal scar detection relative to that of the ^{99}mTc-DMSA scan in 49 children with UTI and VUR, Koçyiğit et al.[81] found that enhanced MRU is a robust technique for the morphologic assessment of the urinary system and detection of renal scars. The lack of radiation and contrast material makes this technique a much safer alternative to DMSA in children with VUR and a history of acute renal infection, particularly in those who require follow-up scanning and, consequently, considerable cumulative radiation exposure.

RENAL MASSES

At different ages, different types of masses are more common, and thus different imaging modalities are indicated. Due to its ease and ubiquitous nature, and the fact that in the neonate a palpable abdominal mass is more often cystic disease or is associated with hydronephrosis, US is the initial imaging modality of choice.[21,27,58] The most common solid renal mass in a neonate will be a congenital mesoblastic nephroma, and as the child gets older, Wilms' tumor (WT) would be the most common; therefore, a CT scan in these cases would most likely be the next imaging modality after an US finding of a solid mass. Certain genetic or familial syndromes carry an increased risk of developing WT, and frequent screening of the child is recommended with US. Although some authors question whether this changes the actual stage of the tumor at presentation if it should occur, most recommend screening renal US every 3 months until the age of 5 years in children with sporadic aniridia and WAGR association, and until the age of 8 years in children with hemihypertrophy, Drash syndrome, Perlman syndrome, and/or Beckwith–Wiedemann syndrome.[82,83]

RENAL TUMORS

When evaluating a solid renal tumor in a child, the goal should be to image the kidney to gain as much information as possible with a single imaging test, with as little radiation exposure as possible. As stated, this usually involves an US at the time of detecting a renal mass. Depending on the cell type and population, solid masses can be hypo-, iso-, or hyperechoic on US. Areas of hemorrhage, cystic degeneration, or necrosis will often appear irregular and hypoechoic. Given this variability, CT or MRI is the likely next step. All solid renal masses should be evaluated for size, laterality, intrarenal or extrarenal extension, focal

or diffuse pattern, cystic or mixed cystic–solid character, presence and pattern of calcification, perirenal or local adenopathy, vascular invasion or encasement, and neighboring organ involvement. The imaging test should also aide in staging and preoperative or neoadjuvant planning. It is also important to exclude any contralateral involvement or congenital renal anomaly that would reshape the treatment to a more renal-sparing plan. In most situations, all this information can be obtained with a single CT or MRI study,[84] but in atypical cases or cases where vascular invasion cannot be excluded, additional imaging is needed.

Wilms' Tumor

WT is the most common solid renal malignancy in childhood and accounts for 5% of all childhood malignancies. Most WTs are solitary, large, and confined to the kidney and of favorable histology. Favorable histology is present in ~90% of WTs.[85–91] Therefore, for the most part, the stage of the tumor is the most important prognostic factor. Anaplastic or unfavorable histologic variants have a much poorer prognosis. As long as they are completely resected at surgery without tumor spill, a tumor that is confined to the kidney (stage I) or an extrarenal tumor, even with lymph node or inferior vena cava involvement (stage II), has a >98% survival with favorable histology and a >80% survival if an unfavorable histology. If there is tumor spill at surgery or an incomplete resection (stage III), survival drops to 94% for favorable histology and 72% for unfavorable histology.[92] Staging and assessment of WT is usually performed with contrast-enhanced CT scan. On precontrast CT scan, the tumor appears heterogeneous and often large (~10 cm average).[58,93] On contrast-enhanced CT scan, the tumor is often heterogeneous as well, with enhancement of viable tumor and lack of enhancement of areas of cystic degeneration and necrosis. Although most tumors are encased in a pseudocapsule of compressed surrounding parenchyma, extrarenal invasion or displacement of surrounding bowel and vasculature can be seen. Synchronous bilateral Wilms' tumor (BWT) occurs in 4%–8% (Figure 28.8). However, approximately 1% of children with unilateral WT develop contralateral disease. Coppes et al.[94] assessed the demographic and histologic features associated with metachronous BWT. Although surveillance for metachronous lesions was recommended for those children with nephrogenic rests (NRs) who are diagnosed after the age of 12 months, children younger than 12 months diagnosed with WT who also have NRs, in particular perilobar NRs, have a markedly increased risk of developing contralateral disease and require frequent and regular surveillance for several years. Although contralateral exploration is still an acceptable practice in equivocal cases, modern CT and MRI have led to a more accurate definition of intrarenal pathology. In a study designed to answer the question of whether contralateral kidney exploration is still necessary in patients with unilateral WT, Kessler et al.[95] found that in all patients, preoperative radiological investigation was accurate in excluding bilaterality. With modern imaging techniques and effective chemotherapy, extensive contralateral renal exploration may no longer be mandatory for managing WT. Ritchey et al.[96] evaluated the incidence and outcome of missed bilateral lesions. In this study, there were 188 patients with BWT, or 5.6% of the total 3335 registered. CT was performed in all patients. After subsequent management of missed lesions and a median follow-up of 9 years, there were no recurrences in any kidney with a missed lesion, and all patients were alive and disease-free at last follow-up. From these studies, it seems that omission of routine exploration will not likely affect the outcome or management of newly diagnosed WT provided preoperative CT or MRI is performed.

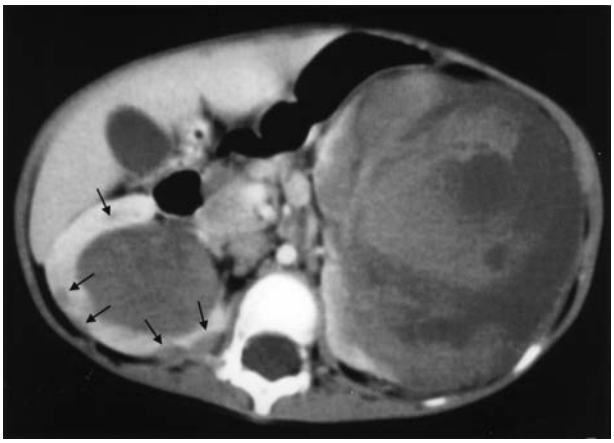

FIGURE 28.8 A 3-year-old girl with bilateral synchronous Wilms' tumors and right nephroblastomatosis. At contrast-enhanced CT, the left kidney is almost entirely replaced by a large, partially necrotic mass (Wilms' tumor) and there is a somewhat smaller mass (Wilms' tumor) distending the right renal sinus. Numerous tiny, low-attenuation perilobar nephrogenic rests (arrows) are visible in the residual enhancing right kidney.

WT staging has to include imaging of at least the entire abdomen and chest since lung is the most common presentation of metastatic disease. For the most part, CT is used most often for staging because it is the most ubiquitous, and does not suffer as much as MRI from motion artifact, which demands anesthesia with all the inherent risks. Depending on final tumor histology, a bone scan and brain MRI scan must be performed as well in the case of clear cell sarcoma and rhabdoid tumor of the kidney, although these are not strictly categorized as WTs any longer. MRI is specifically recommended and often needed, independent of CT scan, in cases where there is suspected vena cava or right atrium tumor thrombus (Figure 28.9), infiltration of the liver and/or diaphragm, or continuous tumor extension into the chest cavity. MRI is superior to CT scan in these situations because postscan software and computer-aided techniques can better differentiate neighboring tissues by either their patterns of gadolinium enhancement, different diffusion coefficients, differing fat suppression properties, or appearance on T1- and T2-weighted images.[62] In the case of screening or for postoperative surveillance, US is the procedure of choice because these are undoubtedly serial examinations over long periods of time, and the inherent anesthesia associated with MRI or radiation exposure with CT scan is an unacceptable risk to the growing child.

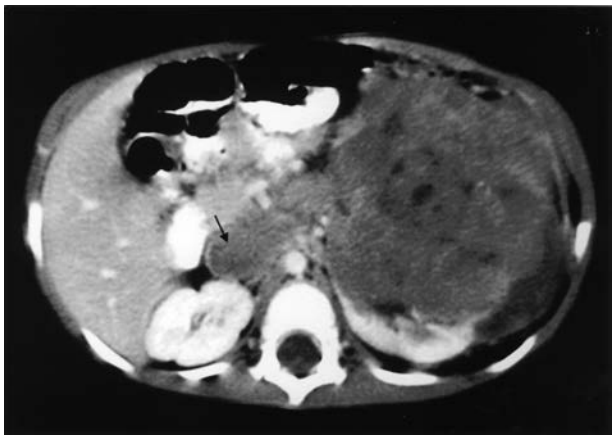

FIGURE 28.9 A 2-year-old girl with large left Wilms' tumor with extension into the left renal vein and inferior vena cava. Contrast-enhanced CT shows a large non-enhancing, solid left renal mass containing multiple small areas of necrosis and hemorrhage. Low-attenuation soft tissue is visible distending the left renal vein and inferior vena cava (arrow).

Nephroblastomatosis

Nephroblastomatosis is when there is nephrogenic blastema that persists in the kidney that can undergo malignant transformation into a WT postnatally. These nephrogenic rests, as they are called, can be either perilobar, intralobar, or very rarely panlobar. The perilobar are much more common (Figure 28.8), while the less common intralobar will more commonly undergo malignant transformation. Although some nephrogenic rests are not macroscopic, most can be seen on US or CT scan, with the majority being identified with a combination of imaging studies, although CT is more sensitive than US. Nephrogenic rests characteristically do *not* enhance with contrast on either CT or MRI (Figure 28.10). They appear as low-attenuation areas on CT. On T1- and T2-weighted MRI, they appear hypointense compared with the normal renal cortex and isointense compared with the renal medulla.[94] Children with nephrogenic rests that are identified on imaging, and those children that have syndromes and conditions that are known to have a high incidence of nephrogenic rests, should have serial renal imaging at least every 3–6 months during infancy and early childhood.[87,89,93] This interval can be increased as the children get older.[58,93,97] The best modality for surveillance of this type is US. Each study should be compared with the previous studies, looking not only for changes in the echotexture of areas of suspicion but also for new suspicious areas, as well as focal or asymmetric enlargement, or changes in the renal contour or outline. Some have suggested power Doppler US to increase the sensitivity for detecting smaller renal masses not seen on routine 2D US. Regardless, any suspicious areas or changes should be followed immediately by contrast-enhanced CT or MRI.

FIGURE 28.10 A 14-month-old boy with panlobar nephroblastomatosis, presenting with a markedly distended abdomen and bilateral palpable flank masses. Contrast-enhanced CT shows the kidneys are almost completely replaced by multiple low-attenuation, non-enhancing, solid masses. Residual compressed strands of functioning renal parenchyma are visible between the masses.

Neuroblastoma

Neuroblastoma (NB) is an adrenal tumor or a tumor of neuroectodermal tissue origin that is separate from the kidney and can arise anywhere along the sympathetic chain. The most common site of origin is in the retroperitoneum. NB is the most common extracranial solid tumor in children, with 90% of them diagnosed before the age of 5 years. It is worth mentioning in this context because 20% of NBs involve the kidney, and oftentimes they cannot be distinguished from WT on routine US and CT images. Both WT and NB are heterogeneous solid masses with mixed areas of cystic degeneration, necrosis, and hemorrhage on CT scan. NB characteristically has a low signal intensity on T1-weighted and high signal intensity on T2-weighted magnetic resonance images. Several imaging clues can distinguish WT from NB. WT arises from within the kidney, while NB arises from the adrenal or retroperitoneum, and therefore will appear to displace the kidney. NB also often lacks a well-defined capsule, whereas WT has a well-defined pseudocapsule of compressed renal parenchyma. WT can invade major renal vessels, whereas NB engulfs major renal vessels, causing compression and clinical hypertension. More than 90% of NBs have calcifications in the tumor, whereas only about 15% of WTs have calcifications. WT most commonly metastasizes to the lungs, whereas NB will metastasize to cortical bone, bone marrow, the liver, and the orbit. Generally, children with NB are often very ill with systemic symptoms such as weight loss, anorexia, and malaise since ~65% present with metastatic disease. There is no absolute best imaging modality for NB, but MRI has emerged over the years to have several advantages over CT, besides the lack of radiation exposure. MRI is excellent at examining the relationship of a mass to surrounding tissues of different water diffusion properties. In addition, often MRI can detect metastases to bone marrow of the extremities in young children and vertebrae in older children. NB can spontaneously regress in infancy (stage IV), making it difficult to distinguish from the more common adrenal hemorrhage, which also presents as a solid and/or cystic adrenal mass. NBs that occur in infancy can be distinguished from adrenal

hemorrhage because the former will have elevated urinary catecholamine. Between 85% and 95% of children with NBs excrete catecholamine or their metabolites in the urine.[98]

Clear Cell Sarcoma

Clear cell sarcoma of the kidney (CCSK) was once considered a variant of WT, and it is reported by the National Wilms Tumor Study Group (NWTSG) to account for 4% of pediatric renal tumors.[99] CCSK tends to manifest with an average age at presentation of 2–3 years, and exhibits a male predominance. CCSK yields a much poorer prognosis than WT, with current long-term survival rates of 60%–70%.[100] CCSK is often misdiagnosed given the infrequency with which it is clinically encountered. The morphological diversity and the lack of specific diagnostic markers also contribute to the high rate of misdiagnosis.[101] Approximately 5% of patients will have metastatic disease at diagnosis. There is a 40%–60% incidence of skeletal metastasis present among patients with CCSK.[102] Additionally, CCSK has been reported to metastasize to unusual sites, such as the scalp, epidural space, nasopharynx, neck, paraspinal area, abdominal wall, axilla, and orbit.[103] Imaging characteristics are usually indistinguishable from WT. US shows heterogeneous echogenicity with cystic components and necrosis. Large fluid-filled cystic spaces with echogenic septa may also be present.[104] CT will reveal inhomogeneous enhancement, with attenuation less than that of normal renal parenchyma. Furthermore, these tumors also contain areas of low attenuation corresponding to necrosis and cysts.[104] Skeletal metastasis tends to be osteolytic in nature, but osteoblastic metastasis also occurs; therefore, both hot and cold defects can be seen on bone scan.[105]

Malignant Rhabdoid Tumor

Although renal malignant rhabdoid tumor was historically included in earlier treatment protocols of the NWTSG, this tumor is now recognized as an entity separate from a WT. In contrast to a WT, a malignant rhabdoid tumor of the kidney is characterized by the early onset of local and distant metastases and resistance to chemotherapy. Whereas the overall survival rate for WTs exceeds 85%, the survival rate for renal malignant rhabdoid tumors is only 20%–25%. Malignant rhabdoid generally presents during the first year of life.[106] Malignant rhabdoid tumor is associated in up to 50% of patients with a histopathologically diverse group of primary central nervous system tumors that include primitive neuroectodermal tumor, ependymoma, and astrocytoma.[107] This group of primary central nervous system tumors can be present when the renal mass is detected, or they may appear later in the disease process. CT, US, and MRI will reveal a large, aggressive, infiltrating, solid renal mass. The mass will often arise centrally, adjacent to the renal hilum, and invade and compress surrounding parenchyma as the mass enlarges. Linear calcifications are common, and may appear to outline distinct tumor lobules. Rapid enlargement of the mass may lead to necrosis and hemorrhage. Peritumor hemorrhage may also occur, and this may lead to characteristic crescent-shaped fluid collections at the periphery of the mass. Given the frequent association of both primary and metastatic central nervous tumors, CT or MRI of the brain should be performed whenever the diagnosis of malignant rhabdoid tumor is suspected.

Renal Cell Carcinoma

Pediatric renal cell carcinomas account for approximately 2% of all new pediatric renal tumors.[108] The most common subtypes seen preferentially in children are the translocation-associated tumors, papillary renal cell carcinoma, renal medullary carcinoma, and oncocytic renal cell carcinoma following NB.[109] The mean age at presentation is 11–12 years old, and it has been reported as early as 6 months of age. Patients commonly present with painless gross hematuria, abdominal pain, or a palpable mass. The imaging features of renal cell carcinoma in children are similar to those found in renal cell carcinoma in adults. The tumor usually appears hyperechoic on US and hyperdense on CT with heterogeneous contrast enhancement (Figure 28.11).[110,111] Necrosis and hemorrhage are common, and calcification is more common than in WT. There is a relatively good prognosis if the entire lesion can be removed surgically. If the lesion is incompletely resected or there is distant metastasis present, the prognosis is poor.[112]

Renal Medullary Carcinoma

Renal medullary carcinoma is a very aggressive malignant neoplasm that occurs almost exclusively in children and young adults with sickle cell trait or sickle cell disease.[113] These patients usually present with hematuria, flank pain, weight loss, fever, and abdominal pain. US and a CT scan usually show an infiltrative and distinct intrarenal mass that frequently arises from the central region of the kidney and commonly invades the renal sinus fat.[113–115] MRI and CT both demonstrate heterogeneous enhancement. Renal medullary carcinoma arises along the urothelial margin of the renal medulla and grows quickly into the renal pelvis, leading to early vascular and lymphatic invasion. Peripheral satellites in the renal cortex and pelvic soft tissue, as well as venous and lymphatic invasion, are usually present. Common sites of metastasis include the contralateral kidney, liver, lungs, and lymph nodes.

Leukemia, Lymphoma, and Lymphoproliferative Diseases

Histologic evidence of renal infiltration is common on postmortem examination of children who die from leukemia or lymphoma. Clinical and radiographic evidence of renal involvement is much less common during life.[116–118] Clinical signs of renal involvement, including palpable mass, hematuria, or reduced renal function, rarely precede other manifestations of the disease. Renal involvement is usually detected during staging or follow-up imaging studies in patients with known disease elsewhere.

Renal involvement is usually bilateral in both leukemia and lymphoma.[117,118] Leukemic infiltration of both kidneys

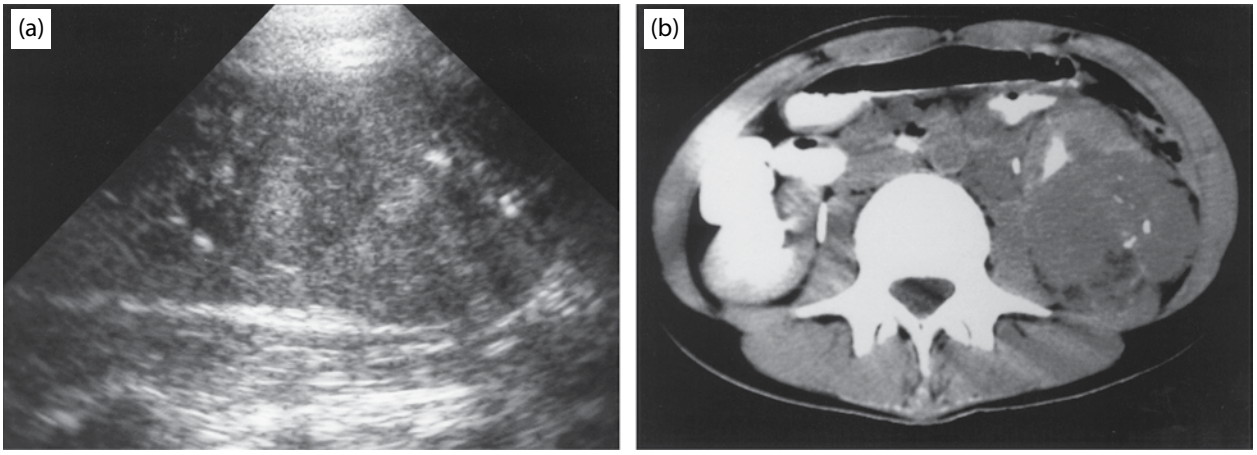

FIGURE 28.11 A 13-year-old girl with renal cell carcinoma of the lower pole of her left kidney, presenting with abdominal pain and a palpable left abdominal mass. (a) Ultrasound: longitudinal view of the left kidney shows a large, solid, slightly heterogeneous lower pole mass. Multiple small calcifications are visible within the mass. (b) Contrast-enhanced CT through the kidneys shows a large, solid mass in the lower pole of the left kidney posteriorly. Small calcifications are present within the mass. The residual functioning portion of the left kidney is visible anteriorly.

causes diffuse renal enlargement with disruption of the normal corticomedullary architecture (Figure 28.12). A discrete mass is less common in leukemia than in lymphoma. In lymphoma, neoplastic infiltration of the renal interstitium initially also causes nonspecific renal enlargement, with a diffuse increase in the parenchymal echogenicity on US. As the infiltrating neoplastic cells coalesce to form larger, hypoechoic masses, the kidney enlarges and loses its reniform shape. The renal architecture is increasingly disrupted, and the parenchyma becomes diffusely more inhomogeneous. At postcontrast CT, multiple coalescing low-attenuation, nonenhancing, solid masses are visible (Figure 28.13).[116–118] Perinephric extension and renal hilum and retroperitoneal lymph node involvement is better demonstrated at CT or MRI than at US. Follow-up imaging after successful treatment and regression of the masses often shows extensive cortical defects that can be indistinguishable from other causes of renal atrophy and cortical scarring. Dystrophic parenchymal calcifications are also occasionally seen following treatment for some forms of renal lymphoma (Figure 28.14).[119]

Lymphoproliferative disorders are an important consideration in patients who have severely impaired T-lymphocyte-mediated immunity, and are potentially life-threatening conditions. Lymphoproliferative disorders have been reported as a complication of immunosuppression for organ transplantation,[120–122] in primary immunodeficiency, and in acquired immunodeficiency syndrome (AIDS). Regardless of the immune defect, Epstein–Barr virus is critical in mediating the induction of polyclonal B-lymphocyte proliferation that leads to the development of lymphadenopathy, focal parenchymal masses, and diffuse infiltration of solid organs.[121,123] Involvement can be focal, multifocal, or widely disseminated. Any organ or body space can be involved. The gastrointestinal tract, solid abdominal organs, and abdominal lymph nodes are most often affected. Renal involvement occurs in 17%–20% of cases and has imaging features similar to those of leukemia and lymphoma.

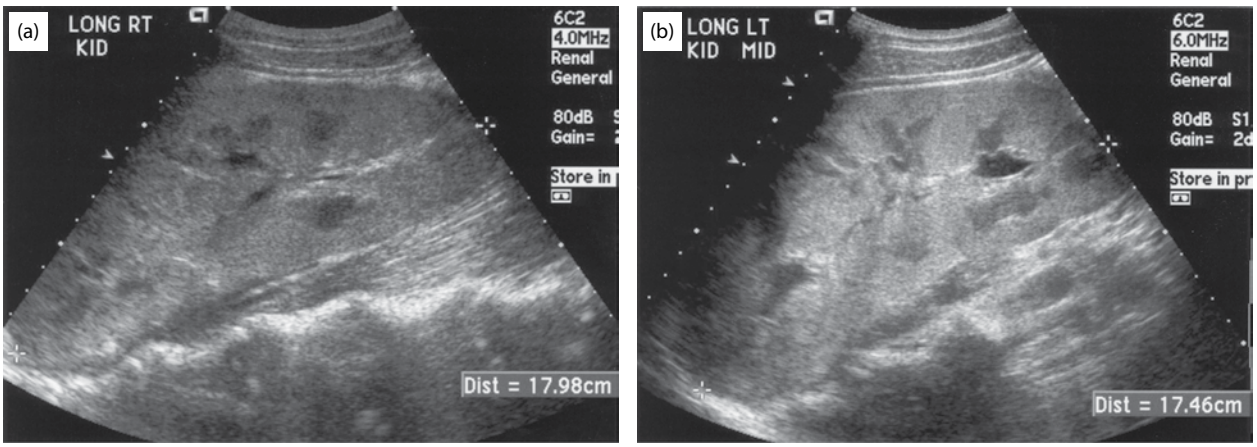

FIGURE 28.12 An 18-year-old boy with relapsed acute lymphocytic leukemia and diffuse bilateral leukemic renal infiltration. Ultrasound shows markedly enlarged, echogenic kidneys with multiple small, relatively hypoechoic, solid masses scattered throughout the parenchyma bilaterally. (a) Ultrasound: longitudinal view of the right kidney (length 18.0 cm). (b) Ultrasound: longitudinal view of the left kidney (length 17.5 cm).

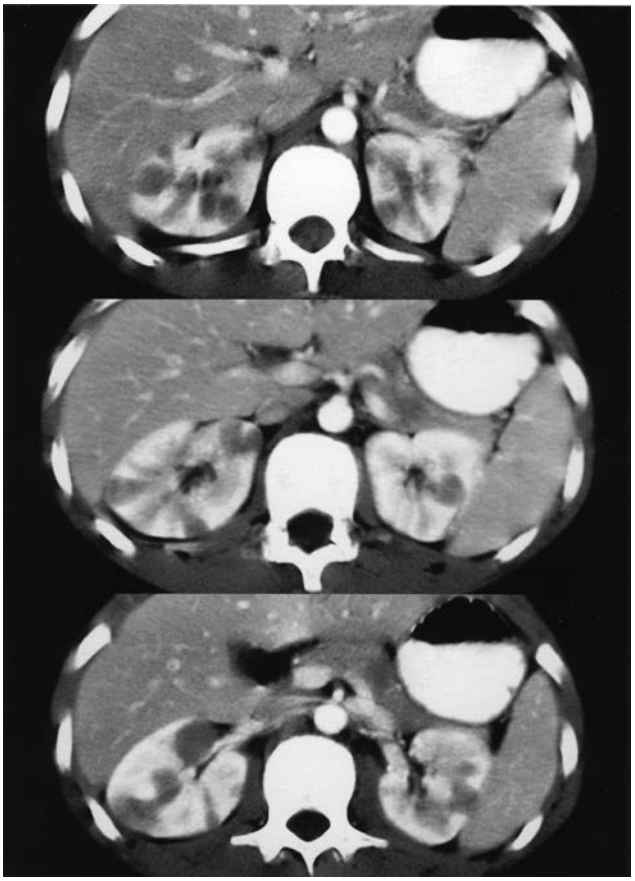

FIGURE 28.13 A 14-year-old boy with Burkitt's lymphoma of both kidneys. Contrast-enhanced CT shows multiple nonsegmental, low-attenuation, non-enhancing solid masses scattered randomly throughout both kidneys.

Congenital Mesoblastic Nephroma (Fetal Renal Hamartoma)

Congenital mesoblastic nephroma (congenital fetal renal hamartoma) is the most common primary, renal tumor in the newborn, and it occurs almost exclusively in the first year of life.[124–127] Once thought of as a congenital form of WT, mesoblastic nephroma is distinguished by its younger presentation, characteristically nonaggressive course, limited growth potential, predominantly mesenchymal derivation, and lack of malignant epithelium. Recurrence is rare as long as the entire mass is removed, although metastatic spread to the lungs and brain has been reported.[128] A palpable mass is generally present at diagnosis. However, mesoblastic nephroma is increasingly being detected at prenatal US. On US, mesoblastic nephroma appears as a large solid renal mass. The mass can appear either homogeneous or complex. Cysts are present in up to 60% of cases, and small, scattered calcifications can also occasionally be visible.[129] On CT, the tumor presents as a nonenhancing, low-attenuation mass surrounded by enhancing residual normal parenchyma (Figure 28.15). Cystic areas of necrosis and hemorrhage are readily demonstrated on CT, as well as calcifications, when they occur.[125,126]

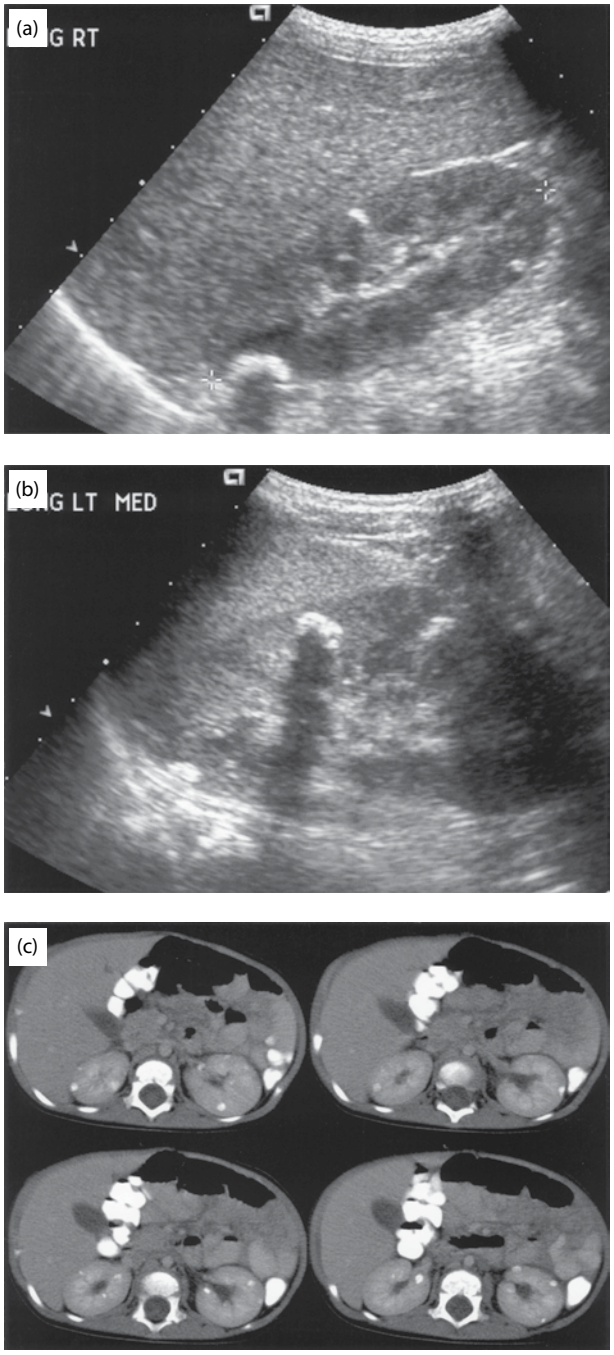

FIGURE 28.14 A young boy with bilateral dystrophic renal parenchymal calcifications 3 months after treatment for acute myelogenous leukemia. (a) Ultrasound: longitudinal view of the right kidney. (b) Ultrasound: longitudinal view of the left kidney. (c) Contrast-enhanced CT: four axial images through the kidneys.

Multilocular Cystic Nephroma

Multilocular cystic nephroma is a benign, cystic renal tumor that is made up of noncommunicating cysts of differing sizes that are separated by thin septa. These septa are composed of fibrous tissue, tubular elements, and immature blastema.[130–132] The tumor can be localized to one part of the kidney or involve the entire kidney. Rarely,

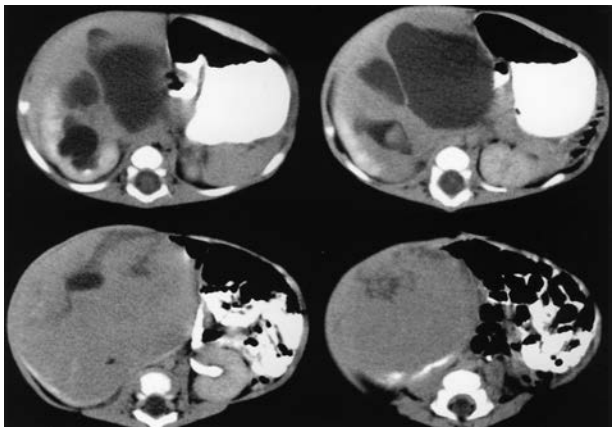

FIGURE 28.15 An 8-week-old girl with right congenital mesoblastic nephroma, presenting with a palpable right abdominal mass. Contrast-enhanced CT shows a large, solid, non-enhancing right renal mass that compresses the renal pelvis, resulting in obstruction and severe hydronephrosis.

multiple discrete lesions are present. Although the cyst walls occasionally contain cellular elements that are histologically similar to WT, multilocular cystic nephroma has no real malignant potential and local recurrence is rare following complete resection. The imaging features of multilocular cystic nephroma are distinctive.[130,131] The tumor appears as a complex, multicystic mass with uniformly thin septa separating the cysts. The septa are usually more conspicuous on US than on CT, although they can enhance somewhat after administration of contrast material. Thicker septa and septa that appear irregular or nodular are unusual in multilocular cystic nephroma, and this finding should raise concern that the lesion might instead represent a cystic WT.[132] Septal calcifications are occasionally present in adults, but are rarely seen in children. On MRI, the tumor capsule and septa appear hypointense on both T1- and T2-weighted images, with minimal enhancement after gadolinium.[133] The signal intensity of the fluid within the locules depends on their hemorrhagic and proteinaceous composition.

Angiomyolipoma

Angiomyolipoma is a benign, nonencapsulated tumor of the kidney composed of blood vessels, smooth muscle, and fat.[134–136] In the pediatric population, angiomyolipoma is highly suggestive of the diagnosis of tuberous sclerosis, and is usually multiple and bilateral (Figure 28.16). Other clinical and imaging features of tuberous sclerosis are usually present. Far less often, angiomyolipomas are diagnosed in a child with undiagnosed tuberous sclerosis who presents with a palpable mass or hematuria. Renal cysts also occur in patients with tuberous sclerosis (Figure 28.17) and can coexist with angiomyolipomas.[135–137] Visualization of fat within a renal mass in a child is highly suggestive of the diagnosis of angiomyolipoma.[134–136] Rarely, the tumor has more vascular and muscular components and contains little or no visible fat. Calcification is usually absent. Angiomyolipomas are usually very echogenic on US and have very low attenuation, similar to perinephric fat on nonenhanced CT scans. On MRI, the tumors are hyperintense on both T1- and T2-weighted images. Because angiomyolipomas are extremely vascular, they enhance very intensely on both CT and MRI. Larger angiomyolipomas tend to bleed, resulting in intratumoral, subcapsular, and perinephric hemorrhage.

Renal Lymphangioma and Lymphangiomatosis

Renal lymphangioma is a rare, benign, cystic renal neoplasm with imaging features similar to those of multilocular cystic nephroma.[138,139] Renal lymphangioma is either unilocular or multilocular in nature and is usually solitary, although multiple lymphangiomas do occur. Renal lymphangiomatosis is an extremely rare disorder that is characterized by massive bilateral nephromegaly. There are residual islands of functional renal parenchyma appearing as irregular bands separating the innumerable cysts, which may simulate the appearance of advanced autosomal dominant polycystic kidney disease or tuberous sclerosis.[140] Lymphangiomatosis can be limited to the kidneys, or it can

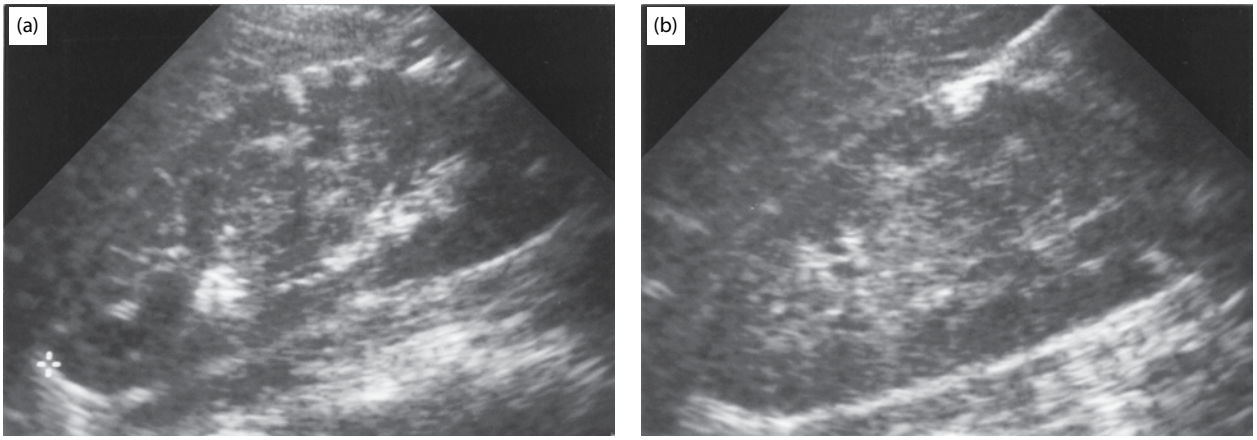

FIGURE 28.16 A 4-year-old girl with tuberous sclerosis and bilateral renal angiomyolipomas. Ultrasound shows multiple small, solid, non-shadowing echogenic masses scattered throughout both kidneys. (a) Ultrasound: longitudinal view of the right kidney (length 7.8 cm). (b) Ultrasound: longitudinal view of the left kidney (length 7.9 cm).

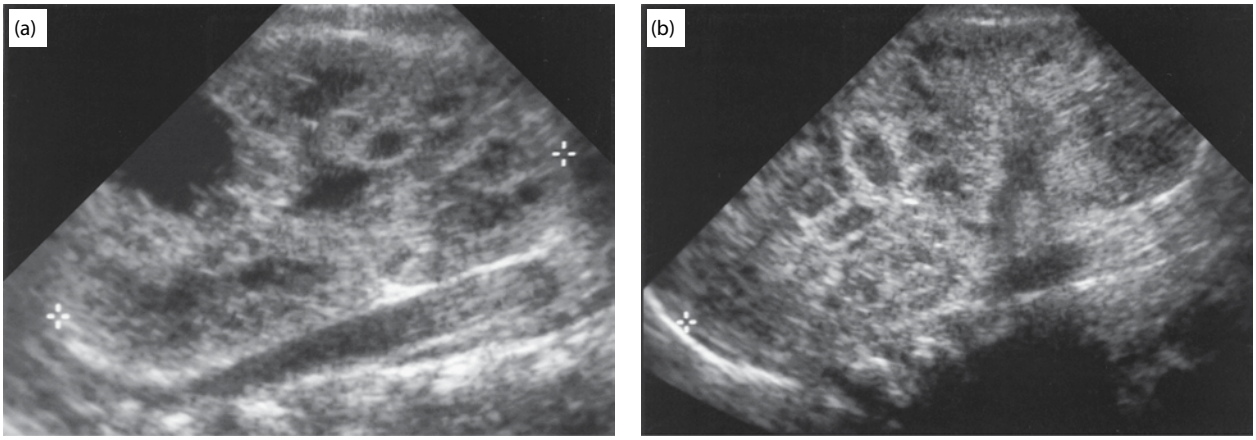

FIGURE 28.17 A 3-week-old boy with tuberous sclerosis and polycystic kidney disease. The kidneys are both enlarged and heterogeneous with numerous irregular cysts bilaterally. (a) Ultrasound: longitudinal view of the right kidney (length 7.0 cm). (b) Ultrasound: longitudinal view of the left kidney (length 7.9 cm).

occur in association with more extensive retroperitoneal involvement. Cystic pulmonary lesion may also occur.[141]

RENAL VASCULAR DISEASE

Renal Vein Thrombosis

Renal vein thrombosis (RVT) in children presents most commonly with gross hematuria, hypertension, and an enlarged, palpable kidney.[21,27,58,142,143] The greatest risk occurs in premature infants, infants of diabetic mothers, neonates and infants with severe dehydration, and infants with hypotension, sepsis, or asphyxia. Children with coagulopathy are also at higher risk of RVT. RVT is usually unilateral, and the affected kidney usually functions poorly. Bilateral thrombosis is rare, but when it occurs, it causes severe renal insufficiency.[144] In neonates and infants, thrombus formation begins in the smaller intrarenal veins, while the main renal vein and inferior vena cava often remain patent. In neonates with adrenal hemorrhage, extension of thrombus into the kidney from the adrenal vein can lead to ipsilateral RVT. This is more commonly on the left, since the left adrenal vein drains directly into the left renal vein.

RVT is usually diagnosed by US.[21,27,58,145–149] In the acute phase, the kidney appears globally enlarged, and the parenchyma is diffusely echogenic with loss of corticomedullary differentiation. Larger thrombi within interlobar and intralobar renal veins appear as linear, echogenic bands radiating peripherally between the renal lobes. Although in some cases thrombus can also be seen extending into the main renal vein and inferior vena cava, the main renal vein may be patent. One indication of extension into the main renal vein that is still patent may be reduced flow amplitude on Doppler US. More importantly, renal artery Doppler US may show reduced or even retrograde flow during diastole, with a markedly increased resistive index.[34] On mercaptoacetyltriglycine (MAG3) renal scintigraphy, the kidney is globally enlarged, with markedly reduced or absent uptake, as well as no excretion of radiotracer. During recovery after hydrolysis, for example, the affected kidney decreases in size as the edema recedes. Restoration of flow and function is variable. Serial USs are required to document renal size stabilization and resumption of normal growth rate. Persistent cortical hyperechogenicity and diminished corticomedullary differentiation indicate parenchymal atrophy and are associated with poor functional recovery. With severe parenchymal infarction and parenchymal necrosis, severe atrophy and cyst formation can result in a small echogenic, poorly functioning kidney.[21,22,27,58,145,146] In the chronic phase, punctate, linear, or branching calcification can appear within the thrombus in the intrarenal veins.[150,151] The presence of linear and punctate renal calcification in a neonate with a small echogenic kidney is strongly suggestive of prenatal RVT.[152]

CT and MRI are rarely performed in children with RVT, since the diagnosis is readily established on US and MAG3 renal scintigraphy.[58,142,147] However, when used, CT and MRI typically show that the affected kidney is enlarged and edematous during the acute phase. Perfusion is diminished with heterogeneous parenchymal attenuation and markedly reduced or no contrast enhancement. Parenchymal infarction and hemorrhage are common, and easily seen on CT and MRI. Associated adrenal hemorrhage and thrombosis of the inferior vena cava are also readily visualized. In the chronic phase, parenchymal atrophy ensues, with calcification of the residual thrombus in the renal rein and inferior vena cava.[148,149,153]

Renal Artery Thrombosis

Nontraumatic renal artery thrombosis can occur primarily following umbilical or femoral artery catheterization, in infants of diabetic mothers, and in infants and children with sepsis, severe dehydration, coagulopathy, or vasculitis.[154] The extent of parenchymal injury depends on the size of the occluded vessel. Complete occlusion of the main renal artery results in global renal infarction.[27,155,156] During the acute phase, the kidney may initially remain normal in size or even be slightly small, and the cortex becomes hyperechoic, although the pyramids remain hypoechoic. Doppler US is the diagnostic imaging of choice, and characteristically shows reduced or absent flow

in the main and segmental renal arteries with a normal or low resistive index.[154] Visualization of the echogenic intraluminal filling defect representing the thrombus within the main renal artery is diagnostic. As parenchymal infarction and hemorrhage develop, the kidney swells and becomes increasingly echogenic and heterogeneous, ultimately leading to complete disruption of the normal corticomedullary architecture. Functional evaluations, such as renal scintigraphy, show no uptake or excretion on the affected kidney. As in RVT, CT and MRI are rarely performed in neonates and infants with renal artery thrombosis.[154] The anatomic and functional outcomes depend on the extent of parenchymal infarction and the timing and degree of revascularization. Chronic ischemia results in an atrophic and a poorly or nonfunctioning echogenic kidney that is small with smooth, reniform contours. Small parenchymal calcifications and cysts can also be seen. Segmental renal artery occlusion causes a wedge-shaped, avascular segmental defect with its apex at the renal hilum and its bases at the renal capsule.[27,156] Doppler imaging can confirm the absence of flow in the infarcted area, although scar formation can be difficult to differentiate from that seen in chronic pyelonephritis. Intravascular sonographic contrast agents may improve visualization of cortical perfusion defects with power Doppler US.[157,158]

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome is a bacterial toxin-mediated vasculitis that is manifested clinically by acute renal failure, microangiopathic hemolytic anemia, fever, and thrombocytopenia. The disease primarily affects children of <5 years of age and is frequently preceded by an episode of gastroenteritis associated with severe abdominal cramping and bloody diarrhea. Initial inflammation with thrombosis of small intrarenal arteries and capillaries leads to acute renal failure with severe oliguria or anuria and hypertension. Spontaneous recovery usually occurs within 3–4 weeks, although dialysis is often necessary during the acute phase.[159,160]

During the acute phase, the kidneys are normal in size or slightly enlarged, as in renal artery thrombosis. The renal cortex is diffusely hyperechoic and the medullary pyramids are hypoechoic.[27,161,162] The resistive index is elevated on Doppler US with markedly reduced or absent forward diastolic flow in the renal arteries. Occasionally, flow can even be reversed during diastole, as in RVT. Normalization of the arterial waveform may precede the onset of diuresis during the recovery phase.[76] Cortical echogenicity also returns to normal in most children who experience complete recovery of renal function.[163,164]

Nephrocalcinosis and Other Causes of Renal Medullary Hyperechogenicity

Medullary nephrocalcinosis is the most common cause of renal medullary hyperechogenicity in infants and children.[27,58,165–167] Hypercalciuria, increased urinary phosphate excretion, and hypercalcemia are important predisposing factors. Dystrophic renal calcification can also form secondary to severe parenchymal injury from trauma, infection, or infarction. US is the optimal imaging method for the detection and monitoring of nephrocalcinosis, which shows a characteristic periphery-to-center progression, with increased echogenicity first developing along the margins of pyramids (Figure 28.18).[27,58,168–171] Over time, this peripheral echogenic rim gradually thickens, eventually filling in the centers of the pyramids. In the most severe cases, the pyramids are diffusely, intensely echogenic with posterior acoustic shadowing. Aggregates of extracellular calcium near the papillary tips (Randall's plaques) can perforate the caliceal epithelium, leading to extrusion of calculi into the collecting system (Anderson–Randall–Carr phenomenon). Even in cases with marked medullary hyperechogenicity on US and increased medullary attenuation on nonenhanced CT, the calcification is not always visible on abdominal radiographs. Cortical calcification usually occurs only in the presence of advanced medullary nephrocalcinosis and is associated with marked hypercalcemia or severe generalized parenchymal injury, or both. Cortical nephrocalcinosis manifested on sonogram by a generalized increase in cortical echogenicity, cortical acoustic shadowing, loss of corticomedullary differentiation, and atrophy. Renal medullary hyperechogenicity is also seen in a number of uncommon lysosome storage diseases, including glycogen storage disease, Lesch–Nyhan syndrome, and Wilson's disease.[165,166,172–174] Both hypercalciuria and microscopic evidence of increased medullary calcium deposition have been reported in patients with these disorders.[171] Hyperuricemia might also contribute in some patients, as it is known to produce hyperechoic pyramids in adults with gout and in children with leukemia. In some subtypes of glycogen storage disease, the kidneys are enlarged and become increasingly echogenic as a result of tubular and interstitial deposition of calcium, uric acid, and glycogen. Increased medullary echogenicity can be punctate or diffuse and is typically progressive and unaffected by therapy. Both nephrocalcinosis and renal calculi can develop.[171,175]

Tamm–Horsfall Proteinuria and Other Inspissation Syndromes

Transient medullary hyperechogenicity as a result of intratubular inspissation of the Tamm–Horsfall protein, also known as uromodulin, has been reported in 3%–5% of otherwise healthy term neonates during the first week of life.[176,177] At US, the pyramids can appear diffusely speckled or the abnormality can appear as a splotchy hyperechoic focus involving the inner third of the pyramid, extending outward from the papillary tip. Discretion is needed, as the Tamm–Horsfall protein deposit within the renal calyces may look similar to nephrocalcinosis in some cases on renal US of neonates, and especially preterm infants.[171] The abnormality can be unilateral or bilateral and is visible shortly after birth. Despite the fact that the deposits can be quite conspicuous on US, they are not visible on nonenhanced CT. Physiologically, decreased tubular flow during the first days of postnatal life is thought to be important. The Tamm–Horsfall protein is known to precipitate and form intratubular aggregates when present in a larger than normal quantity. Urinary excretion of the Tamm–Horsfall protein is normally higher at

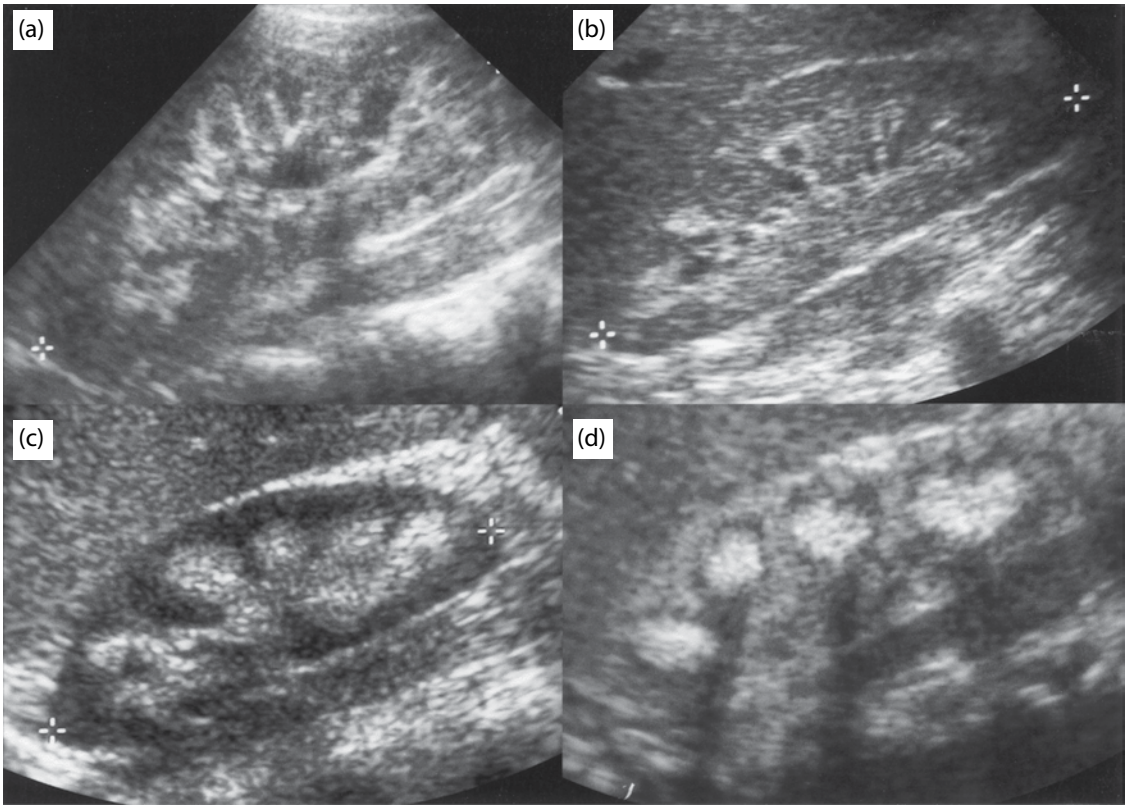

FIGURE 28.18 Sonographic patterns of medullary hyperechogenicity in nephrocalcinosis. (a) Longitudinal view of the left kidney in a 3-year-old girl with Williams syndrome shows thin, peripheral hyperechoic linear bands outlining the pyramids with the centers remaining hypoechoic. The cortex appears normal. (b) Longitudinal view of the right kidney in a 14-year-old boy with familial hypophosphatemic rickets shows thicker peripheral echogenic margins of the pyramids. Some pyramids appear almost uniformly hyperechoic. The cortex appears normal. (c) Longitudinal view of the right kidney in a 7-year-old boy with distal renal tubular acidosis shows diffusely and nearly homogeneously hyperechoic medullary pyramids. There is no posterior acoustic shadowing and the cortex appears normal. (d) Longitudinal view of the right kidney in a 7-week-old girl with severe idiopathic hypercalcemia shows very intense, diffuse medullary hyperechogenicity with posterior acoustic shadowing. The cortex is also thin and echogenic, consistent with cortical nephrocalcinosis.

birth and declines during the first week. Some authors have reported a temporal relationship between the disappearance of hyperechogenicity and the establishment of a consistent pattern of micturition toward the end of the first week of life. Similar sonographic appearances have been reported in children and adults with oliguric renal failure and persistently increased urinary Tamm–Horsfall excretion.[27] Medullary hyperechogenicity is also observed in patients with intratubular deposition of other large macromolecules, such as in rhabdomyolysis, myoglobinuria, and toxic shock syndrome, and in children with leukemia and tumor lysis syndrome. The resistive index is usually increased on Doppler US, and renal dysfunction is common. The reversibility of US findings depends on reestablishment of a normal urine flow rate.

Renal Cystic Diseases

US is the primary imaging modality that is used in renal cystic diseases.[21,22,27,178] CT and MRI are generally reserved for those cases in which either the sonographic appearance is uncertain or complications, such as cystic rupture, hemorrhage, or neoplasm, are suspected. Because isolated, simple renal cysts occur only very rarely in children,[21,22,179,180] the presence of renal cysts in a child should at least lead to consideration that these might be an underlying renal disorder, such as renal dysplasia. On the other hand, many renal lesions that appear cystic on US in children are often not cysts. For example, caliceal diverticula, dilated calices, and even very prominent and hypoechoic medullary pyramids should not be mistaken for cysts. On US, renal cysts appear as round or ovoid, thin-walled, fluid-filled structures.[27,67,178–180] The fluid within uncomplicated cysts is anechoic, and the wall is thin and slightly hyperechoic. Cellular, purulent, or proteinaceous debris or blood clot in complicated cysts causes the fluid to appear more echogenic. Particular debris within the cyst fluid is best visualized with US. The fluid in uncomplicated cysts appears homogenous with low attenuation on CT, and has a low signal intensity on spin-echo and inversion recovery T1-weighted magnetic resonance images.[58,181,182] On spin-echo T2-weighted images, the signal intensity of the fluid increases and the wall of the cyst and the fluid may not be distinguishable. Although larger clots within cysts can often be identified with CT, differences in fluid composition and small debris within cyst fluids are more readily identified with MRI. The signal intensity in hemorrhagic cysts is generally brighter and more heterogeneous on both T1- and T2-weighted

images, but can vary considerably depending on the age of the hemorrhage and the relative proportions of hemoglobin, deoxyhemoglobin, and hemosiderin. On children, mural calcification is rare in renal cysts, although it is well described in adults. Mural calcifications are best evaluated with CT or US, although larger calcifications are sometimes identifiable with MRI as a signal void within the cyst wall.

Caliceal Diverticulum

Caliceal diverticula are a urothelium-lined, saccular, outpouching of the collecting system that typically arises from one of the caliceal fornices.[58,176,183,184] Caliceal diverticula are believed to be congenital lesions. Rarely, a cyst hematoma, or abscess that ruptures into a calyx, will form a permanent communication with the collecting system and can be indistinguishable from a congenital diverticulum. On US, a caliceal diverticulum appears as a cystic lesion and is characteristically located centrally in the kidney, adjacent to the pyramids and collecting system.[58,176,183,184] Caliceal diverticula range in size from several millimeters to many centimeters. Individual diverticula can also vary considerably in size, depending on the degree of distention. Most diverticula communicate freely with the collecting system and will be opacified during either anterograde or retrograde urography, as well as during contrast-enhanced CT and MRI.[185] However, when the neck of the diverticulum is stenotic, the fluid within the diverticulum will opacify only faintly or not at all. Comparing the attenuation within the diverticulum on nonenhanced images with similar measurements on delayed contrast-enhanced images may increase the chance of detecting faint opacification in a stenotic diverticulum. For this reason, use of sonography may be insufficient for accurately diagnosing this condition, requiring retrograde or anterograde contrast urography or contrast-enhanced CT, or both.[198] On nonenhanced CT and MRI, caliceal diverticula will similarly be difficult to differentiate from other centrally located cystic lesions.

Autosomal Recessive Polycystic Kidney Disease

Autosomal recessive polycystic disease is caused by mutations in a single gene, PKHD1[186] (polycystic kidney and hepatic disease). This disease is manifested by bilateral severe dilation and ectasia of the interstitial portion of the collecting tubes.[162,187] On US, the kidneys are usually dramatically enlarged, heterogeneous, and echogenic.[27,67,179,188,189] The echogenic appearance of the parenchyma relates to the abnormally enhanced reflection of sound waves of the walls of the distended and ectatic tubules. The compressed renal cortex is studded with innumerable tiny cysts and appears as a relatively hypoechoic marginal halo around the kidney and occasionally around the individual renal lobes (Figure 28.19).[188–190] The same architectural changes are visible on CT, with relatively poorly enhancing ectatic tubules producing a peripherally radiating striated appearance to the enlarged central portions of the individual renal lobes surrounded by brightly enhancing compressed cortex studded with countless tiny cysts.[58]

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease is recognized as a monogenic disorder caused by mutations in two genes: PKD1, which accounts for 85% of cases, and PKD2, which accounts for 10% of cases.[185] When autosomal dominant polycystic kidney disease presents in childhood, the cysts are usually small, bilateral, and few in number.[21,27,58,179] In neonates, the kidneys appear large and contain multiple small cysts, mimicking the appearance of the recessive form of the disease.[191–195] As the child becomes older, the cysts increase in size and number. Mural calcification is rarely seen in children. Complications such

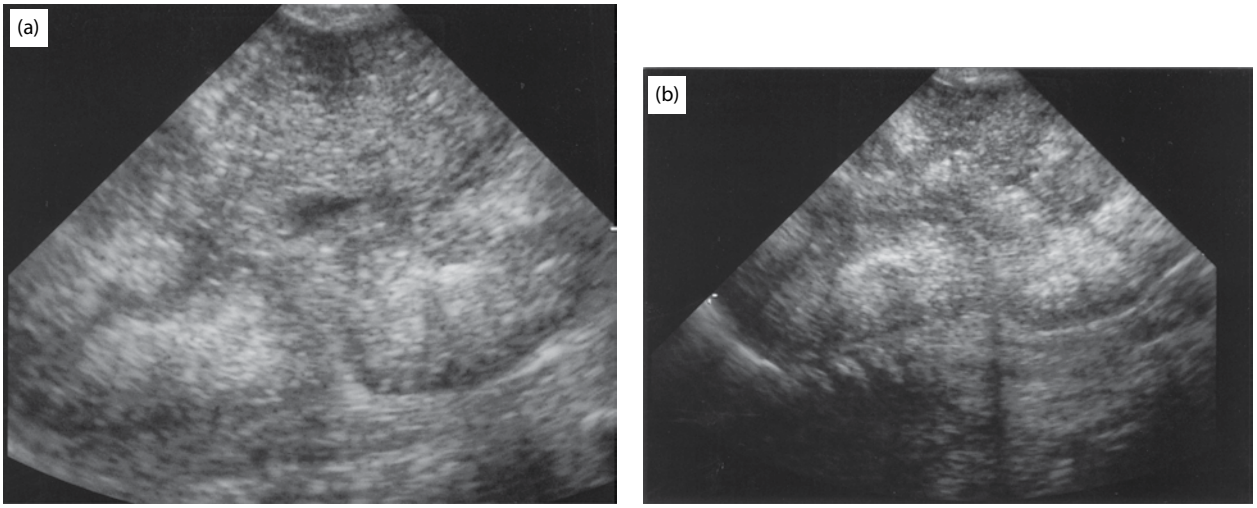

FIGURE 28.19 A newborn boy with autosomal recessive polycystic kidney disease. Ultrasound shows markedly enlarged kidneys, with accentuation of the renal lobar anatomy. The medullary portions of the renal lobes appear enlarged and very echogenic and are surrounded by a thin peripheral cortical halo. No larger macrocysts are visible. (a) Ultrasound: longitudinal view of the right kidney (length 12.7 cm). (b) Ultrasound: longitudinal view of the left kidney (length 13.2 cm).

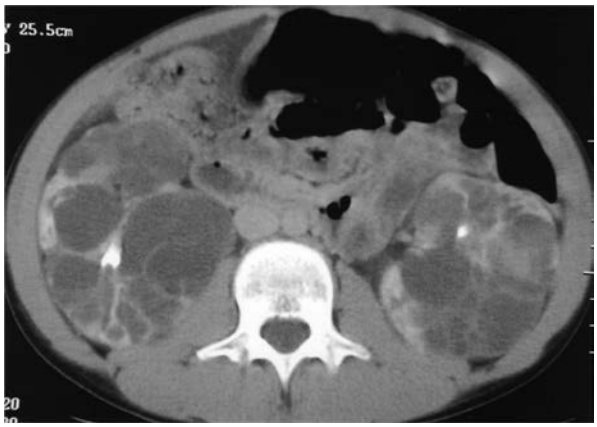

FIGURE 28.20 A 12-year-old girl with autosomal dominant polycystic kidney disease, presenting with abdominal pain and hematuria after a minor motor vehicle accident. Contrast-enhanced CT shows the kidneys to be almost entirely replaced by numerous large cysts, with strands of residual enhancing parenchyma visible between the cysts.

as a hemorrhage within a cyst can be visualized on either CT or MRI (Figure 28.20). MRI often shows striking differences in the signal intensity of the fluid in the cysts, reflecting differences in protein of the fluid.[196]

Glomerulocystic Disease of the Kidney

Glomerulocystic kidney disease presents as a cystic dilation of the space within Bowman's capsule surrounding the glomeruli on histology.[197] Glomerulocystic kidney disease is a rare disorder that is frequently indistinguishable, based on its imaging and clinical features, from classic recessive polycystic disease in the neonate and from other cases of dominant polycystic kidney disease. Autosomal dominant transmission has been suggested in some lineages, with the parents of the affected infants presenting with the classic dominant polycystic disease imaging. Liver disease similar to that in recessive polycystic disease can also occur. Glomerulocystic disease can also occur in trisomy 13, oro-facial-digital syndrome, Zellweger syndrome, tuberous sclerosis, and Meckel–Gruber syndrome, and similar histologic changes are seen in some patients with renal dysplasia. Such widespread clinicopathologic overlap has led some clinicians to suggest that glomerulocystic disease might in reality represent a nonspecific histologic appearance rather than a specific disease.[198] Countless small cysts, with a predominantly cortical and subcapsular distribution, are found in glomerulocystic diseases on US.[27,189,199–203] Bilateral renal enlargement in neonates is common, although not as dramatic as in classic recessive polycystic disease.[203] The kidneys can decrease in size over time without apparent deterioration in renal function. In other cases, the appearance progresses over time to that of dominant polycystic disease. Furthermore, glomerular cysts are often small; thus, high-resolution US or very thin-sliced CT may be needed, along with MRI, to confirm the diagnosis.[203] Because of the considerable overlap in the imaging appearance between this disorder and other more common forms of polycystic kidney disease, definitive diagnosis may ultimately require biopsy or a genetic testing.

Medullary Cystic Disease

Juvenile nephronophthisis and adult-onset medullary cystic disease of the kidney are both familiar forms of chronic tubulointerstitial nephritis that are associated with a urinary concentrating defect and progressive azotemia.[27,144,202,204–206] Medullary cysts are present in both diseases. However, the clinical manifestations and patterns of transmission are different. Juvenile nephronophthisis is an autosomal recessive disorder that primarily affects children and is characterized clinically by polyuria, growth failure, and progressive renal insufficiency, usually leading to death in later childhood. Juvenile nephronophthisis is frequently associated with a variety of extrarenal manifestations, including retinitis pigmentosa, cone-shaped epiphyses, hepatic fibrosis, and cerebella aplasia. Adult medullar cystic disease is an autosomal dominant disorder with no extrarenal involvements that typically presents in the third decade of life or later and is rarely diagnosed in children. In juvenile nephronophthisis, the kidneys are small or normal in size on US, with diffusely increased parenchymal echogenicity and medullary cysts.[27,177,178,197] Although medullary cysts are regarded as a characteristic sonographic feature of juvenile nephronophthisis, increased parenchyma echogenicity with loss of corticomedullary differentiation can precede development of visible macrocysts, resulting in a nonspecific appearance in some patients. Very thin-section (1.5 mm) CT or MRI can confirm the presence of medullary cysts in children with atypical sonographic appearances.[144,202,205,207]

Medullary sponge kidney is a rare, nonhereditary disorder of unknown causes that is characterized by nonprogressive medullary ductal ectasia, renal tubular acidosis, hypercalciuria, and nephrocalcinosis.[27,208,209] On excretory urography, the appearance reflects the severity of the ductal ectasia.[210] In very mild cases, the medulla has a thin, striated appearance. With more severe involvement, the linear medullary striation first becomes thicker and then cystic in appearance. Small calculi from within the tubules and the papillae enlarge as the calices become progressively more distorted. In most advanced cases, abdominal radiographic studies reveal nephrocalcinosis or nephrolithiasis, or both. The appearance of multiple clusters of tiny calculi overlying the medullary pyramids is diagnostic of medullary sponge kidney. Calculi that have eroded into the collecting system are visible in the renal pelves, ureters, or bladder. On US, renal size is normal and the medullary pyramids appear hyperechoic as a result of intraluminal calcium deposition.[27,163,210] Shadowing intratubular calculi appear later in the disease. CT is generally inferior to excretory urography in detecting tubular ectasis in medullary sponge kidney and is invariably normal early in the disease. However, nonenhanced CT may be better in identifying small intratubular calculi that would be obscured by contrast material on excretory urography.

Renal Dysplasia and Multicystic Dysplastic Kidney

Normal nephroureteral development entails a series of complex interactions between the ureteric bud and the developing metanephros, beginning in the seventh

gestational week. Failure of these interactions to proceed normally can result in renal dysplasia. Although renal dysplasia is frequently associated with congenital obstructive uropathy,[164,211,212] it can also occur in the absence of detectable obstruction in patients with severe VUR and as an isolated anomaly.[23,212–215] On US, dysplastic kidneys are usually small for age or body size and grow slowly.

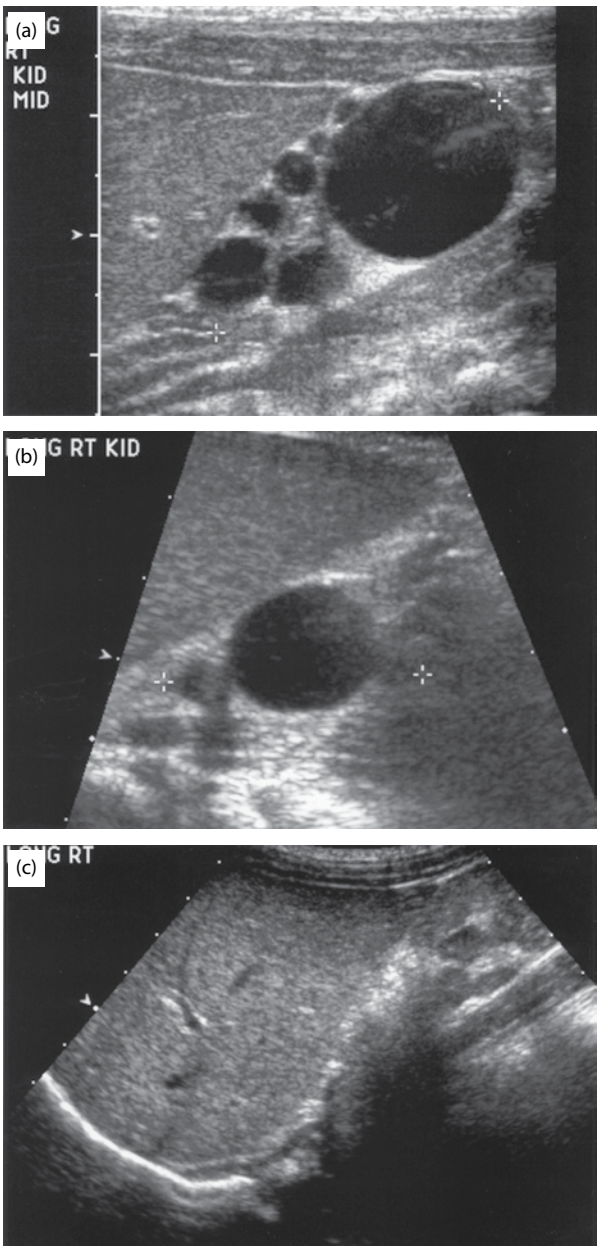

FIGURE 28.21 A newborn boy with right multicystic dysplastic kidney and subsequent involution. (a) Ultrasound: longitudinal view of the right kidney at 2 days old shows the right kidney (length 4.2 cm) is entirely replaced by multiple non-communicating cysts of different sizes separated by thin bands of echogenic, dysplastic parenchyma. (b) Ultrasound: longitudinal view of the right kidney at 8 months old shows all of the cysts have decreased in size and the kidney now measures 3.1 cm in length. (c) Ultrasound: longitudinal view of the right renal fossa at 18 months old shows no residual visible cysts or right kidney.

The renal parenchyma appears abnormally echogenic, with reduced or absent corticomedullary differentiation.[21,22,27,215–217] Cysts are present in 40%–50% of cases. In the cases of severe dyplasia associated with obstruction, the collecting system can be dysmorphic, with poor differentiation of calices, infundibula, and renal pelvis.[22] When cysts or hydronephrosis are present, the renal measurement may underestimate the reduction in total renal parenchymal volume.[213] On scintigraphy, the dysplastic kidneys typically have reduced function, although complete absence of function is uncommon, a feature that is important in distinguishing typical renal dysplasia from multicystic dysplastic kidney (MCDK). Although the US findings of small, echogenic kidney that functions poorly on scintigraphy is usually diagnostic of dysplasia in the neonate, this sonographic appearance is not specific. In an infant or child, a variety of chronic and atrophic renal parenchymal disorders, including interstitial nephritis and chronic glomerulonephritis, are indistinguishable from renal dysplasia in the absence of suggestive or historical or biochemical information or previous imaging studies.[22,216,217]

In MCDK, atresia of the ureteral bud at or just below the ureteropelvic junction early in nephrogenesis results in a severely dysplastic, nonfunctioning, cystic kidney.[22,218–220] The diagnosis of MCDK is usually easily established based on characteristic imaging findings on US and renal diuretic or cortical scintigraphy of a nonfunctioning kidney that is replaced by multiple noncommunicating cysts with no residual normal-appearing parenchyma.[22,220] On CT and MRI, the kidney is replaced by multiple cysts of different sizes that are separated by a small amount of nonfunctioning dysplastic parenchyma (Figure 28.21). In the hydronephrotic variant of multicystic dysplasia, the kidney is nonfunctioning and contains one or more small peripheral cysts, with a large central cyst representing a rudimentary, dilated collecting system.[213,214,219] In segmental MCDK, the anomaly affects only one moiety of a partially or completely duplicated collecting system. When bilateral, MCDK is incompatible with extrauterine life and is usually accompanied by severe oligohydramnios, pulmonary hypoplasia, and other features of Potter's syndrome.

In most patients with MCDK, the fluid within the cysts is gradually absorbed and the kidney progressively decreases in size until it is no longer identifiable on US (Figure 28.21).[207,221–223] Because the dysplastic renal remnant has no function, it will not be identifiable on renal scintigraphy. This process of "involution" ultimately results in an appearance that is indistinguishable from unilateral renal agenesis.[224]

CHAPTER 29

Assessment of Renal Obstructive Disorders: Ultrasound, Nuclear Medicine, and Magnetic Resonance Imaging

James M. Elmore, Wolfgang H. Cerwinka, and Andrew J. Kirsch

INTRODUCTION

The widespread use of maternal sonography and the routine radiographic evaluation of children with febrile urinary tract infections have resulted in the increased diagnosis of both antenatal and postnatal hydronephrosis. Hydronephrosis is the most common abnormality detected by prenatal ultrasound (US) and is seen in an estimated 1 in 100 to 1 in 500 pregnancies.[1] One of the most important distinctions in the assessment of these children is determining which patients would benefit from surgery and which can be safely observed. This distinction is important since unnecessary intervention exposes patients needlessly to the morbidity of surgery, whereas inappropriate observation places patients at risk for infection and renal parenchymal loss.

The common pediatric renal obstructive disorders are listed in Table 29.1. Of these, ureteropelvic junction obstruction (UPJO) is the most common and accounts for nearly half of all prenatally detected uropathies.[1] Ureterovesical junction obstruction (UVJO), ureteroceles, and ectopic ureters are responsible for the majority of the remaining cases. The natural history of renal pelvic dilatation is largely related to the underlying diagnosis. For example, hydronephrosis secondary to an ectopic ureter is unlikely to resolve spontaneously, whereas patients with megaureter can often be followed for years without renal functional loss.[2] The outcome of patients with UPJO is more variable, and as a result, management is more controversial. Some clinicians recommend early surgery, whereas others advocate simple observation.[3–5] Regardless, most urologists will initially follow hydronephrotic kidneys conservatively and use decreasing differential renal function (DRF) or worsening hydronephrosis as an indicator that surgery may be required. Radiographic approaches to the diagnosis and assessment of renal obstructive disorders have evolved significantly over the past several decades. Intravenous urography (IVU) and the antegrade pressure–flow test, referred to as the Whitaker test, were once mainstays in the evaluation of these patients and are now only rarely used. Technologic advances have given way to US, diuretic renal scintigraphy (DRS), and more recently, magnetic resonance imaging (MRI) for the evaluation of hydronephrosis. Voiding cystourethrography (VCUG) is frequently performed in conjunction with these studies to rule out vesicoureteral reflux (VUR) as the cause of hydronephrosis. Each of these diagnostic modalities has relative advantages and disadvantages (Table 29.2). In general, these studies provide either good anatomic or good functional information, whereas none of these studies, save MRI, provide both. Some tests are more invasive than others, which also influences test selection. Currently, no study is considered a gold standard for the evaluation of renal obstructive disorders, and complete assessment typically involves a series of studies, including US, VCUG, and DRS. Consequently, a thoughtful diagnostic strategy is necessary to proceed with appropriate management at minimal cost and morbidity to the patient.

TABLE 29.1 Causes of pediatric hydronephrosis

Obstructive causes
• Ureteropelvic junction obstruction
• Ureterovesical junction obstruction
• Ectopic ureters
• Ureteroceles
• Posterior urethral valves
• Urethral atresia
• Anterior urethral valves
• Congenital urethral stricture
Nonobstructive causes
• Vesicoureteral reflux
• Primary nonobstructive megaureter
• Megacalicosis
• Fetal folds
• Neurogenic bladder
Conditions mimicking hydronephrosis
• Extrarenal pelves
• Multicystic dysplastic kidney
• Peripelvic cysts
• Neonatal kidneys (hypoechoic renal pyramids)

TABLE 29.2 Advantages and disadvantages of various diagnostic modalities for the assessment of renal obstructive disorders

Imaging study	Advantages	Disadvantages
Intravenous pyelography	Good anatomy if function is good	Inaccurate if poor function; nephrotoxic contrast; radiation exposure
Whitaker test	Only study that measures directly the pressure in the renal pelvis/bladder	Invasive; not reproducible; no functional information; radiation exposure
Ultrasound	Inexpensive; portable; no contrast or radiation exposure	No functional information; limited anatomy
Diuretic renal scintigraphy	Good functional and drainage information	Limited information in bilateral disease; no anatomic information; interpretative error; 15% false negatives/positives
Gd-MRU	Superior anatomic and functional information even if poor function or bilateral disease; no radiation; contrast nonnephrotoxic	Expensive; not yet widely available; requires sedation and monitoring

ULTRASONOGRAPHY

Ultrasonography (US) constitutes a cornerstone in the radiologic evaluation of renal obstructive disorders. It is noninvasive, inexpensive, and portable; does not require ionizing radiation or contrast media; and is not limited by renal failure. As a result, US is ideally suited as a screening study and for following patients with known abnormalities. A properly performed study provides information regarding renal size, cortical thickness and architecture, and the degree of dilatation of the collecting system. Nomographic charts are available that give "normal" renal lengths for children of varying ages and body weights (Figure 29.1). The sonographic examination, however, is operator dependent, and a skilled sonographer is essential for informative and reproducible studies. The US examination may be limited by body habitus, overlying bowel gas, and poor patient cooperation.

The hallmark finding of hydronephrosis on US is separation of the hyperechoic central renal sinus by anechoic branching structures that represent the dilated calices. With more chronic and severe forms of hydronephrosis, cortical thinning may be seen. Often, if the process is unilateral and leads to renal parenchymal loss, the contralateral kidney may undergo compensatory hypertrophy in young children. In moderate and severe UPJO, pronounced caliceal and renal pelvic dilatation may occur, giving the kidney a classic "bear paw" appearance on US (Figure 29.2). The ureters can usually only be seen on US if they are dilated, and the presence of a dilated ureter lying posterior to the bladder helps distinguish megaureter from UPJO. When either diagnosis is a consideration, a VCUG to rule out VUR as the cause of dilatation should be performed. It should be kept in mind that VUR may coexist with UPJO in as many as 10% of children.[7]

The Society for Fetal Urology (SFU) has proposed a grading system for reporting hydronephrosis detected by US.[8] This system takes into consideration the appearance of the calices, renal pelvis, and parenchyma to grade the degree of hydronephrosis from 0 to 4 (none to severe). SFU grades 1 and 2 represent mild to moderate degrees of pelviectasis and should not be considered hydronephrosis. Grades 3 and 4 represent true hydronephrosis, with grade 4 being the most severe, with cortical atrophy (Table 29.3). The degree of hydronephrosis is used to assist in decision making with regard to treatment and, additionally, provides some prognostic information. For example, SFU grades 1 and 2 hydronephrosis secondary to UPJO have a tendency to resolve with time and usually only require a VCUG to rule out VUR and sonographic reevaluation. For SFU grades 3 and 4, some type of functional evaluation, in addition to a VCUG, is usually recommended since these patients are more likely to have significant urologic pathology and to require surgical intervention.

There is a well-documented correlation between the anteroposterior diameter (APD) of the renal pelvis on prenatal US and the probability that a significant postnatal pathology will be present. Although controversy exists over cutoffs for abnormal and normal APDs, most authors agree that an APD of <4 mm is considered normal and that an APD of >15 mm represents severe hydronephrosis. The SFU published a consensus statement that is based on a meta-analysis and suggests how to evaluate and manage antenatal hydronephrosis.[9] Antenatal hydronephrosis grading by APD and gestational age is summarized in Table 29.4. Mild, moderate, and severe hydronephrosis carry a risk for postnatal pathologies in 12%, 45%, and 88%, and consequently, postnatal evaluation varies according to the degree of antenatal hydronephrosis.[10] UPJO is found in 5%, 17%, and 54% in mild, moderate, and severe antenatal hydronephrosis, while VUR occurs in 5%, 14%, and 9%.[10]

The term *hydronephrosis* implies obstruction, and exposes an important limitation of US. No functional information is obtained from conventional US, and obstruction cannot be diagnosed based solely on anatomic information. Therefore, although US is highly accurate in the diagnosis of renal dilatation, it is not reliable in predicting obstruction or providing information regarding renal function. Even in the presence of renal pelvic dilatation secondary to an obstructive process, the degree of dilatation does not necessarily reflect the degree of, or functional significance of, the obstruction. Indeed, numerous cases have been reported of mild dilatation with complete obstruction and marked dilatation when no obstruction is present. False-positive studies may result

from an extrarenal pelvis, a peripelvic cyst, residual dilatation from previous obstruction, dilatation resulting from VUR, and pyelonephritis. The fetal and neonatal kidney may also appear hydronephrotic on US secondary to the hypoechoic appearance of the medulla and pyramids (Figure 29.3). False-negative studies are less frequent, but obstruction may be present in the absence of dilatation in acute obstruction and in certain extrinsic processes, such as metastases and retroperitoneal fibrosis. Oliguric states may also lead to false-negative studies. This is particularly true in the newborn, in whom renal sonography may underestimate or completely overlook renal dilatation because of the oliguric state of the healthy newborn. It is rare that this results in missing significant renal obstruction, however.

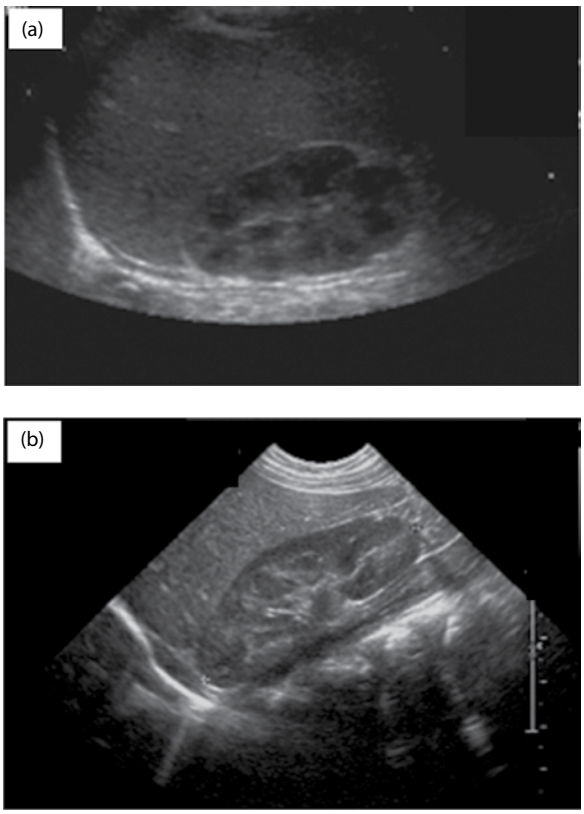

FIGURE 29.3 Right kidney of a 3-week-old by US. (a) Note the relatively hypoechoic renal pyramids, which may be mistaken for hydronephrosis. (b) Follow-up US 15 months later demonstrates resolving hypoechogenicity.

REFINEMENTS OF ULTRASONOGRAPHY

Given the limitations of conventional US in distinguishing obstructive from nonobstructive causes of hydronephrosis, several sonographic techniques have been developed in an effort to improve the diagnostic accuracy of US. Due to their high operator dependence, poor predictive value, and inconsistent study results, these techniques are rarely applied today. Among these methods, Doppler US with calculation of the resistive index (RI) has been shown to have some value in the diagnosis of renal obstructive disorders. This adjunct to US is based on the fact that obstruction causes an increase in intrarenal arterial resistance, resulting in a relative reduction in diastolic flow compared with systolic flow. Renal arterial resistance is quantified using the formula

$$\frac{\text{Peak systolic velocity} - \text{Minimum diastolic velocity}}{\text{Peak systolic velocity}}$$

The result of this formula is referred to as the RI (Figure 29.4). Different criteria have been proposed to suggest obstruction, including an RI of >0.70, an interrenal RI difference of >0.06–0.10 with unilateral dilatation, and an abnormal RI response to a diuretic challenge.[11] For children, and especially the neonate and infant, the RI tends to be elevated compared with adult standards. RIs of 0.7–1.0 can be normal in these populations and usually decrease to adult ranges by about 2–4 years of age.[12] Therefore, the latter two criteria appear most helpful in the pediatric age group.

Another sonographic modality is based on the determination of renal longitudinal parenchymal area and renal longitudinal pelvicaliceal area by computer planimetry. The ratio of parenchymal-to-pelvicaliceal area less than 1.6 was found to be predictive of renal obstruction and the need for subsequent pyeloplasty.[13] Diuretic Doppler US seeks to assess the significance of UPJO with a fluid challenge by evaluating the RI of the intrarenal vasculature

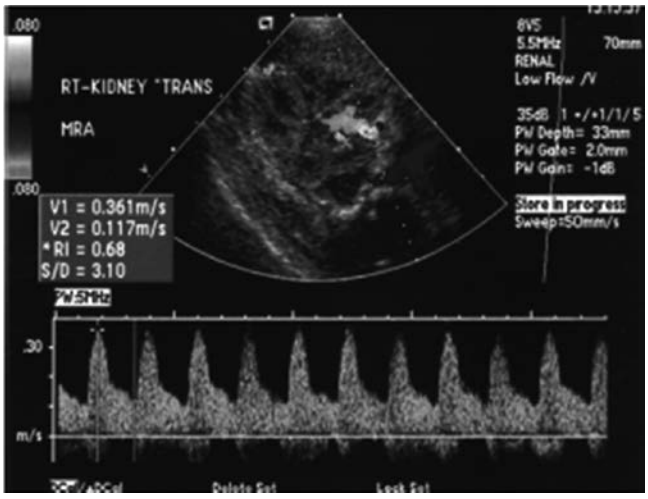

FIGURE 29.4 Duplex Doppler image taken from a 4-year-old boy. Note the arterial waveform and the normal RI of 0.68 (asterisk).

before and 10 minutes after administration of furosemide. A small study of 10 patients demonstrated that the preoperatively measured abnormal RIs were reversed after pyeloplasty.[14] Determination of APD or pelvicaliceal area yields one- or two-dimensional values and consequently does not account for the often disproportionately dilated three-dimensional (3D) collecting system. In order to determine the degree of dilatation of the entire pelvicaliceal space 3D US has been recently applied in prenatal and postnatal studies.[15] In a postnatal study, the renal parenchymal volume obtained by 3D US compared well with measurements obtained by magnetic resonance urography (MRU) and with DRF determined by renal scintigraphy.[16]

In summary, US is most commonly utilized as a screening method for the diagnosis of renal obstructive disorders. Although in theory duplex Doppler US can provide useful functional information, in practice other studies are used to better delineate the cause and functional significance of hydronephrosis once it is detected. Most commonly, after VUR has been ruled out by VCUG, the next study of choice is DRS.

DIURETIC RENAL SCINTIGRAPHY

DRS was developed in the late 1970s as a noninvasive method for evaluating patients with renal obstructive disorders. The introduction of better radiopharmaceuticals and gamma cameras has led to an increased use of nuclear imaging in pediatric urology. Once hydronephrosis is detected by other imaging methods, usually US, DRS is considered by many to be the preeminent method for estimating DRF and characterizing the severity of obstruction. Worsening renal function by DRS is often the impetus for pyeloplasty in patients being observed with UPJO. DRS also remains the most commonly used method for serial follow-up and postoperative assessment of patients with UPJO and megaureter.

The radiopharmaceuticals used for DRS comprise a radionuclide, most commonly technetium 99m (^{99m}Tc), bound to a carrier macromolecule. Renal handling of the various radiopharmaceuticals, and therefore the information gained from DRS, is dictated solely by the biochemical properties of the carrier macromolecule. The ability to label these macromolecules, which have known physiologic destinations within the body, forms the basis of renal scintigraphy. The principal radiopharmaceuticals used for DRS are ^{99m}Tc mercaptoacetyltriglycine (MAG3) and ^{99m}Tc diethylenetriamine pentaacetic acid (DTPA) (Table 29.5). ^{99m}Tc MAG3, one of the newest radiopharmaceuticals, is 90% bound to plasma proteins and is principally cleared by tubular secretion. It shows both the parenchyma and collecting system well and provides excellent functional quantification. These qualities and the fact that it requires lower radiation doses than other radiopharmaceuticals make it the current agent of choice for evaluating renal function and drainage. In contrast, ^{99m}Tc DTPA has little plasma protein binding and is cleared almost exclusively by glomerular filtration. It is rapidly filtered into the urine and therefore provides excellent visualization of the pelvicaliceal system, ureter, and bladder, but may not be retained in the renal parenchyma long enough for good visualization of parenchymal abnormalities. Also, since ^{99m}Tc DTPA relies principally on glomerular filtration, results are often suboptimal in infants with immature kidneys and a low glomerular filtration rate (GFR) or in patients with compromised renal function. In these scenarios, ^{99m}Tc MAG3 is the preferred agent. ^{99m}Tc dimercaptosuccinic acid (DMSA) is unique among the other commonly used radiopharmaceuticals in that it tightly binds to the renal tubular cells and only a small amount is excreted into the urine. Therefore, it allows excellent visualization of the renal parenchyma and is primarily used for evaluating cortical lesions, such as scars that occur as a result of pyelonephritis.

TABLE 29.5 Common radiopharmaceuticals used in renal scintigraphy

Radiopharmaceutical	Renal handling	Application
^{99m}Tc MAG3	Principally cleared by tubular secretion	Renography
^{99m}Tc DMSA	Localizes and binds to the proximal convoluted tubules	Renal parenchymal imaging
^{99m}Tc DTPA	GFR dependent for clearance	Renography

The basic principles of DRS are as follows. The radiopharmaceutical of choice is injected intravenously. Normally, during the first 2–3 minutes, renal parenchymal uptake occurs. The radionuclide emits gamma radiation that is detected by a gamma counter. This emitted radiation is temporally and spatially quantified with computer-assisted digital processing and represented morphologically and graphically as a scan (Figure 29.5). This information is analyzed and compared, allowing for the computation of DRF. It is generally accepted that the error in determining the DFR is ±5%. After about 20 minutes, furosemide is injected intravenously to promote diuresis and the velocity and pattern of drainage from the kidneys to the bladder are analyzed. In the absence of obstruction, half of the radionuclide is cleared from the renal pelvis within 10–15 minutes, termed the $T_{1/2}$. A $T_{1/2}$ of >20 minutes indicates obstruction, whereas a $T_{1/2}$ of <15 minutes is generally considered normal. Times between 15 and 20 minutes are indeterminate. Indications for surgical intervention based on DRS generally include a DRF of <35–40% and a $T_{1/2}$ of >20 minutes, and US findings consistent with anatomic obstruction. Despite these parameters, neither should be used as an independent variable to determine if obstruction is present or absent.

Over the years, a wide variety of protocols and techniques for diuretic renography have been used. Unfortunately, this has produced variability in interpretation among different institutions. In an attempt to promote standardization of the technique, the SFU and the Pediatric Nuclear Medicine Council of the Society for Nuclear Medicine published guidelines for the "well-tempered" diuresis renogram in 1992.[17] Its purpose was to allow easy comparison between studies and institutions. The guidelines standardize many of the facets of the study, including intravenous hydration, bladder catheter placement, patient

	Right	Left
DRF	50%	50%
Tpeak	8 min	38 min
$T_{1/2}$	11 min	>30 min
Wash-out	98%	0%
Curve	Downsloping	Plateauing

	Right	Left
DRF	48%	52%
Tpeak	8 min	9 min
$T_{1/2}$	4 min	9 min
Washout	95%	77%
Curve	Downsloping	Downsloping

FIGURE 29.5 Diuretic renal scan (^{99m}Tc MAG3) taken from a 9-year-old boy with severe left UPJO (a) before and (b) after dismembered pyeloplasty. Note that preoperatively the $T_{1/2}$ of the left kidney is never reached.

position, data acquisition and analysis, timing of diuretic administration, and regions of interest (ROIs) for which to monitor the diuretic effect. However, in practice, local protocols are still frequently used, which makes comparing results from different centers problematic.

Despite the widespread use of DRS, there are significant limitations with the technique. For example, DRS only provides DRF and, as a result, is less informative in patients with overall poor renal function or solitary kidneys. Caution must be taken when interpreting results in these scenarios. Very capacious collecting systems can also prove problematic, since radionuclide retained in the renal pelvis may be included in the ROI and falsely elevate differential function. Although debatable, this artifact may be responsible for the supranormal function (>55%) reported for some hydronephrotic kidneys.[18] When dilated collecting systems are included in the ROI, the resulting renogram may be false positive for renal obstruction. To eliminate the confounding effects of slow radiotracer passage through a dilated pelvicaliceal system, careful ROI placement solely around the renal parenchyma was proposed. A review of a large number of ^{99m}Tc MAG3 renal scintigraphies revealed that if the renal parenchyma drained (i.e., downsloping curve), the kidney was not obstructed.[19] Another review from the same group suggested that ^{99m}Tc MAG3 renal scintigraphies performed in neonates do yield meaningful results even when the entire kidney is included in the ROI. While a downsloping renogram correlated with future resolution, an upsloping renogram was predictive of subsequent pyeloplasty.[20] Interpretation is also somewhat subjective and may lead to reporting error (Figure 29.6). Other disadvantages of DRS are its poor anatomic resolution and long examination times. Not infrequently, patients will fall into the equivocal category. These patients may require a repeat DRS or, less commonly, a Whitaker test, to further assess renal obstruction. Overall, DRS may fail to determine the presence or absence of obstruction in at least 15% of cases.[21]

Clearly, there are strengths and weaknesses associated with US and renal scintigraphy. Specifically, whereas US provides useful anatomic information, it provides no functional information. Conversely, renal scintigraphy provides functional information, but little anatomic information. Therefore, although these studies are highly informative in tandem, neither study alone is typically sufficient for making clinical decisions. Recently, contrast-enhanced MRI of the urinary tract, as a single study, has been shown to have promise in the investigation of renal obstructive disorders.

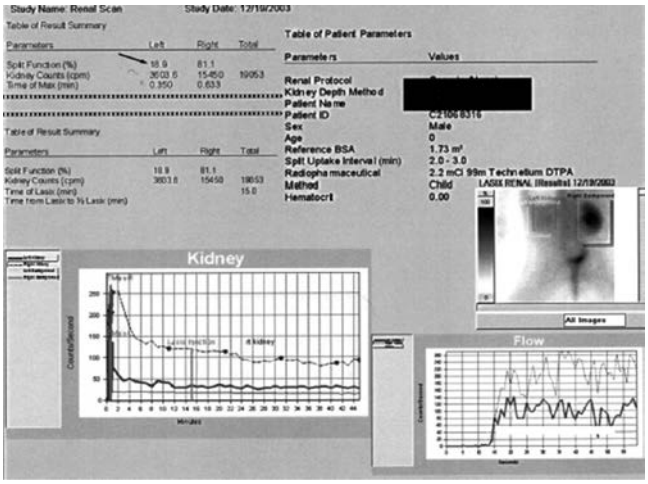

FIGURE 29.6 Diuretic renal scan from a 3-month-old boy. Note that the scan shows 18% differential left renal function. Further evaluation showed that the patient had a solitary right kidney, which highlights the interpretative error possible with scintigraphy.

MAGNETIC RESONANCE IMAGING

The use of MRU in the diagnosis of pediatric renal obstructive disorders has increased dramatically since it was introduced in the late 1980s. This has been the result of a series of recent technological advances that have enabled faster image acquisition, improved resolution, reduced motion artifact, and 3D reconstruction. Even today, newer imaging sequences and shorter acquisition times are improving image quality and expanding the diagnostic capabilities of MRU. The advantages of MRU for evaluating renal tract anomalies in children are that it has multiplanar capabilities, offers excellent anatomic resolution and soft tissue contrast, and does not use ionizing radiation. Possibly, one of the most important developments occurred in the late 1990s when gadolinium-DTPA (Gd-DTPA) was first used in conjunction with MRU. Gd-DTPA and ^{99m}Tc DTPA share the same carrier macromolecule and are handled by the kidneys in an identical fashion. As a result, Gd-DTPA-enhanced MRU (Gd-MRU) measurements of renal perfusion, uptake, and excretion correlate with those obtained by ^{99m}Tc DTPA renal scintigraphy. Gd-MRU is the only study to date that has the capability of providing excellent morphologic detail typical of MRI, as well as functional information that is equivalent or superior to DRS. Even at very low concentrations, Gd-DTPA has high signal intensity on MRI, giving Gd-MRU the ability to reliably detect hydronephrosis and transition in ureteral caliber even in nonfunctioning systems (Figure 29.7). The results of one study showed that Gd-MRU may be a useful tool for distinguishing an obstructed from a nonobstructed dilated system, even when ^{99m}Tc MAG3 renography results were compromised by reduced renal uptake in the affected kidney.[22] While gadolinium is not nephrotoxic per se, the use of gadolinium-based contrast agents in patients with renal failure has been linked to nephrogenic systemic fibrosis. This debilitating and, in 5% of cases, fatal disease can be avoided if safety guidelines are strictly followed.[23]

Although protocols for Gd-MRU differ slightly among institutions, the basic principles are preserved. The study involves initial T1- and T2-weighted images through the kidneys, ureters, and bladder. Gd-DTPA is then administered intravenously, and dynamic contrast-enhanced T1-weighted imaging using a volumetric gradient echo technique is performed over the entire urinary tract. In a fashion similar to IVU, the uptake, excretion, and drainage of Gd-DTPA can be visualized sequentially. The advantage of Gd-MRU is that, in addition to providing anatomic information that exceeds that of US, computer-assisted postprocessing techniques can be employed to objectively quantify function and the degree of obstruction, similar to DRS.

During postprocessing, image sequences are viewed as cinematic loops. This permits the assessment of renal perfusion and excretion and the generation of signal intensity versus time curves. Following contrast administration, three distinct phases of enhancement are recognized (Figure 29.8). In the first phase, the renal cortex enhances vividly, differentiating renal cortex from medulla. This is followed by a medullary phase, where the medulla enhances greater than the cortex. The third phase consists of excretion of contrast medium into the collecting system and ureters. Gadolinium transit through these anatomic areas causes a variation in the magnetic resonance signal intensity over time, which can be represented graphically by signal intensity versus time curves (Figure 29.9). When function is reduced in one kidney, signal intensity is reduced compared with the normal side. The 3D maximum intensity projection (MIP) images from delayed images of the renal pelvis and ureters that exhibit good contrast enhancement provide excellent anatomic resolution of the collecting system and ureters.

The diagnosis of obstruction on MRU is based morphologically on the findings of renal pelvic dilatation and ureteral narrowing. Functionally, obstruction is suggested by reduced enhancement, delayed excretion of contrast into the collecting system and ureter, swirling

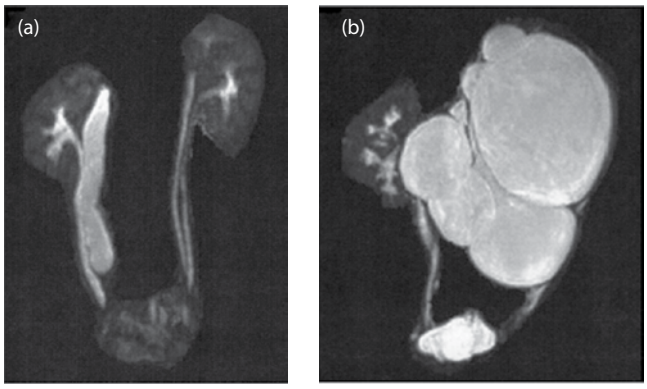

FIGURE 29.7 Gadolinium-enhanced MRU permits hydronephrosis and transition in ureteral caliber to be reliably detected even in nonfunctioning systems. (a) An 8-year-old patient with a dysmorphic right upper pole, with a dilated ureter down to the pelvis consistent with ureteral atresia. These findings could not be appreciated on either US or DRS. (b) Left multicystic dysplastic kidney that had no function on DRS.

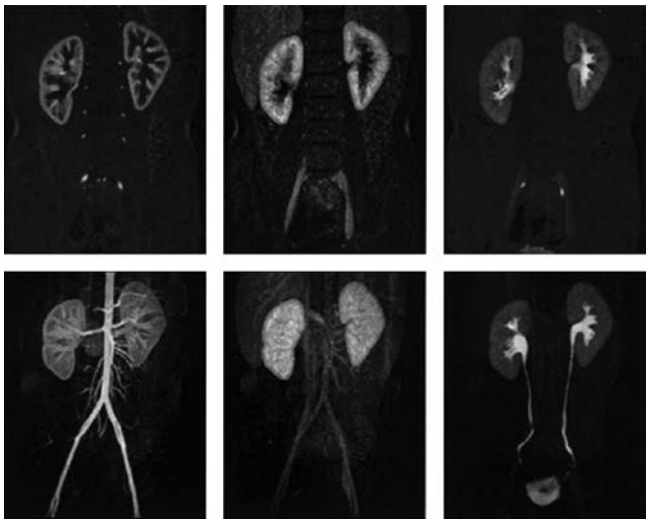

FIGURE 29.8 Following contrast administration, three distinct phases of renal enhancement can be recognized. Top row, left to right: Cortical phase, medullary phase, and excretory phase. The bottom row shows the MIPs from which images were generated.

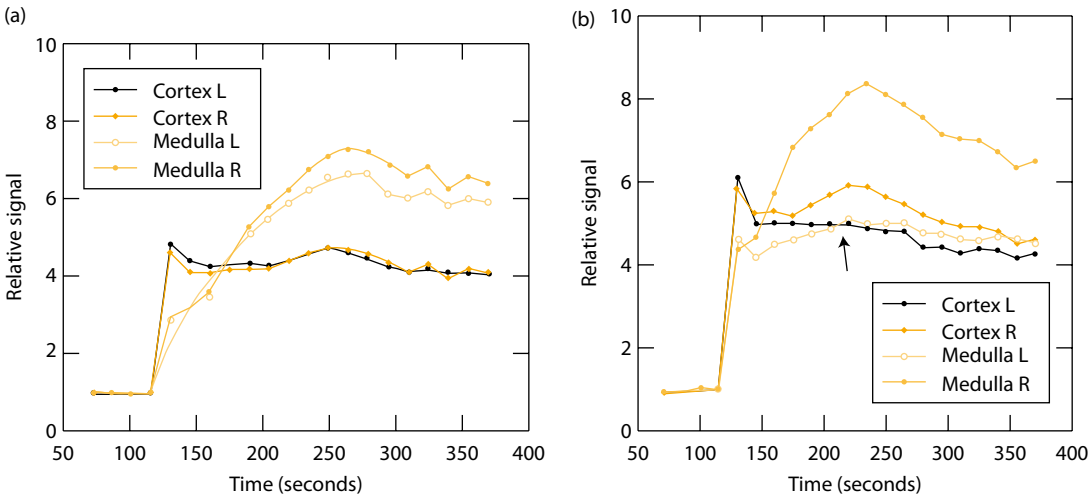

FIGURE 29.9 (a) Normal time–intensity graph. Parenchymal enhancement by MRU occurs in a predictable fashion. The CMC point (arrow) is the time at which the medulla has a higher relative signal intensity than the cortex. (b) Time–intensity graph taken from a patient with left UPJO. Delayed CMC (arrow) indicates increased intratubular pressure, which is suggestive of obstruction.

contrast, and fluid–fluid levels within the renal pelvis. With Gd-MRU, reduced enhancement and delayed excretion can be objectively quantified through the calculation of DRF and the renal transit time (RTT), which are of tantamount significance to the split renal function and $T_{1/2}$ time obtained by DRS. Using a two-compartment mathematical model, referred to as the Rutland–Patlak plot, single-kidney GFR can also be calculated with Gd-MRU.[24] This technique enables MRU-based assessment of function in patients with bilateral disease or solitary kidneys, a distinct advantage over DRS, which only provides differential information.

DRF is determined using images acquired at the time there is homogeneous enhancement within the kidney but prior to excretion of contrast into the collecting system. With 3D reconstruction, the volume of enhancing renal parenchyma is selected manually as an ROI. Vivid contrast enhancement of the renal parenchyma makes it possible to omit the collecting system and background. DRF is then calculated using the formula

$$\text{Percent renal function} = \frac{\text{Individual kidney volume}}{\text{Right kidney volume} + \text{Left kidney volume}} \times 100$$

Data published by the authors, as well as those of other clinicians, show a high correlation between DRF as determined by MRU and renal scintigraphy.[25–27]

The RTT refers to the time between the appearance of the contrast in the kidney and its appearance in the ureter (below the UPJ) and is based on 3D sequences that allow the passage of contrast to be tracked through the kidneys. Based on the RTT, drainage can be classified as normal (RTT $\leq$ 4 minutes), equivocal (4 $<$ RTT $\leq$ 8 minutes), or obstructed (RTT $>$ 8 minutes).[28] Receiver operating characteristic analysis for comparison of results by MRU and DRS shows good agreement between the modalities for the diagnosis of renal obstruction. Since the RTT includes passage of contrast through the renal pelvis, it may be falsely prolonged in cases of significantly enlarged collecting systems. As with renal versus parenchymal drainage in DRS, the caliceal transit time (CTT) (time from cortical enhancement to appearance of contrast in the calyces) eliminates the effect of a large renal pelvis on RTT. A short or symmetric CTT is highly suggestive of a nonobstructed system.[29] The unique ability of MRU to provide quantitative functional information, such as DRF and RTT, in addition to excellent anatomic characterization of the parenchyma and collecting system, makes this the most comprehensive of the currently available diagnostic studies.

Rohrschneider et al. prospectively evaluated 62 patients with static–dynamic MRU and compared the results with DRS for split function and urinary excretion, which served as the reference standard.[26] DRF, by MRU, was determined by comparing right versus left parenchymal uptake and volume, and dynamic sequences were used to generate whole-kidney ROIs, which were used to assess urinary excretion. Urinary excretion was classified similarly by MRU and DRS in 81% of the abnormal kidney–ureter units and in 100% of normal kidney units. Interestingly, in their study, MRU tended to overestimate the severity of obstruction compared with DRS. However, MRU never indicated sufficient urinary drainage when DRS indicated relevant obstruction. The higher sensitivity of Gd-MRU compared with DRS explains this finding.

One study, by Chu et al., offers limited evidence that Gd-MRU may also be more specific in the prognostication of renal deterioration than DRS.[22] In this study, eight children with unilateral hydronephrosis were evaluated by both MRU and DRS. DRS showed drainage in three hydronephrotic kidneys and poor washout in five. By contrast, Gd-MRU showed drainage in all but one of these patients. Four of the five hydronephrotic units labeled as obstructed on DRS, but that had drainage by MRU, had no evidence of worsening hydronephrosis or functional deterioration at a mean follow-up of 18 months. Furthermore, antegrade pyelography performed on two of these patients who were classified as obstructed by DRS, but not on MRU, showed

no evidence of high-grade UPJO. The one patient with an obstructive pattern by both MRU and DRS was confirmed to have significant UPJO on antegrade pyelography, and this patient subsequently underwent dismembered pyeloplasty. In a prospective study at Children's Healthcare of Atlanta comparing US, DRS, and MRU in the evaluation of hydronephrosis, MRU provided equivalent information about renal function but superior information regarding morphology in a single study without ionizing radiation.[30] Gd-MRU has also been shown to have a higher sensitivity (100% vs. 96%), positive predictive value (86% vs. 76%), negative predictive value (100% vs. 90%), and diagnostic efficiency (90% vs. 79%) than DRS.[25]

At Children's Healthcare of Atlanta, we have used Gd-MRU to evaluate more than 1500 children with hydronephrosis. MRU has been found to be particularly useful for the diagnosis and evaluation of a wide range of renal obstructive anomalies, including UPJO, megaureter, and ectopic ureters (Figure 29.10), and currently, the technique is also used to evaluate surgical results in patients pre- and postoperatively. For example, kidneys following pyeloplasty have shown statistically significant improvements in GFR (Patlak), CTT and RTT, and degree of hydronephrosis following dismembered pyeloplasty.[31] Indeed, the availability of MRU has influenced our diagnostic strategy for the evaluation of pediatric hydronephrosis. We have adapted our diagnostic algorithm to include MRU and currently use this modality in the evaluation of most patients with SFU grades 3 and 4 hydronephrosis on confirmatory sonography. Indications for surgical intervention based on Gd-MRU are more rigorous than DRS and include

- DRF of <35%–40%
- RTT of >8 minutes
- Prolonged corticomedullary crossover (CMC) times
- Decreasing GFR, as indicated by the Patlak index
- Anatomic findings

As for DRS, surgical decisions should not be based on isolated MRU criteria. Despite the advantages of MRU, there are obstacles to its widespread acceptance. First, standardized equations and values used to determine function and classify drainage have not yet been wholly agreed on. Larger studies with longer-term follow-up are still needed. Second, sedation is required for most children. Although techniques using phenobarbital or chloral hydrate have been shown to be safe, patients must be monitored throughout the study with oxygen saturation monitors. Last, there are increased costs associated with MRU and availability remains limited. Although MRU is currently more costly than renal scintigraphy, the comprehensive information obtained may justify its use, especially since it does not use ionizing radiation, and companion studies (e.g., retrograde urography) are no longer needed. Furthermore, cost and availability issues are likely to become less important in the future as use of this modality continues to increase. Indeed, over the next several years it is likely that MRU will replace renal scintigraphy in the evaluation of the pediatric urinary tract.

FIGURE 29.10 (a) A 6-year-old patient with left UPJO as seen by MRU. (b) A crossing vessel can be appreciated (arrow). (c) A 5-year-old child with bilateral nonobstructing megaureter. (d) A 9-year-old child with a right ectopic ureter, inserting below the bladder neck (asterisk), causing severe hydroureteronephrosis.

CONCLUSIONS

The accurate diagnosis and assessment of pediatric renal obstructive disorders is a principal task in pediatric urology. As a result of ongoing technologic advances, the diagnostic armamentarium available to clinicians for accomplishing this task has increased dramatically. Nevertheless, a series of radiologic studies, consisting of US, DRS, and VCUG, are still typically used to comprehensively evaluate many children. MRU has the potential to become a gold standard in the evaluation of these children. This single study, which does not require ionizing radiation, provides superior anatomic detail and, arguably, more accurate renal functional information than any other combination of studies. Cost and availability issues remain future challenges and may be the only factors preventing MRU from completely replacing renal scintigraphy.

CHAPTER 30

Ureteropelvic Junction Obstruction and Multicystic Dysplastic Kidney: Surgical Management

Michael C. Carr and Aseem R. Shukla

INTRODUCTION

The surgical management of a kidney with obstruction at the ureteropelvic junction (UPJ) has many nuances with respect to approach, degree of invasiveness, and timing of surgery. The objective remains the same: to relieve the obstruction and thus preserve or improve the overall renal function, and maintain normal development while lessening the morbidity to the patient and yet not compromising the surgical outcome. Pyeloplasties remain among the most rewarding surgeries that we, as surgeons, perform.

The decision to recommend surgical intervention for a UPJ obstruction is based on radiographic findings that are consistent with obstruction. Debate continues as to whether a single radiographic study provides all the information necessary to make that decision. There is little argument when a mercaptoacetyltriglycine (MAG-3) lasix renogram shows markedly diminished function of the affected kidney with no apparent washout following lasix administration. These cases tend to be the exception rather than the rule. Thus, we are left with monitoring serial changes over time that indicate that there is a degree of obstruction that warrants surgical intervention. Rarely in pediatrics is a nephrostomy tube placed that allows for decompression of the kidney. If present, though, this affords antegrade assessment of the kidney. Whitaker defined obstruction in the kidney as impedance to flow such that proximal pressure must be raised to transmit the usual flow rate through it. His study involved placing catheters into the renal pelvis and bladder, infusing at 10 mL/s into the kidney, and measuring the intrapelvic pressure of the kidney. How one applies the Whitaker test to a pediatric population remains a fundamental concern. In this situation, though, a number of other tests can be performed that may be more physiologic. Performing a standard MAG-3 lasix renogram in which the nephrostomy tube is then transduced to measure intrapelvic pressure can provide physiologic data. Fung et al.[1] extrapolated the measurements of intrapelvic pressure and the decrease in pressure with time to determine a pressure decay curve. The pressure decay half-life reflects both efficient urine transport and the relative compliance and volume of the collecting system. A less compliant system with increased intrapelvic pressures could become increasingly detrimental to the overall function of that kidney.

Magnetic resonance (MR) urography has become increasingly popular as a way of providing both functional and exquisite anatomic assessment of the genitourinary system. Much like the well-tempered renogram that was described in the late 1980s, several centers have refined MR urography, both in how the study is performed and how ultimately it is interpreted. The issues now include the requirements for sedation and the overall expense of the studies. These are issues that are currently being addressed, and newer protocols are being designed to overcome these issues.[2,3]

Currently, the majority of multicystic dysplastic kidneys (MCDKs) are detected prenatally. Once detected, parents are provided with information, including natural history, postnatal evaluation, and long-term sequelae for a child with an MCDK. Subsequent prenatal imaging may be recommended by the perinatologist, which has little bearing on the ultimate outcome.

The evaluation of an infant who is known to have a prenatally detected MCDK has undergone many changes even in the past decade. The amount of imaging that was recommended previously, in most situations, is no longer necessary. Studies such as voiding cystourethrograms, renal scans, and serial ultrasounds are no longer routinely done. Nonoperative management has become the mainstay, and it has been suggested that a single postnatal ultrasound alone is all that is required.[4] In my practice, I have recommended postnatal imaging at 6–8 weeks of age. An MCDK has multiple noncommunicating cysts without the presence of renal parenchyma. The contralateral kidney is assessed for evidence of compensatory growth, in addition to documenting whether ureteral dilation is present. If the size of the MCDK is initially greater than 5 cm, the involution rate of this kidney will be less than if it is less than 5 cm.[5] A subsequent renal and bladder ultrasound done at 1 year of age is beneficial to determine whether involution has occurred or whether the kidney has actually become larger over time. Since the overwhelming majority of kidneys do

show involution, no further urologic follow-up is needed.[4] If the kidney has become larger and the infant is now 1 year of age, open or laparoscopic nephrectomy can be offered to the family. A review of data from the Children's Hospital of Philadelphia between July 2007 and June 2012 showed that a total of 75 laparoscopic or open nephrectomies were performed. Twenty-one of these patients during this time interval had an MCDK. Thus, less than one nephrectomy for an MCDK per surgeon per year was being done at a large tertiary referral center, indicating that nonoperative management has become the norm.

Once a surgeon diagnoses a UPJ obstruction, prompt intervention is necessary to relieve the obstruction, provide for appropriate drainage, and reduce the intrapelvic pressure and stasis that contributes to progressive renal damage. This is particularly important in the neonatal period in order to maximize functional renal development and increase the ultimate number of perfused and filtering nephrons.[6] In those kidneys where the differential function is less than 10%, a temporary nephrostomy tube or double-J stent placement may allow for separating kidneys with recoverable function from those with irreversible damage.[7,8] Renal biopsies may also be performed to identify diffuse glomerulosclerosis that would indicate little chance for improved postpyeloplasty function.[9] No test, though, is reliable to predict renal recoverability.

TECHNICAL POINTS OF OPEN PYELOPLASTY OR SIMPLE NEPHRECTOMY

The approach for a pyeloplasty or nephrectomy has migrated from an open approach to a minimally invasive one, utilizing laparoscopic techniques. A standard flank, anterior subcostal, or posterior lumbotomy skin incision may be used to expose the kidney for pyeloplasty or nephrectomy, when approached in an open fashion. I recommend the minimally invasive approach with mobilization of the kidney for older patients. In the child or infant, however, where the anterior and posterior muscles are less well developed, most pediatric urologists favor an anterior extraperitoneal approach or a dorsal lumbotomy incision. The anterior extraperitoneal approach is performed as follows: A subcostal incision is made after the patient is placed supine with a roll placed transversely beneath the patient to elevate the flank (Figure 30.1). An incision is made from the edge of the rectus muscle to just below the tip of the 12th rib. An intraoperative retrograde pyelogram allows one to identify precisely the position of the UPJ and aide in the placement of the incision. Each muscle layer encountered is split in the direction of the muscle fibers until the surgeon defines Gerota's fascia by sweeping the peritoneum medially. The fascia is then incised posterior to the lateral aspect of the kidney. The renal pelvis is identified by medial retraction of the peritoneum and lateral traction of the kidney. If the pelvis is dilated, an angiocath can be inserted to decompress the pelvis and facilitate identification of the UPJ.

Alternatively, the lumbotomy approach in infants and younger children can be employed. A transverse skin incision, which follows Langer's lines to avoid postoperative spreading of the scar, is made with subsequent mobilization of the skin before a vertical incision through the lumbodorsal fascia. This allows the surgeon direct access to the renal pelvis. The kidney is then mobilized to gain access to the renal pelvis (Figure 30.2).

FIGURE 30.1 Appropriate positioning of patient for left anterior subcostal incision. The tips of 11th and 12th ribs have been outlined and 4 cm incision has been drawn.

FIGURE 30.2 Appropriate positioning of patient for left posterior lumbotomy approach. A curvilinear incision is marked, which can be used, or a transverse skin incision can be employed.

The closure is in one layer, which shortens operative time. In the case of bilateral UPJ obstruction, the surgeon may approach both sides without repositioning the patient. The lumbotomy approach is contraindicated if one is dealing with an incompletely rotated anterior renal pelvis. If there is an anomaly of position, the surgeon must locate the position of the UPJ before planning the incision. If the obstructed pelvis is mostly intrarenal, small or high, then a lumbotomy approach may be more difficult. In addition, muscular patients with a steep angle between the spine and the 12th rib may also present difficulties with exposure of a small or high pelvis. If caught unprepared with a particularly superior renal pelvis, the 12th rib can be disarticulated and rotated cranially to improve exposure, but in these cases, an anterior approach is preferable.

The flank approach is another option. The child is placed over the kidney rest in a flank position; the kidney rest is elevated and the operating room table is flexed. The incision is made anterior to the tip of the 12th rib, or if necessary, a supracostal 12th rib incision is made. Both the external oblique and latissimus dorsi muscles are divided. Next, the internal oblique and serratus posterior inferior muscle are divided. A transversalis muscle is often thin and can be separated with digital dissection. The peritoneum is identified and retracted medially. Gerota's fascia is then encountered and opened longitudinally to gain exposure to the perinephric space. Following identification of the renal pelvis and the ureter, the pyeloplasty is performed.

In a redo pyeloplasty, the anterior transperitoneal approach is preferred. Once the colon is reflected, the anatomy can be rapidly identified and damage to the ureter, renal pelvis, or renal vessels can be avoided by exploring a scarred retroperitoneum through a posterior approach to the kidney.

In the situation of a simple nephrectomy to remove an MCDK, any of the above-described approaches are applicable. If a small incision is utilized, decompression of the largest cysts will optimize exposure and allow for improved visualization of the renal hilum. Invariably, the renal vasculature is atretic in most situations, but careful dissection will avoid meddlesome bleeding. Bipolar cautery can be advantageous for such a dissection.

SURGICAL REPAIR

The successful pyeloplasty depends on a carefully designed anastomosis with care taken to ensure that the ureter and pelvis will lie in a normal anatomic position at the completion of the pyeloplasty. In the past, surgeons have described a series of various techniques to repair the UPJ, with open approaches being divided into three main groups: the flap type, the incisional-intubated type, and the dismembered type. The incisional techniques included incision through the strictured area with healing over a stent. This approach is no longer used with open repair. The older flap techniques to maintain the continuity of the ureter and pelvis included the Foley Y-V plasty and the Culp spiral flap. The Foley operation was designed for the correction of UPJ with a high ureteral insertion (Figure 30.3).[10] This technique cannot be used in conjunction with transposition of a lower-pole vessel, nor does it allow for any reduction of the renal pelvis. If this redundant pelvis remains at the completion of the pyeloplasty, then a fixed kink with resultant obstruction may persist. Culp and DeWeerd's spiral flap is created from the renal pelvis, which is then used to repair the defect at the UPJ. Such a flap is able to bridge the gap between the pelvis and healthy ureter over a distance of several centimeters (Figure 30.4).[11] Scardino and Prince[12] used a vertical flap that was designed in a situation of a dependent UPJ with a large, square-shaped extrarenal pelvis (Figure 30.5).[13]

The approach of dismembering the ureter was borne out of necessity in the repair of a retrocaval ureter (Figure 30.6).[14] This technique was slow to gain popularity because of the reluctance of surgeons to sever the apparent neural continuity between the pelvis and ureter. Experimental work demonstrated that the arborization of blood vessels in the renal pelvis would ensure appropriate healing even with dismembering. Despite the theoretical risk of poor coordination of peristalsis across the incised and reconstructed UPJ, the reconstructed pelvis empties well following successful dismembered pyeloplasty.

The renal pelvis and upper ureter must be carefully handled to maintain the integrity of the blood supply. The tissues surrounding the ureter should not be trimmed or separated from the ureter. Placement of several traction

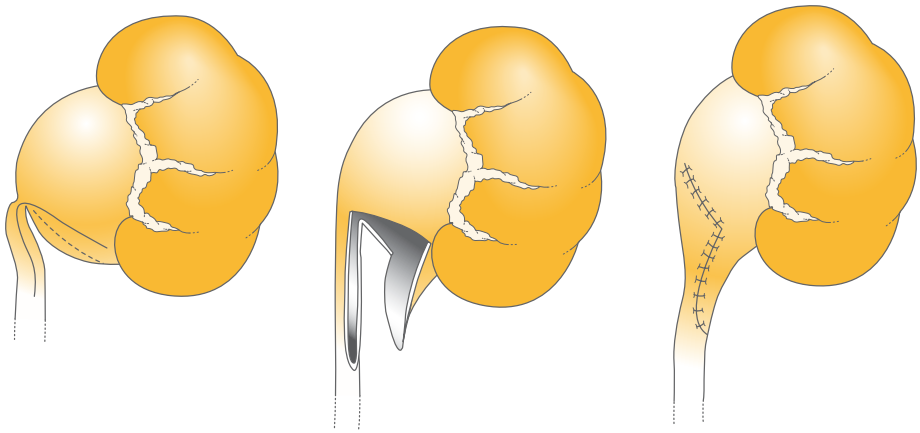

FIGURE 30.3 Foley Y-V plasty.

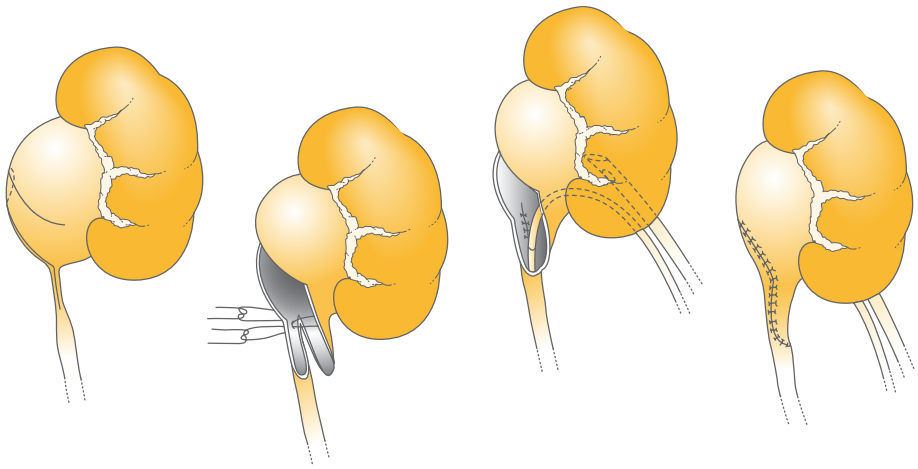

FIGURE 30.4 Culp–DeWeerd spiral flap ureteropelvioplasty.

sutures in the renal pelvis and the anterior aspect of the ureter facilitates this dissection and minimizes the handling of the tissues. We then open the ureter opposite the traction suture distally into the healthy tissue just below the poorly peristaltic segment. A fine pair of forceps will open the ureteral lumen as the ureter is divided using a straight pair of Pott's scissors. The forceps should spring apart once the scissors meet the healthy ureter distal to the obstructing segment. Bleeding from the cut edge of the urothelium, which is usually diminished in the region of the obstructed segment, will be brisk when the normal urothelium is opened distal to the obstruction. As long as the renal pelvis is not reconstructed before examination of the ureter, if the aperistaltic segment is unusually long, a flap can be fashioned from the pelvis to help bridge a discontinuity between the renal pelvis and distal ureter that may be

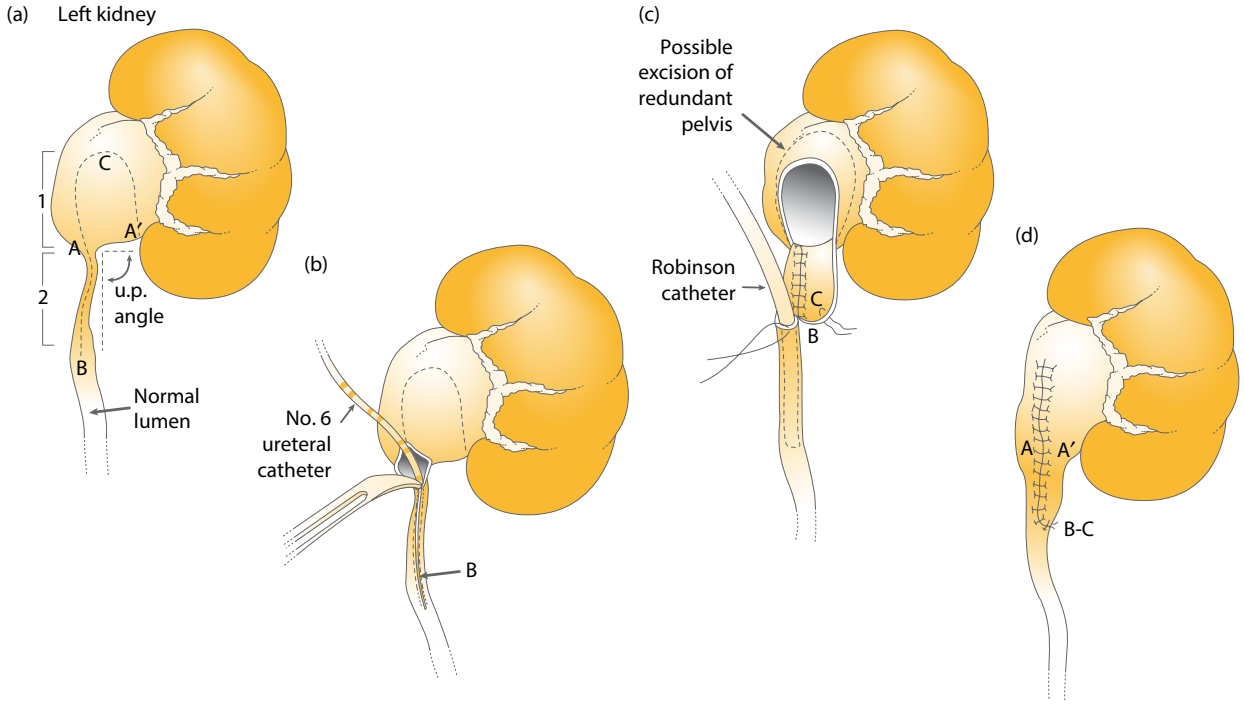

FIGURE 30.5 Scardino–Prince vertical flap pyeloureteroplasty. (a) The length of the pelvic flap (1) should adequately traverse the segment of ureteral obstruction (2). (b) A pyelotomy incision is made in the lower pelvis along the medial border of the proposed pelvic flap incision. A 6 French catheter is used to cannulate the ureter and the tip of a #12 blade is inserted into the catheter. The catheter acts as a guide to make a clean, precise ureterotomy incision. (c) A 5-0 prolene (Ethicon) suture is placed within the ureteral wall at the lower angle of the ureterotomy. A rounded pelvic flap is fashioned, and a second traction suture is placed in the tip of the flap. A 7-0 maxon (Davis–Geck) suture or comparable suture is used to suture the medial margin of the flap to the lateral ureteral margin. The mucosa margins should be identified for accurate approximation. (d) The tip of the flap (C) is carefully sutured into the lower angle of the ureterostomy (B). Any redundant pelvis may be excised and the anterior margins reapproximated (B and C, A and A′).

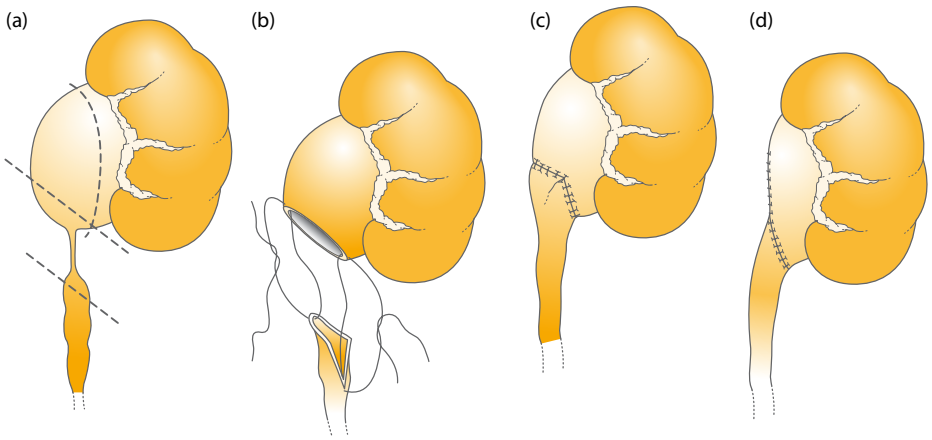

FIGURE 30.6 Anderson–Hynes dismembered pyeloplasty. (a) Two options: The pelvis may be reduced in size or not. (b and c) Anastomosis alone is performed. (d) A reduction pyeloplasty is included.

created with removal of a long ureteral segment. A ventral rotational flap from the lower portion of the pelvis can be used to bridge a gap of 2–3 cm, more if the kidney is mobilized. Reduction of the renal pelvis is completed before beginning the anastomosis. Prior to the anastomosis, the interior of the renal pelvis should be inspected to precisely identify the anatomy of the renal pelvis and its relationship to the lower-pole infundibula. In some cases, a very dilated pelvis may be associated with dilated, extrarenal infundibula. In these cases, it is possible to unknowingly create the ureteral pelvic anastomosis in such a manner that the lower-pole infundibulum, rather than the renal pelvis, is anastomosed to the ureter. If this occurs, the upper portions of the collecting system will be bypassed and will fail to drain. If an infundibulum is divided, a Heineke–Mikulicz advancement can satisfactorily prevent this complication. In the face of aberrant lower-pole vessels that contribute to the UPJ obstruction, the appropriate repair is to divide the ureter below the UPJ and perform a standard dismembered pyeloplasty with reconstruction of the UPJ anterior to the offending vessel or vessels.

TISSUE HANDLING, SUTURES, AND STENTING

The judicious use of traction sutures allows for minimal handling of the pelvis and ureter. The more the surgeon handles (or mishandles) the tissue, the more postoperative edema that will result. Without the use of urinary diversion, attention to atraumatic handling of the tissues becomes critical. In mobilizing the pelvis, similar care is required. An avascular plane is usually located outside the intrinsic blood supply of the pelvis, unless there has been significant preoperative infection or extravasation of urine around the kidney that makes mobilization of the pelvis more difficult.

Monofilament absorbable suture is preferable for performing a dismembered pyeloplasty. I prefer 7-0 Maxon suture (Davis–Geck) for the majority of children, regardless of age. Construction of the anastomosis begins at the apex, with meticulous placement of sutures, allowing for eversion of the skin edges and a watertight anastomosis. Some surgeons prefer interrupted sutures to prevent reduction of the anastomotic diameter. Others employ a running closure. Before completing the anastomosis, it is helpful to place a small angiocath or feeding tube in the renal pelvis to irrigate the reconstructed pelvis free from clotted blood.

Antegrade placement of a double-J stent is fraught with hazard, particularly in infants. It is safe for the surgeon to place a small feeding tube several centimeters below the anastomosis. If the tube is advanced to or through the intramural portion of the ureter, however, the catheter may traumatize the ureterovesical junction and raise a mucosal flap that can lead to a permanent obstruction requiring redo surgery.[15] Either preoperative retrograde pyelography or antegrade visualization of the ureter with placement of the catheter over a wire under fluoroscopic guidance may help prevent this complication.[16]

Surgeons continue to debate the use of internal stenting versus the use of nephrostomy tubes. A routine dismembered pyeloplasty with minimal handling of the tissues may not warrant the placement of either nephrostomy tube or internal stent. On the other hand, infant pyeloplasties may benefit from internal stenting, particularly if the retrograde pyelogram shows evidence of a "beaded ureter" appearance. This signifies peristaltic abnormalities of the immature, proximal ureter that benefit from internal stenting.

Advances in instrumentation, sutures, and technique have enabled the construction of such a satisfactory anastomosis that even if transient leakage from the anastomosis occurs after surgery, a very satisfactory outcome is likely. A Penrose drain left in the proximity of the anastomosis to ensure that a perinephric urinoma does not occur is required in these cases. If the child has persistent drainage from the Penrose, he or she can be discharged from the hospital with the drain still in place. For the most part, however, drainage gradually ceases after the first few days following surgery, and then the Penrose drain can be safely removed.

The routine use of a nephrostomy tube is a very safe approach with few complications.[17] Selective use of a nephrostomy tube, particularly in the child with a solitary or poorly functioning kidney or a very small infant where the

ureter may not be nearly as robust as in a toddler, is usually preferable. The nephrostomy tube not only prevents high renal pelvic pressures if there is transient edema at the anastomosis, but also provides access for radiographic studies before removal of the tube.

In a redo pyeloplasty, scarred urothelial tissue may result in greater difficulty when performing a watertight anastomosis. For this reason, a nephrostomy tube along with a small silastic stent across the anastomosis for 3–5 days following surgery is beneficial. This splenting of the repair, in addition to the nephrostomy tube, allows one to remove the stent before the nephrostomy tube so that a subsequent nephrostogram can be performed to ensure that the anastomosis is patent before removal of the tube.

ROBOTIC-ASSISTED LAPAROSCOPIC PYELOPLASTY

Robot-assisted laparoscopy, using the only currently available platform, da Vinci® (Intuitive Surgical Inc., Mountainview, California), has greatly augmented the reconstructive utility of laparoscopy in children. The system overcomes the visual, spatial, maneuverability, and ergonomic limitations of traditional pediatric laparoscopy, and recent studies confirm the efficacy, safety, and applicability of robot-assisted laparoscopy in children. The da Vinci system allows the "transitioning" surgeon to attempt complex laparoscopic surgery with its inherent advantages: three-dimensional visualization (now in high definition), articulating instruments with greater degrees of freedom, and dampening of tremor. The robot is an "enslaved device" under the control of the surgeon that has electromechanical arms equipped with sensors and actuators that move precisely under the control of a surgeon seated at a remote console. The most obvious advantage of pediatric robotic surgery, then, is manifest in its facilitation of intracorporeal suturing.

Extensive experience with the robotic-assisted laparoscopic pyeloplasty (RALP) has now been documented by multiple institutions.[18–22] Longer-term experience seems to confirm the viability of the repair, and reduced morbidity and hospital stay in older patients. Definitive data confirming that even small infants may safely undergo RALP are emerging,[4] although postoperative outcome advantages measured in metrics of length of hospitalization, narcotic analgesic use, intraoperative time, and cosmesis are lacking.

TECHNIQUE

All children complete a routine outpatient bowel preparation with oral polyethylene glycol the night before RALP. Immediately after a broad-spectrum intravenous antibiotic is administered, general anesthesia is induced and the child is positioned in a low dorsal lithotomy position. Cystoscopy and retrograde ureterography are performed to characterize the ureteral defect. We prefer to place a double-J stent in advance with its tether secured to the ipsilateral groin. There are several alternatives for stenting of the ureter, and opinions diverge as to putative advantages. Alternatives include the placement of a 5 French open-ended catheter up to the midureter and then securing it to the Foley catheter. A guidewire can then be inserted under direct vision after dismembering of the ureter for retrograde stent placement. Antegrade placement of a guidewire into the distal ureter via an angiocath sheath percutaneously placed is also a popular option.

After a Foley catheter is inserted, the child is repositioned and secured in a mild lateral decubitus position, exposing the affected side. We prefer to position and carefully secure the child's contralateral flank as close to the operating table edge as possible. We prefer to secure the ipsilateral arm along the patient's side, especially in children where positioning that arm over the face can be difficult due to extremity length. This positioning allows maximal subsequent movement of the camera in an inferior direction to visualize the ipsilateral side intracorporeally. An infraumbilical 12 mm camera port is placed using a modified Hasson technique to obtain the pneumoperitoneum. A 30° down-looking camera is introduced into the peritoneal cavity. Under direct vision, two 5 mm instrument ports are placed in the midclavicular line triangulating approximately 7 cm apart from the umbilical port and 10 cm apart from each other.

We utilize the 5 mm ports in children and have done so for our last 50 robotic cases, fully aware that this accommodation requires the surgeon to compromise on the superior instrumentation available with the more commonly available 7 mm port system. Most apparent is the lack of a 5 mm robotic scissor that also provides monopolar diathermy. Still, the enhanced cosmesis and easier closure for 5 mm instrumentation has encouraged us to transition to the smaller port size. In our early experience, we preferred placement of a fourth 5 mm port for insertion of an assistant port for laparoscopic retraction and passing and cutting of sutures. Over the last 6 years, we have obviated the need for a separate assistant port by passing sutures and handheld instruments into the peritoneal cavity via the 5 mm robotic instrument ports.

This three-port template is rotated about the umbilicus in a patient-specific manner based on the location of the ureteral defect. The patient is then maximally rotated in the direction contralateral to the ureteral lesion side after careful securing of the patient. The da Vinci robot system is then docked in the standard fashion with the robotic patient cart advanced to a position equidistant from two 5 mm ports. The 5 mm ports are placed such that the camera arm and instrument arms triangulate towards the location of the ureteral lesion. In advancing the camera arm to dock to the camera port, care is taken to ensure that the specifically demarcated "sweet spot" of the camera arm is preserved.

After mobilization of the colon and incision of Gerota's fascia, the ureteral defect is meticulously isolated with minimal manipulation and potential devascularization. A short proximal ureteral obstruction can readily be isolated via a transmesenteric approach, especially on the left side, limiting the need for medial retraction of the descending colon. For distal ureteral lesions or right-sided lesions, the colon may be mobilized. Our preference is to identify normal ureter distally, even as it passes over the bifurcation of the iliac vessels if necessary, and then following the ureter proximally until the site of the obstructive lesion is identified.

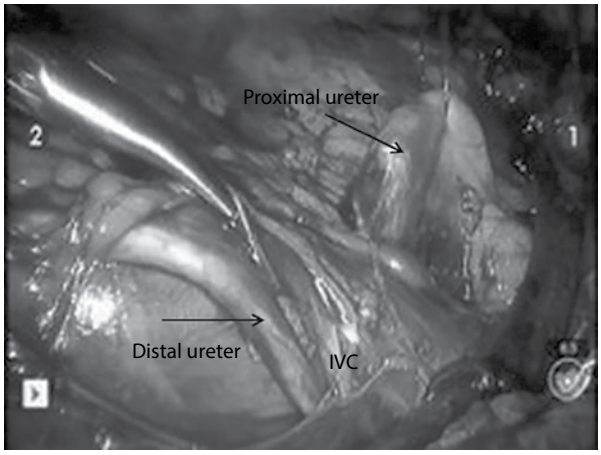

FIGURE 30.7 Intraoperative view of right retrocaval ureter. The robotic-assisted dissector is seen holding the proximal right ureter that then disappears behind the IVC.

The ureter is then transected sharply and spatulated ventrally and dorsally as needed. Ureteral manipulation to transpose over a potentially compressive vascular structure—as with a lower-pole renal crossing vessel or inferior vena cava (IVC)—is then accomplished. In a case with a retrocaval ureter (Figure 30.7), the proximal ureter is sharply divided lateral to the IVC and the retrocaval portion of the ureter is freed medially and transposed anterior to the IVC (Figure 30.8). The proximal ureter is stabilized with a 2-0 polypropylene hitch stitch to facilitate reconstruction. A tension-free watertight ureteroureterostomy is then fashioned over the double-J stent using separate posterior and anterior wall closures of running 6-0 polydioxane. We do not hesitate to use 5-0 polydiaxone for older children. We utilize a running anastomosis that begins at the vertex of the spatulation and proceeds superiorly on the medial and lateral walls of the ureter. Gerota's fascia is reapproximated with interrupted 6-0 polydioxane stitches. A 10 French round bulb suction drain is positioned over the renal fossa via the inferior instrument port. The umbilical port site fascia is closed using 2-0 polyglactin suture. All port sites are then closed using subcuticular 5-0 absorbable monofilament. The Foley catheter and Jackson–Pratt drain are removed the morning after surgery. Patients are routinely discharged to home the day after surgery. The double-J stent is removed 10 days postoperatively, either at home or in the clinic, via the externalized tether. Patients are followed up at 1 month postoperatively with a renal ultrasound to evaluate for changes in hydronephrosis or as per the institutional routine for standard open pyeloplasty.

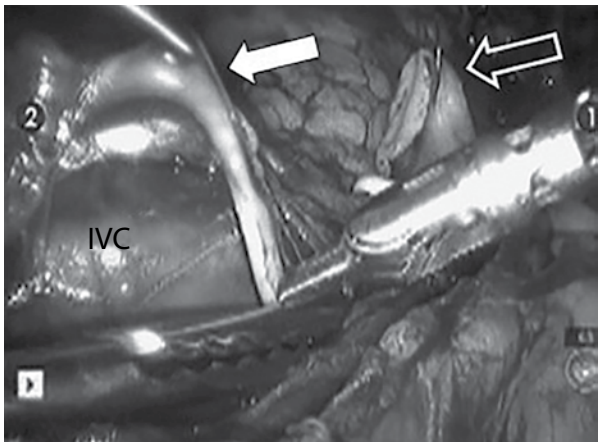

FIGURE 30.8 Intraoperative photograph of the transected proximal ureter (open arrow), which is lateral and anterior to the IVC, being stabilized with an abdominal wall hitch stitch. It will be sutured to the distal ureter (solid arrow) after being transposed anterior to the IVC.

UPJ OBSTRUCTION IN A DUPLEX KIDNEY

A UPJ obstruction can occur in a duplex kidney. Although the obstruction can occur in either the upper or the lower pole, because the lower pole is nearly always dominant and associated with the renal pelvis, in practice the UPJ obstruction is nearly always encountered in the lower-pole system. When this occurs, hydronephrosis is noted in the lower pole of a kidney on ultrasound, or a diuretic renogram shows a small, nonobstructed upper-pole segment (Figure 30.9). The anatomy of the duplication of the ureter dictates the type of procedure required. If the ureter is incompletely bifid and there is a long lower-pole ureteral segment, then a standard dismembered pyeloplasty is appropriate. However, more commonly, a high bifurcation of the ureter is present and the segment of the lower-pole ureter distal to the obstruction may not be long enough to permit direct ureteropyelostomy. In this situation, the renal pelvis is anastomosed to the side of the ureter (Figure 30.10). The lower-pole ureter may be opened with an incision that runs through the bifurcation with the upper-pole ureter. The anastomosis is the same as for a single system kidney, except that an apex is present at either end of the lower-pole pelvis. Meticulous care with the suture placement at the apices is important because the anastomosis will be narrow at these two points. If the anastomotic sutures are placed in discordant positions, the lumen at either apex will be narrowed, resulting in surgical failure.

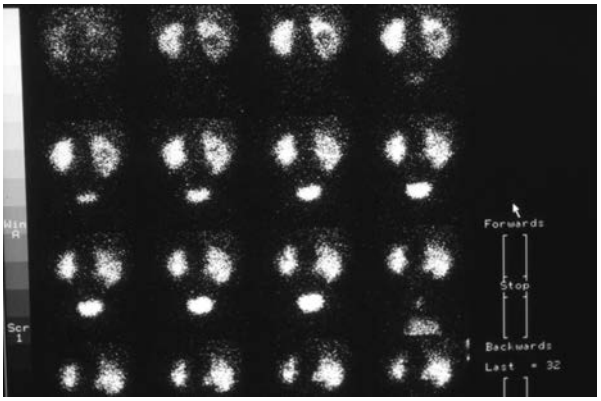

FIGURE 30.9 MAG-3 lasix renogram demonstrating normal right upper-pole perfusion and excretion with delayed uptake and excretion to the lower pole, consistent with lower-pole UPJ obstruction.

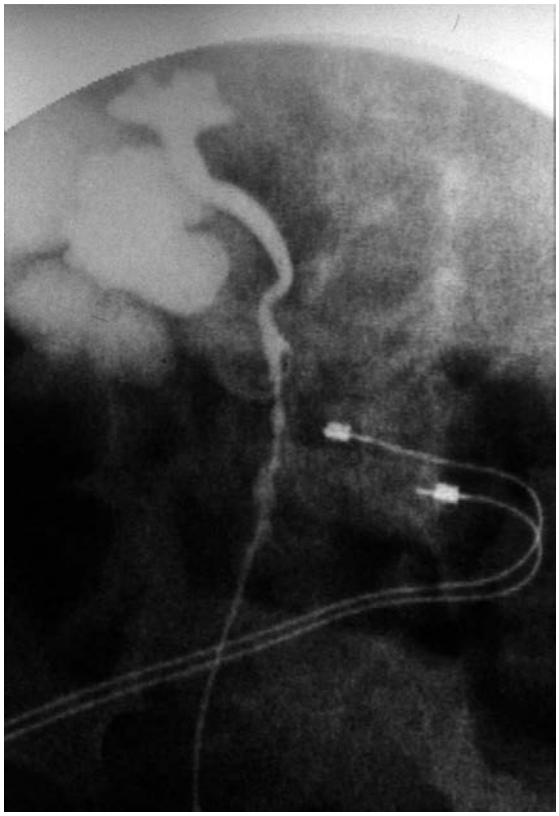

FIGURE 30.10 Anatomy of right lower-pole UPJ obstruction with atretic lower-pole ureter. An end-to-side anastomosis between the lower-pole renal pelvis and upper-pole ureter is favored.

URETEROCALICOSTOMY

In redo surgery, or in cases where the pelvis is intrarenal, or the relative length of the obstructed ureteral segment to the renal pelvis is unusually long, or if there is an unusually small intrarenal pelvis, the proximal ureter distal to the obstruction may be anastomosed to a dependent lower-pole calyx instead of to the renal pelvis. Success depends on amputation of an adequate portion of the renal parenchyma in order to facilitate the anastomosis between the calyx and the ureter. This procedure is therefore best suited for kidneys with a large, dilated lower-pole calyx with overlying parenchymal thinning. The calyx must be partially mobilized to create a tension-free urothelium-to-urothelium anastomosis (Figure 30.11). There should be no remaining renal cortex at or below the level of the repair. Redundant renal capsule, omentum, or perinephric fat can then be used to cover the repair to minimize postoperative scarring. I recommend stenting of the anastomosis with a double-pigtail stent or nephroureteral stent, in addition to a Penrose drain.[23]

A robotic-assisted laparoscopic approach to the ureterocalicostomy is also feasible.[24] In cases where the initial pyeloplasty was completed from a retroperitoneal, flank approach, there may even be putative advantages to laparoscopy as an intraperitoneal access enters a potentially undisturbed tissue plane.

Prestenting of the ureter may be preferable in these cases to easily identify the proximal ureter distal to the scarred operative field. After docking the robot in the aforementioned manner as with a standard pyeloplasty—triangulating ports toward the region of the UPJ—the ureter is transected as proximally as possible. The ureter is spatulated generously to ensure normal, well-vascularized ureteral mucosa is visible. The lower pole of the kidney is then identified, and the dependent lower pole is amputated using the 8 mm robotic shears connected to monopolar diathermy. We utilize 5-0 polydioxane suture material to then perform a mucosa-to-mucosa anastomosis of the proximal ureter to the lower-pole calyx in an interrupted and continuous fashion. No attempt is typically made to cover the anastomosis with friable renal capsular material, but omentum or perinephric fat may be affixed over the repair site. The stent is then removed 4 weeks postoperatively.

ENDOPYELOTOMY

A purely endoscopic approach to a UPJ obstruction can arguably be considered the most minimally invasive surgical treatment. Surgical techniques include antegrade and retrograde approaches that are guided fluoroscopically, and incisions performed with direct ureteroscopic visualization utilizing holmium laser or electrosurgical incision. The advent of the Accucise® endopyelotomy catheter, and success in adults, led to clinical trials in the pediatric population with UPJ obstruction.

The procedure is performed after fluoroscopically guided placement of a guidewire across the UPJ. The Accucise cutting balloon catheter is introduced over the wire in an antegrade or retrograde fashion, depending on the preferred access percutaneously or cystoscopically. The balloon is inflated, and once a narrowing within the midpoint of the balloon catheter is noted, the Accucise blade is activated with cutting current positioned laterally. A double-J stent is typically placed and removed after 3–8 weeks. When ureteroscopy is preferred, a holmium laser with a right-angle electrode is focused laterally at the UPJ until periureteral fat is visualized.[25]

While preliminary reports indicated success in the pediatric population ranging from 70% to 88%,[26,27] Kim et al.[28] recently published a 25-year experience with pediatric endopyelotomy. The long-term success for primary endopyelotomy—regardless of approach or whether performed with Accucise or with laser—was only 65%. Consistent with previous studies, the authors found that higher grades of hydronephrosis significantly impaired renal function and the presence of a crossing lower-pole vessel was associated with failure in their cohort.[28,29] The results were more encouraging, however, for secondary endopyelotomy after previously failed pyeloplasty. The success rate for this cohort of 31 patients was 94% at a median 5 years of follow-up, which compares favorably to open approaches, and confirms a continued role for the endoscopic option in select patients without a crossing vessel and retained renal function.

OUTCOME

Adherence to sound surgical principles, minimal handling of the ureter at the time of the repair, and judicious use of internal stenting or nephrostomy tube drainage all may

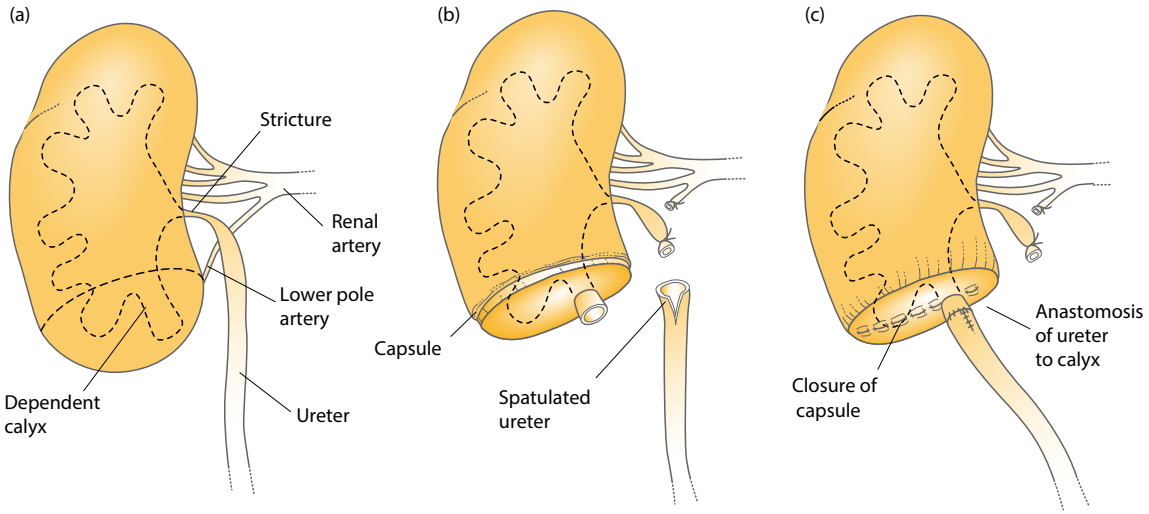

FIGURE 30.11 Ureterocalicostomy of a kidney with an intrarenal pelvis and preserved lower-pole parenchyma. (a) The lower-pole arterial supply is ligated. (b) The lower pole is resected exposing dependent calyx. (c) Anastomosis of the ureter to the calyx is accomplished without tension.

help to ensure a successful outcome. I have found that bipolar cautery is useful, particularly around the renal hilum, where the blood supply may be suspect.

Postoperative imaging of the kidney depends on whether a nephrostomy tube or an internal double-J stent has been used. A nephrostogram performed 10–14 days after surgery allows for visualization of the anastomosis. If a double pigtail ureteral stent is left indwelling, it is removed 2–6 weeks after the initial procedure. A renal ultrasound is obtained 6–8 weeks after pyeloplasty or following stent removal to ensure that the hydronephrosis (pelvicaliectasis) is improving. An overall decrease in the degree of pelvicaliectasis over time is a good indication that the obstruction has been relieved. Longer-term imaging 1 year after surgery will provide one with a good idea of whether pelvicaliectasis persists. Imaging beyond this point is debatable in an asymptomatic patient, and functional studies are generally reserved for situations in which there was a marked disparity in overall renal function prior to surgery (e.g., differential function of 70%/30% prior to pyeloplasty) or if one is not happy with the degree of persistent pelvicaliectasis that exists after surgery and there is concern that ongoing obstruction exists. Modern open repairs can be performed with an overall success rate exceeding 97%.[30]

CHAPTER 31

Laparoscopic and Robotic Nephrectomy and Pyeloplasty

Daniel Avery and Thomas Lendvay

INTRODUCTION

Beginning in the 1990s, minimally invasive surgical techniques were being applied to primarily adult and some pediatric patients, the impetus being a reduction in incision sizes, less perioperative pain, scar reduction, and a decreased convalescence. Laparoscopic surgery was initially adopted for extirpative operations. Clayman et al. described the first laparoscopic nephrectomy in 1991.[1] This was translated into the pediatric population and expanded to include many renal surgeries, such as heminephrectomy, partial nephrectomy, nephroureterectomy, cyst excision, and pyeloplasty.[2–4] The type of approach was also broadened from transperitoneal to retroperitoneal.[5] Given the steep learning curve, limited degrees of freedom for the instruments, and two-dimensional (2D) imaging of the operative field, laparoscopic surgery in pediatrics had a slow adoption rate. This was particularly true for reconstructive techniques, such as pyeloplasty, due to the difficulty of intracorporeal suturing.[6]

Robotic-assisted laparoscopic surgery improved on pure laparoscopy with three-dimensional (3D) vision, motion scaling, tremor abatement, and increased degrees of freedom of the instruments, but the high cost of equipment and relatively larger trocar sizes led to a delayed adoption in the pediatric patient population. There was also concern about the large physical size of the robot limiting anesthesia access to the patient and the inadequate size of the operative field to maneuver the instruments in pediatric patients.[7] An elegant study by Thakre et al. showed that there is a minimum size of the working operative field for the surgical robot—130 mL—about the size of a 2-year-old's bladder.[8] The rapid adoption of surgical-assisted laparoscopy in the adult population, the development of smaller instrument and camera sizes, the ease of intracorporeal suturing, and the increase in safety literature in children have led to a recent increase in the adoption of the surgical robotic platform in pediatric cases. Robotic-assisted laparoscopic urologic procedures have expanded to include nephrectomies, partial nephrectomies, dismembered pyeloplasties, ureteroureterostomies, ureteral reimplantations, varicocelectomies, orchiopexies, appendicovesicostomies, antegrade continence enema channels, urachal cyst removals, bladder neck reconstructions, and bladder augmentations.[9–17] We will highlight the most common renal procedures performed using the robot in children.

NEPHRECTOMY AND HEMINEPHRECTOMY

Indications

Nephrectomy and heminephrectomy are generally employed to remove poorly functioning or nonfunctioning renal moieties due to vesicoureteral reflux, obstruction, or ectopic insertion of the ureter. When the decision is made to remove the offensive moiety, special considerations must be made, such as ensuring the preservation of the retained functional renal moiety and ureter if possible. Nonfunctioning upper- or lower-pole renal moieties tend to have hypoplastic renal vasculature; however, some have hila that require suture ligation. Laparoscopic surgery provides excellent visualization of the renal hilum, and furthermore, a robotic-assisted approach allows for easy suture ligation. In addition, transposition under the "good" renal hilum of the typically dilated upper-pole ureter in the case of a duplex system with a dysplastic upper-pole renal moiety is facilitated by the dexterous capabilities of the robot.

Pediatric patients also undergo total nephrectomy for multicystic dysplastic nonfunctioning kidneys and renal tumors, or prior to renal transplantation if severe hypertension, nephrotic syndrome, or hemolytic uremic syndrome exists. The setups for heminephrectomy and nephrectomy are the same. The key considerations revolve around control and division of the renal hilum. The dexterity of the robotic end effectors facilitates precise dissection of the perihilar lymphatics without injury to the renal vasculature. We prefer to use either titanium clips or suture ligation of the renal vessels. The monopolar shears, Ligasure™ bipolar, or ultrasonic devices are then used to divide the vessels and complete the upper-pole perirenal dissection.

Renal Access

The traditional access for open renal surgery is usually through a flank or subcostal incision. With the introduction of laparoscopy, the access became the classic transperitoneal triangulated port placement with an umbilical access usually for the camera, and two or three working ports—one in the midline subxiphoid, one along the

ipsilateral midaxillary line at or below the level of the umbilicus, and possibly an assist port between the camera and either working port. Retroperitoneal access is also possible, and surgeon comfort should be the driver for this decision.

The setup for a robot-assisted laparoscopic nephrectomy is a modification of the pure laparoscopic approach. We will describe the setup and note differences between the two modalities where necessary. Furthermore, the positioning, port placement, and procedure are essentially the same for nephrectomy and heminephrectomy. Since heminephrectomy is technically more intricate, it is described in detail. For nephrectomy, since there is no healthy moiety the entire hilum is dissected and ligated, as is the ureter if necessary.

Transperitoneal Access

For renal access, patient positioning involves a modified flank orientation with the ipsilateral side up. We usually use gel rolls or rolled-up blankets to support the roughly 30° patient plane (Figure 31.1). This low flank position precludes the need for axillary rolls to prevent brachial plexopathies and avoids the need to raise the ipsilateral arm over the patient's chest. We support the ipsilateral arm at the shoulder with additional gel rolls. For a robotic approach in children less than 2 years of age, the robot arms may collide with the table (especially with older iterations of the da Vinci®) unless the child is raised up, so we create a blanket stage roughly 4–6 inches off the table (Figure 31.2). The patient must be brought close to the contralateral side of the table's edge; however, we leave enough room for the contralateral arm to lie next to the child, as opposed to using perpendicular arm boards. Both arms must be appropriately padded and maintained in a position of function with foam or tiny gel rolls supporting a mild flexion of the elbow and fingers.

For right-sided upper-pole heminephrectomies, liver retraction may be required. Ensuring that the contralateral subcostal margin is within the sterile field for additional retraction port access is imperative. We use an additional

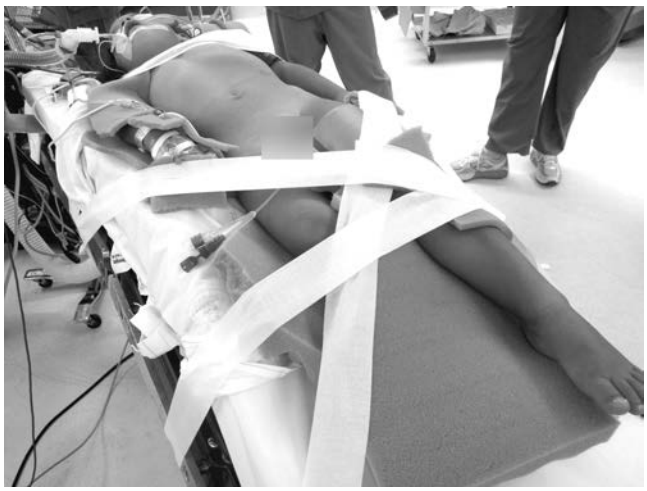

FIGURE 31.1 Patient is rolled to mild 30° flank with a straight arm at the side position.

FIGURE 31.2 Infant positioning for left pyeloplasty. Patient is bumped up on a padded stage composed of blankets and foam to avoid robotic arm collisions with the bed.

3–5 mm disposable radially dilating port below the left costal margin to insert a locking reusable grasper, which suspends the right lobe of the liver cephalad by clamping the grasper to the lateral superior peritoneum below the diaphragm. In addition, the child should be placed in a slightly steeper flank position, anticipating complete reflection of the colon. This degree of flanking may require an axillary role to be placed to prevent brachial plexopathies, especially in heavier older children. Maintaining extremity position of function and appropriate padding is necessary. Once the patient is secured to the table after mild flexion of the bed, the patient's position should be tested for stability by rotating the bed from the "patient-flat" position to the greatest degree of lateral rotation that is expected to ensure that the patient does not move. A urinary catheter is placed to decompress the bladder.

We place our superior working port in the midline subxiphoid under direct vision and cheat toward the ipsilateral side of the falciform ligament so as not to create potential bleeding from the ligament, which in infants may still have a slight degree of vessel patency (Video 31.1). The inferior port is placed either on the ipsilateral midaxillary line or even in the midline infraumbilically, avoiding the decompressed bladder (Figure 31.3). This is done to ensure that the distance between the trocar tips and the target organ is not too close; in small children and infants, the distance from the skin to the target may only be 2–3 cm. If a distal ureterectomy is planned after the resected renal moiety is free, then placing the lower port more medial or along the midline infraumbilically is favorable. This affords using the existing port configuration for a manual laparoscopic completion ureterectomy in the pelvis. If the robot is to be used, an additional port may have to be placed below the umbilicus and the robot may need to be undocked and redocked to the lower ports. Because this process is cumbersome and time-intensive, not to mention more invasive since an additional port is required, we prefer laparoscopically dissecting out the distal ureter even if a surgical robot is used for the renal portion of the case.

Once the ports are placed, if a robot is to be used, it is brought in to the patient from the ipsilateral side, with the camera arm being oriented directly on the line drawn from the umbilicus to the center of the kidney, which

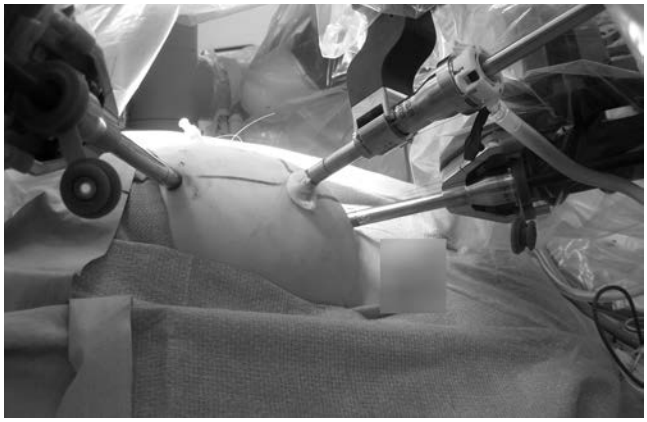

FIGURE 31.3 In-line port positions for left pyeloplasty in the infant. Suprapubic port replaces left anterior iliac crest port position to obtain more distance between this port and the UPJ.

usually is 10°–30° cephalad to the transverse umbilical line (Video 31.1).

NEPHRECTOMY OR HEMINEPHRECTOMY BY TRANSPERITONEAL APPROACH

Once the colon is reflected, identification of the ureter or duplex ureters is performed. In the case of duplex ureters, if the identification or discrimination of the good ureter is in question, we place a stent in the good ureter retrograde at the time of the cystoscopy and retrograde pyelogram. The ureters are followed up to the renal hilum and the unwanted ureter is mobilized. If a heminephrectomy is desired, the ureter is mobilized from underneath the lower-pole renal hilum for an upper-pole heminephrectomy or up to the lower-pole renal pelvis for a lower-pole heminephrectomy. This portion of the surgery is one of the steps that can lead to renal compromise. If too much traction is placed on the healthy vessels while trying to free up the nonfunctioning ureter or pelvis, the healthy pole moiety may experience ischemia temporarily or even permanently.

If an upper-pole partial nephrectomy is planned, identification of the upper-pole vasculature is performed. Many times, these are small vessels that can be treated with cautery; however, if they are greater than 1–2 mm, either titanium clip application or suture ligature can be done. Ensuring that these vessels are indeed the vessels to the unwanted moiety is critical, and identification of the preserved moiety's vessels is helpful in this regard. Once ligation of the vessels is completed, the nonfunctioning moiety may become dusky along the demarcation between the good and divided watershed. This facilitates resection of the moiety. We prefer to use monopolar shears or hook cautery, although using the robotic ultrasonic shears is also a possibility. We do not use the ultrasonic modality because there is no articulation capability. We recommend low cautery settings (<10) when resecting the poor renal cap off of the good moiety, as thermal spread may injure the spared moiety. Once the cap is freed, it can be carefully delivered under the lower-pole vessels. The remainder of the ureter can be mobilized distally to the bladder using either laparoscopy or redocking of the robot. We have used suture ligation as well as Endoloop® ligation or clip ligation for the distal ureterectomy in refluxing systems. Alternatively, if the ectopic system is obstructed, we leave the remaining ureteral end open.

Most moieties are small and can be removed through the umbilical port site. If there is a large cystic component to the moiety, direct laparoscopic needle aspiration can be done to decompress the segment. Occasionally, the umbilical fascial incision will need to be extended underneath the skin to facilitate removal of the specimen.

Inspection of the remaining renal resection bed is necessary to confirm that no violation of the remaining renal moiety's collecting system has been made. If a collecting system tear is recognized, we close with absorbable monofilament suture and try to cover the defect with the lateral and medial edges of the remaining kidney. If a leak is noted, a stent is left in the good ureter. If no stent had been placed prior to the renal surgery, one can be placed by making a small pelvotomy just cephalad to the ureteropelvic junction (UPJ) and passing a stent antegrade. Confirmation of the distal stent position can be made with intraoperative bladder ultrasonography.[18] The ligated hilum is also inspected for bleeding with partial abdominal decompression. All port sites (>2 mm) are closed at the level of the fascia, and any hitch stitches or angiocatheter percutaneous sites are observed for bleeding.

Robotic Considerations

The rules for triangulation are modified in robotics. The ideal transperitoneal robotic port placement follows a gradual arc, with the center usually being the camera port (Video 31.1), for which we use the da Vinci 8.5 mm trocar for the 3D 8.5 mm scope. The reduction in the camera size from 12 to 8.5 mm in 2008 allows for a smaller umbilical incision, which is measureable especially in infants. The 5 mm 2D scope for the robot is no longer available in the newest da Vinci iteration. We have tended to use the 8 mm ports, as opposed to the 5 mm ports, because we feel that the instrumentation is better for the 8 mm setup. The snaked joints of the 5 mm instruments require a longer distance outside of the trocar for the instruments to articulate, and the finest graspers available for the 5 mm ports are not as delicate as the 8 mm Diamond® tip forceps.

Since the robotic ports are not ribbed, they have a tendency to slip out of the thin abdominal wall of infants during rapid desufflation; therefore, we secure the ports to the skin with nylon suture (Video 31.1). This also facilitates drawing back the ports out of the abdominal wall such that only the distal unmarked tip of the trocar is within the abdomen. Care must be taken to observe the movements of the trocars in this position so as not to stress the abdominal wall, since this will bring the "remote center" or the fulcrum of the ports slightly outside of the abdomen in thin patients. If this is observed, the port will need to be pushed in further to prevent trauma to the port site.

Intuitive Surgical recommends maintaining 8–10 cm between the working ports and the camera port, which,

in infants and small children, is unattainable. However, due to the pliability and convexity of the young child's abdominal wall, we find that intertrocar distances as low as 3–4 cm are possible without arm collisions. This is also due to the extremely small field of surgery required. Large distances within the abdomen do not need to be traversed, and initial port placement is the most critical portion that facilitates a successful procedure.

Retroperitoneal Access

Lateral Approach

The patient is placed lateral, with sufficient flexion of the operating table so as to expose the area of trocar placement, between the last rib and the iliac crest. In infants and young children (under 6 years), use lumbar padding to laterally flex the patient without flexing the operating table. Retroperitoneal access is achieved through the first incision, 10 mm in length, and one finger width from the lower border of the tip of the 12th rib (Figure 31.4). The use of narrow retractors with long blades allows a deep dissection despite a short incision. Gerota's fascia is approached by a muscle-splitting blunt dissection; it is then opened under direct vision, and the first blunt trocar (5 or 10 mm) is introduced directly inside the opened Gerota's fascia. A working space is created by gas insufflation dissection, and the first trocar is fixed with a purse-string suture that is applied around the deep fascia to ensure an airtight seal and to allow traction on the main trocar if needed to increase the working space. A second trocar (5 mm) is inserted posteriorly in the costovertebral angle, in front of the lumbosacral muscle. A third trocar (5 mm) is inserted, in the anterior axillary line, a finger width from the top of the iliac crest. To avoid transperitoneal insertion of this trocar, the working space is fully developed and the deep surface of the anterior wall muscles is identified before trocar insertion.

Insufflation pressure does not exceed 12 mmHg, and the CO_2 flow rate is progressively increased from 1 to 3 L/min. Access to the retroperitoneum and creation of the working space are the keys to success in retroperitoneal renal surgery. Age is not a limiting factor for this approach. Young children have less fat, and the access is easier.

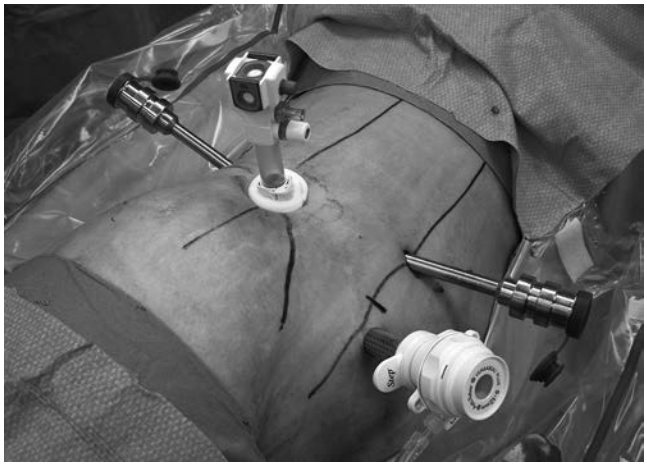

FIGURE 31.4 Port placement for retroperitoneal renal surgery. (Courtesy of Dr. Jim Porter, Swedish Medical Center, Seattle, Washington.)

Prone Posterior Approach

The access begins with an incision in the costovertebral angle at the edge of the paraspinous muscles. The secondary trocars are placed just above the iliac crest, one medially at the edge of the paraspinous muscles, and one laterally at the posterior clavicular line.[19] In a randomized prospective study on 36 complete and 19 partial nephrectomies, Borzi compared the lateral with the posterior retroperitoneal approach in children.[20] There was no significant difference in the operative time.

Other Techniques to Access the Retroperitoneal Space

Since the description by Gaur, balloon dissection has been the method applied by most urologists.[21] Disadvantages of the balloon are the cost of the disposable material and the possible complications related to rupture of the balloon.[22] On the other hand, balloon dissection allows creating a working space without opening Gerota's fascia, which is important for radical removal of malignant tumors in adults. Capolicchio et al. described a modification of lateral access.[23] They recommend the insertion of the first trocar through the costovertebral angle. This modification helped them to avoid an accidental peritoneal tear during access through the first lateral incision, and also allowed a smaller incision for the laparoscope. Micali et al. reported the use of the Visiport visual trocar to access retroperitoneal space directly, which was originally described by Kavoussi.[24] The advantage of this method is the possibility of using a small incision for the first trocar, which is helpful in reconstructive surgery but not in ablative surgery, as the first incision is needed for organ retrieval.

NEPHRECTOMY BY LATERAL RETROPERITONEAL APPROACH

The landmarks of the retroperitoneal space are first identified in order to be oriented with the retroperitoneal exposure. The psoas muscle is the posterior landmark, and should remain in the bottom of the screen. The kidney remains attached anteriorly to the peritoneum, and should remain upward on the screen. The renal pedicle is identified and approached posteriorly; it is dissected close to the junction with the aorta and vena cava, to avoid multiple ligations of branches of the renal vessels. On the left side, the vein is ligated distal to the genital and adrenal branches. On the right side, the vein is short and a careful dissection at its junction with the vena cava will avoid confusion with dissecting the vena cava. After dissecting the renal artery, and then the vein, the vessels are clipped, ligated, or coagulated. In the absence of reflux, the ureter is coagulated and divided at the lumbar level (especially in pretransplant nephrectomy, the native ureter might be used for the transplantation).

In the presence of reflux, the dissection is followed distally, the vas deferens is identified in males, and the ureter is ligated as close as possible to the ureterovesical junction.

During this distal dissection, the surgeon moves toward the head of the child, and the screen goes toward the feet of the child. One can use an Endoloop or a percutaneously passed suture to fix the ureter to the abdominal wall to facilitate its distal dissection and ligation. A fourth trocar is used if the dissection is not sufficiently close to the bladder, and it is inserted at the edge of the lumbosacral muscle close to the iliac crest. As the peritoneum is very close to the ureter in this distal part, its dissection is left at the end of the procedure to avoid an early peritoneal tear. The last part of dissection is the anterior surface of the kidney. The kidney is dissected from the peritoneum very close to its capsule in the cleavage plane of areolar tissue. Usually, no hemostasis is necessary in this plane, whereas in inflammatory adherent kidneys, a sharp dissection with bipolar coagulation may be necessary.

Postoperative Care

We leave a urethral catheter in overnight, and children will typically be discharged the 1 or 2 days after the surgery. No activity, diet, or bathing restrictions are required. Follow-up includes a renal bladder ultrasound to identify any perirenal fluid collections and to assess the residual functional renal pole with Doppler if a heminephrectomy was performed.

Outcomes

Multiple studies have looked at laparoscopic nephrectomy and partial nephrectomy in the pediatric population. Several have compared the outcomes of the laparoscopic technique with the open technique and found it to be safe and efficacious.[25–28] These studies have results suggesting equal success between the laparoscopic and open procedures. The trend of safe and efficacious minimally invasive nephrectomy continues with new research of robotic partial nephrectomy. Lee et al. had good results in nine patients undergoing robotic-assisted laparoscopic partial nephrectomy, again showing that expanded roles of robotic surgery in pediatric urology are not only safe but also efficacious.[16]

Pyeloplasty

The second most common fetal abnormality picked up on antenatal ultrasounds is hydronephrosis, the dilation of the kidney pelvis where urine first collects before draining down the ureters. The incidence of hydronephrosis is 1% of all prenatal ultrasounds; within this group, almost half are due to obstruction at the junction between the kidney pelvis and the ureter. The etiology of the obstruction may be intrinsic or extrinsic. The repair of the obstruction involves dividing the narrowed segment and broadening the cross-sectional area of each end and then suturing the ends back together.[29]

Transperitoneal Approach

We recommend initial bladder decompression with an indwelling urethral catheter to avoid bladder injury upon initial access. A urethral catheter is placed either at the end of the preprocedural cystoscopy and retrograde pyelogram or prior to patient positioning. After draining the bladder, we keep the urethral catheter capped so that the renal pelvis remains distended and prep the catheter into the field so that if fluid needs to be instilled into the bladder for recognition of the ureteral stent, we have immediate and sterile access.

As this is a renal surgery, the patient position is the same as in a nephrectomy described above. Standard robotic renal surgery port placement is carried out with the camera port in the umbilicus. We have frequently observed a natural fascial defect at the umbilicus in many children, facilitating ease of open laparoscopic port placement in a Hasson fashion. For left-sided repairs, we use two working ports. On the right side, we place ports in the same orientation as the left side and occasionally need to add a left lateral subcostal 3–5 mm assist port to retract the. The same robotic considerations stated for nephrectomies above also apply here. The robot will approach the patient from the ipsilateral side cephalad to the umbilical line bisecting the arc created by three ports (Video 31.1).

For most left-sided and some right-sided pyeloplasties, a transmesenteric approach is possible since the renal pelves are frequently very distended and are seen bulging up through the mesenteric veil of the lateral colon. This avoids mobilizing the colon, which can lead to a longer return of bowel function. The patient positioning allows for sweeping the small bowel to the dependent contralateral side, exposing the space between the tented unreflected ipsilateral colon and the residual small bowel. In many children, even adolescents, the mesentery is not laden with fat and remains merely a reflection of the peritoneum, through which a small window (quarter sized) can be made with sharp dissection, avoiding obviously visible mesenteric vessels. Small vessels may be divided, but primary colonic arcade vessels must be preserved.

In many right-sided cases or cases where the mesentery is fatty or the renal anatomy is distorted, the lateral colonic attachments can be taken down to allow the colon to fall medial. Again, we have experienced many right-sided cases where minimal reflection of the colon is required, as the hepatic flexure tends to be thin and broad, usually displaying most of the kidney before any reflection has been done. This in situ approach whereby the kidney is not mobilized and the colon is not disturbed demonstrates an advantage to the robotic approach (Videos 31.2 and 31.3).

Transperitoneal Procedure

A standard Anderson–Hynes dismembered pyeloplasty technique is used.[30] Mobilization of the UPJ is facilitated by first exposing the inferior half of the renal pelvis and the proximal ureter. Judiciously grasping the adventitia and using more indirect retraction techniques minimizes potential tissue trauma. Since only two working ports are used, we utilize percutaneous hitch stitches for stabilization of the renal pelvis and sometimes the ureter (Figure 31.5). These allow for retraction by the bedside assistant and they keep the operative target out of pooled urine that accumulates once the ureter is dismembered. In addition,

FIGURE 31.5 Demonstration of percutaneous hitch stitch through renal pelvis to lift up the operative site.

we have described the use of a 14 G angiocatheter placed percutaneously above the operative site to allow passage of 2 mm off-the-shelf cystoscopic graspers or shears, 4 French open-ended angiocatheters, and antegrade stents for bedside retraction and suture cutting, urine or smoke evacuation, and UPJ stenting with up to 4.8 French JJ stents, respectively.[31] This avoids another laparoscopic port, which could be a potential site for herniation or trauma (Figure 31.6).

If an aberrant crossing lower-pole renal vessel unit is identified compressing the UPJ, the junction must be mobilized from underneath the vessels. In certain circumstances, the lower-pole vessels create extrinsic compression on the UPJ without any intrinsic narrowing. If the ureter is able to be slid cephalad and caudad to the vessels and appears to have a broad luminal cross section, a vasculopexy or vascular hitch procedure may be performed.[32] This requires adequate mobilization of a redundant renal pelvis so that the lower-pole renal vessels may be secured within a renal pelvis wrap. The robot facilitates this maneuver since we use interrupted 3-0 dyed absorbable monofilament stitches to bring the pelvis around the vessels. Special care must be taken to make sure that (1) the final resting position of the vessels is far cephalad to the UPJ and (2) the wrap is not so tight as to constrict blood flow. We check this by placing the tips of a robotic large needle driver between the wrap and the vessels. If the UPJ appears to be intrinsically narrowed, then a standard dismembered pyeloplasty and transposition of the ureter on top of the lower-pole vessels is performed. We have employed the vascular hitch procedure for a few children, although we recommend a conventional dismembered pyeloplasty for most.

Once the UPJ is dismembered, the distal ureter is spatulated along the lateral side and the renal pelvotomy is spatulated along the medial side, facilitating a broad anastomosis at the most dependent portion of the pelvis. This maneuver can be one of the most challenging portions of a pure laparoscopic pyeloplasty but is dramatically facilitated by the articulating robotic instruments. We typically use 5-0 or 6-0 dyed absorbable monofilament suture first, with a few interrupted stitches at the distal apex and then one running stitch along the posterior wall and one along the anterior wall. We have not found the need to reduce the renal pelvis. Prior to anterior wall closure, a 0.025-inch hydrophilic wire loaded with a 3.7 or 4.8 French JJ stent is inserted through the 14 G angiocatheter and driven antegrade down the ureter using the Seldinger technique. Since we pass stents antegrade and not retrograde, we need to confirm placement of the distal stent coil in the bladder, so we employ the use of an off-the-shelf ultrasound (Sonosite, Bothell, Washington), which anesthesia uses for regional blocks to confirm the distal coil.[18] The anterior wall is then closed. We do not close the mesenteric window and have not had a case of internal herniation; however, some describe closing the window merely to provide a safe and easy robotic suturing task for junior trainees. In addition, we do not suture the reflected colon back to the lateral abdominal wall. We do not place abdominal drains other than the JJ ureteral stent. We close all port sites at the level of the fascia under direct vision and make sure that there is no bleeding from the 14 G angiocatheter or hitch stitch puncture sites while the abdomen is partially decompressed. Skin incisions are closed with absorbable monofilament subcuticular sutures and cyanoacrylate skin glue.

FIGURE 31.6 Insertion of percutaneous 14 G angiocatheter (assist port) for venting, antegrade wire and stent passage, and cystoscopic shears and grasper placement.

Robot Considerations

In addition to the robotic considerations in the nephrectomy section, additional tips apply. Since the robot, unlike laparoscopy, does not provide good tactile feedback, surgeons must rely on visual cues to sense potential tissue trauma. This is hardly scientific, and therefore adhering to the principles of delicate open surgery, such as "no touch" processes, is ideal for our pediatric patients. We use a limited number of instruments, such as the Diamond tip forceps, which minimize the trauma to the fine suture material while also providing the least amount of grip strength for potential tissue injury. These are not good for larger children, as they provide very poor tissue-grasping capabilities. We use 8 mm instruments because we use 6-0 monofilament suture material for our anastomosis and have found that the 5 mm needle drivers alter the integrity of the suture; therefore, we use the da Vinci Diamond tip needle drivers for fine suturing. We have not observed large residual port site scars, even in infants, and only one patient to date developed a port site hernia. We close all port sites at the level of the fascia with absorbable braided polyglycolic acid suture. The working ports are placed in the midline below the xiphoid and on the midclavicular line and on the ipsilateral side below the umbilicus (Figure 31.7).

Retroperitoneal Approach

The same access is used as described for nephrectomy. Yeung et al.[33] used different positioning according to the side of the kidney: semiprone for the right side and semilateral for the left side. The three-trocar technique uses one 3 or 5 mm port for the laparoscope at the tip of the 12th rib, a 3 mm port at the costovertebral angle, and a third trocar of 3 mm at the top of the iliac crest. The kidney is approached posteriorly, and the renal pelvis is first identified. The pyeloureteral junction is identified, and a minimal dissection is done to free the junction from connective tissue. Small vessels are divided using bipolar electrocoagulation. Care is taken not to section ureteral blood vessels. A stay stitch is placed at the junction. Aberrant crossing vessels are identified.

The renal pelvis is partially divided using scissors at the most dependent part, and gentle traction on the stay suture helps to define this point. Keeping the traction, the ureter is partially divided and incised vertically for spatulation. The traction suture helps to mobilize the ureter, so the scissors can be in the axis of the ureter, usually introduced through the last trocar. The anterior surface of the kidney is left adherent to the peritoneum, so that the kidney is retracted medially without the need for individual kidney retraction. The ureteropelvic anastomosis begins using a 6-0 absorbable suture, placed from the most dependent portion of the pelvis to the most inferior point or vertex of the ureteral spatulation. The suture is tied using the intracorporeal technique, with the knots placed outside the lumen. The same stitch is used to run the anterior wall of the anastomosis. The UPJ is kept intact for traction and stabilization of the suture line, and removed just before tying the last suture on the pelvis. This stay suture may be fixed to the psoas muscle to give stability and facilitate the suturing. A double-pigtail stent is inserted through the costovertebral angle trocar, and if there is doubt, its position in the bladder is ensured with intraoperative ultrasound, as above. The posterior ureteropelvic anastomosis is then performed. In cases of aberrant crossing vessels, the technique is slightly different. After placement of the stay suture, the ureter is completely divided and the UPJ and the pelvis are delivered anterior to the vessels with the help of the stay suture; then the anastomosis is performed as described.

FIGURE 31.7 Port placement incisions.

Postoperative Care

The majority of our patients are discharged the day after surgery after a successful trial of void and oral intake or analgesia tolerance. We have no activity restrictions, and bathing is permissible immediately. The JJ stents are removed 3–6 weeks after the repair under a brief general anesthetic and cystoscopic procedure. Patients with preoperative hydronephrosis are followed up in 1–2 months with a renal bladder ultrasound, and if there is any equivocation or if the patients initially presented with transient hydronephrosis due to Dietl's crisis, a nuclear renogram is ordered.

Outcomes

Success with both laparoscopic and robotic pyeloplasty is comparable to that with open pyeloplasty.[34] Evidence continues to prove that both modalities have excellent success rates and low complication rates. A recent article by van der Toorn et al. found that laparoscopic pyeloplasty had a 98% success rate and a decreased length of postoperative stay compared with an open pyeloplasty cohort.[35] The case for robotic-assisted pyeloplasty is also mounting, with several recent studies showing not only that it has similar success rates as open pyeloplasty with low complication rates[36,37] but also that practices without prior laparoscopic

experience can transition from open to robotic pyeloplasty with good success.[38]

Other Minimally Invasive Modalities

Laparoendoscopic Single-Site Surgery

In efforts to reduce poor cosmetic outcome and incision sites, laparoendoscopic single-site surgery (LESS) was developed. With this technique, there is a single 10–25 mm incision made transumbilically, through which all of the laparoscopic instruments fit. This is accomplished with either commercially available products or homemade products (one in particular is made with a retractor ring and surgical glove[39]) that allows placement of three or four laparoscopic ports that all enter the body through the umbilical incision. This can result in a "scarless" surgery.

Desai et al. first described the LESS technique for nephrectomy and pyeloplasty in 2008.[40] There have been several papers describing the technique in the pediatric population.[41–44] All had excellent outcomes but remark on the advanced and difficult skill set that is required. This stems from the inherent lack of triangulation of the instruments. The instruments are essentially parallel to each other and in very close proximity. Articulating instruments make this configuration possible. This is a developing area in surgery and certainly an interesting new avenue in pediatric urology.

Endopyelotomy

About the time that laparoscopy was beginning, new endoscopic procedures were also being developed for minimally invasive treatments. The endopyelotomy is a procedure that could be accomplished antegrade or retrograde with a balloon dilator, cold knife, electrocautery, or laser. Several studies have been conducted in children for primary and salvage repair of UPJ obstruction. Unfortunately, success rates have never approached those of open, laparoscopic, or robotic-assisted laparoscopic pyeloplasty. In one study by Patel et al.,[45] adults treated for secondary UPJ obstruction with endopyelotomy had a 83.5% success rate, but children under 5 years of age had a 75% failure rate. Tallai et al.[46] looked at endopyelotomy in 37 children. They had a success rate of 85%, but also two nephrectomies. Endopyelotomy for salvage after failure of pyeloplasty has also not compared well with open, laparoscopic, or robotic-assisted laparoscopic techniques. In one study, Braga et al.[47] compared salvage endopyelotomy to redo open pyeloplasty. The redo open pyeloplasty had a 100% success rate, but the salvage endopyelotomy only succeeded in 39% of patients.

CONCLUSION

The minimally invasive techniques of laparoscopy and robotic-assisted laparoscopic treatment of renal anomalies in the pediatric population are safe and efficacious. Laparoscopy continues to be a reasonable approach, but the steep learning curve and difficult intracorporeal suturing keep it out of reach of many pediatric urologists. Robot-assisted laparoscopic renal surgery is growing in popularity and can be adopted by practices that did not previously perform pure laparoscopic surgery. Many studies have shown that the complication rates and success rates for laparoscopic and robotic-assisted laparoscopic partial nephrectomy, nephrectomy, and pyeloplasty are comparable to those of open procedures. Furthermore, the benefits of decreased hospital stay and postoperative pain after minimally invasive surgery on the kidney have been realized. In the future, these techniques may be able to be performed through single incisions without any resulting scar.

CHAPTER 32

Wilms' Tumor

Kristen Scarpato, Patrick H. McKenna, and Fernando Ferrer

INTRODUCTION

Nephroblastoma, or Wilms' tumor, is an embryonal tumor that develops from the remnants of the immature kidney. It is the most common renal tumor of childhood.

As a result of work performed in the last decades by cooperative groups, survival of children with Wilms' tumor is generally excellent, save for some specific subpopulations. Our advancing capabilities related to molecular staging continue to allow us to identify those who are at higher risk, and require more intense therapy. Simultaneously, those at lower risk are becoming eligible for a reduced therapeutic burden and, we hope, fewer long-term effects. Unfortunately, we are still wanting for new, effective therapeutic agents. Hopefully, the evolving field of cancer pharmacogenomics will address this need. This chapter is a comprehensive review of Wilms' tumor and briefly discusses other less common renal tumors.

EPIDEMIOLOGY

The annual incidence of Wilms' tumor is approximately 7.6 cases per million children under 15 years of age, or about 500 new cases annually in the United States. Wilms' tumor accounts for 6%–7% of all childhood cancers.[1] It typically affects young children (median age 3.5 years), although older children and occasionally even adults can be affected. Wilms' tumor occurs at an earlier age in children with bilateral tumors (median 29.5 months for boys and 32.6 months for girls). The disease occurs nearly equally in girls and boys worldwide.[2]

Children with Wilms' tumor frequently have associated congenital anomalies or recognizable syndromes. Syndromes associated with a predisposition to develop Wilms' tumor may be divided into those characterized by overgrowth and those lacking overgrowth. Syndromes with overgrowth features include hemihypertrophy, which may occur alone or as part of the Beckwith–Wiedemann syndrome (BWS). BWS is a rare disorder, characterized by excess growth at the cellular, organ (macroglossia, nephromegaly, and hepatomegaly), or body segment (limb hemihypertrophy) levels (Figure 32.1).[3] The incidence of tumor development in BWS is 10%–20%. Common cancers in these patients include Wilms' tumor, adrenocortical neoplasms, and hepatoblastoma. The risk of Wilms' tumor development in patients with hemihypertrophy and BWS is estimated to be in the order of 4%–10%, with 21% of those children presenting with bilateral disease.[3–7]

Data from the BWS registry suggest that nephromegaly is a strong risk factor for the subsequent development of Wilms' tumor in this population.[8] The mean age at diagnosis of Wilms' tumor in hemihypertrophy patients is similar to that of the general Wilms' tumor population.[9] Other overgrowth syndromes, such as the Perlman and Simpson–Golabi–Behmel syndromes, are also associated with the development of Wilms' tumor (Table 32.1).[10,11]

Wilms' predisposition syndromes not associated with overgrowth frequently have associated genital or urinary tract anomalies. Genitourinary anomalies (hypospadias, cryptorchidism, and renal fusion anomalies) are present in 4.5% of patients with Wilms' tumor.[12] Denys–Drash syndrome (DDS) represents the specific association of male pseudohermaphroditism, renal mesangial sclerosis, and nephroblastoma. The classic presentation consists of ambiguous genitalia, with up to 40% of children appearing phenotypically female.[13] Genetic studies indicate that DDS is associated with mutations of the 11p13 Wilms' tumor gene.[14] Roughly 1% of Wilms' tumor patients are diagnosed with the WAGR (Wilms' tumor, aniridia, genital anomalies, and mental retardation) syndrome.[15] Most affected individuals have a constitutional deletion on chromosome 11. The incidence of Wilms' tumor formation in these children is 42%. Children with WAGR present at an early age and have lower birth weights and an increased incidence of bilateral disease.[16] Wilms' tumors have also been reported in association with neurofibromatosis, Sotos's syndrome, and Klippel–Trénaunay–Weber syndrome (Table 32.1).[17]

There is an increased risk of Müllerian duct anomalies in girls with Wilms' tumor.[18] Approximately 10% of girls have abnormalities, such as duplication of the cervix or uterus, or bicornuate uterus. Patients with horseshoe kidney have been noted to develop Wilms' tumor at a higher than expected rate.[19,20] Wilms' tumor has been reported in patients with multicystic dysplastic kidney (MCDK), but there is insufficient evidence to support that the incidence is higher than in the general population.[21] The frequency of ultrasound follow-up for children with MCDK and indications for nephrectomy in these patients remain controversial, with some suggesting that no follow-up is needed.[21,22]

FIGURE 32.1 Young female patient with hemihypertrophy.

Surveillance imaging with renal ultrasound has been recommended in children with hemihypertrophy (WAGR), BWS, or aniridia (and other predisposition syndromes), with the intent of discovering tumors at an earlier stage. A review of BWS patients reported by the National Wilms Tumor Study Group (NWTS) found more stage I tumors, and noted that high-risk children undergoing periodic screening have smaller tumor diameters.[7,23] There were not enough patients in this retrospective review to determine if early detection had an impact on patient survival. Craft et al. reported on 13 high-risk children undergoing screening with abdominal ultrasound and did not find any significant difference in stage distribution compared with children not undergoing screening.[24] Nevertheless, screening for high-risk children is recommended, and the suggested interval is every 3–4 months.[25,26] It is important to note that not all new lesions in these children represent a Wilms' tumor, as there is an increased incidence of nonmalignant renal lesions in children with BWS.[27,28]

TABLE 32.1 Syndromes associated with Wilms' tumor and estimated risk of tumor development

Syndrome	Tumor risk
BWS with hemihypertrophy	5%
Perlman	30%–60%
Simpson–Golabi–Behmel	7.5%
Denys–Drash	90%
WAGR	30%–50%
Neurofibromatosis	<1%
Sotos	5%–20%
Frasier	Rare

Unfortunately, nephrectomy has been performed for benign disease due to false-positive screening.

BIOLOGY, GENETICS, AND BASIC RESEARCH

The role of genetic alterations in Wilms' tumor development has been intensely studied. Most Wilms' tumors arise from somatic mutations. These mutations occur in the tumor tissue only, and cannot be transmitted to the progeny of the affected individual. A much smaller percentage of Wilms' tumors (~10%) appear to be the result of germline mutations. Mutations arising in germ cells can be inherited (in some cases, they can also occur de novo). Patients with germ cell mutations are characterized by syndromic conditions, associated congenital anomalies, family history of tumor, and tumors that occur at an earlier age.[29] It was this group of patients that prompted Knudson to suggest that his "two-hit" theory, originally developed by studying children with retinoblastoma, might apply to Wilms' tumor.[30,31] The Knudson model predicts that two genetic events are required for tumor formation. Individuals with a genetic predisposition carry an initial lesion in their germline, either inherited from a parent or resulting from a de novo mutation. In these individuals, all body cells have been affected by the first event. Consequently, only one new event, in any one cell, is required for tumor development. By contrast, in individuals that are not genetically predisposed (sporadic cases), two relatively rare, independent events are required in the same cell. Subsequent genetic studies in a number of tumors have confirmed the Knudson model, demonstrating that the two postulated "genetic hits" constitute the inactivation of both alleles of a tumor suppressor gene.[32] The clearest example of tumorigenesis following the inactivation of both copies of a single tumor suppressor gene is the development of retinoblastoma following the inactivation of the retinoblastoma gene *RB1*.[33] By contrast, the two-hit theory, which was so elegantly confirmed in patients with retinoblastoma, has not stood the test of time in Wilms' tumor. Today it is recognized that the biologic pathways leading to the development of the majority of Wilms' tumors are complex and involve multiple genetic loci.[29,31]

The observation that patients with aniridia, genital anomalies, and mental retardation were at a high risk for Wilms' tumor led to cytogenetic studies that identified a heterozygous deletion at band 11p13 of chromosome 11. Using cloning techniques, the *WT1* gene was identified.[34–36] The chromosome 11p13 locus encompasses various genes, including *PAX6*, in which abnormalities are responsible for aniridia.[37] *WT1* is expressed in the normal-developing kidney and abnormally expressed in some Wilms' tumor specimens. *WT1* encodes a zinc finger transcription factor that is thought to function as a tumor suppressor gene. A partial list of genes that are targets of *WT1* regulation include *EGFR*, *PDGF*, *IGF*, *N-Myc*, *PAX2*, *MDR-1*, and *P-21*, all notable for their association with tumorgenesis.[38] *WT1* mutations have been shown to occur in human DNA from sporadic Wilms' tumor, as well as the germline of patients with a genetic predisposition to cancer.

Although at first *WT1* was considered a classic tumor suppressor gene (i.e., loss of both copies of the gene are required for tumor development), it is now clear that specific alterations in only one of the two *WT1* alleles may contribute to abnormal cell growth and associated genitourinary abnormalities.[32] Normal function of *WT1* is necessary for genitourinary development. Mutations at the *WT1* locus, particularly in males, may confer extensive genitourinary defects, most notably male pseudohermaphroditism.[14,39]

DDS, characterized by pseudohermaphroditism, renal failure, and Wilms' tumor, is the result of point mutations in the binding domain of *WT1*.[14] Interestingly, the kidneys and gonads of patients with DDS are heterozygous for germline mutations. The resulting phenotype is far more severe than that observed in children with a constitutional deletion of one *WT1* allele (i.e., WAGR patients) and suggests that the mutated protein can inhibit the activity of the wild-type protein, resulting in a "dominant negative" effect.[40] A spectrum of phenotypes can be demonstrated by patients with the DDS depending on the type of *WT1* mutation.[29] Interestingly, renal dysfunction, once thought to be limited to those with DDS, is now known to occur years after treatment in patients with WAGR syndrome as well.[16]

In addition to WAGR and Denys–Drash patients, germline mutations have also been found in familial Wilms' tumor. Families harboring a constitutional *WT1* abnormality constitute only a small percentage of the reported pedigrees.[41] Germline *WT1* mutation has been correlated with a predominantly stromal pathology.[42] Constitutional mutations of *WT1* are rarely seen in patients with nonsyndromic, unilateral tumors in the absence of genitourinary abnormalities.[42]

In summary, the majority of Wilms' tumors do not have genetic alterations at chromosome 11p13. Germline *WT1* mutations are associated with genitourinary anomalies. No increased risk of mutation is found in patients with nephrogenic rests (NRs), bilateral Wilms' tumor (BWT), or a family history of Wilms' tumor.[43]

A second potential Wilms' tumor gene, *WT2*, was identified on chromosome 11p15, based on the observation of loss of heterozygosity (LOH) at this site.[44,45] The actual gene responsible remains to be determined, although several candidates genes, such as insulin-like growth factor 2 (*IGF2*), have been proposed.[43] Like the association between *WT1* at chromosome 11p13 and WAGR syndrome, *WT2* has been linked to BWS.[44,46] BWS is an overgrowth disorder that is associated with a 5%–10% risk of Wilms' tumor. Eighty-five percent of BWS cases are sporadic, while 15% are familial.[44] Recent studies suggest that abnormal expression of *IGF2* and the growth repressor *CDKN1C* are involved in the pathophysiology of BWS.[44,47]

A minority of Wilms' tumors are explained by currently described chromosomal abnormalities. For example, *WT1* mutations are only seen in 5%–10% of patients. The search for other candidate genes has continued. In 2007, another putative Wilms' tumor gene was discovered, *WTX*. Located on the X chromosome, the gene was reported to be inactivated in about 33% of Wilms' tumors. Subsequent reports have suggested that the prevalence of *WTX* mutations is less than originally thought, and that these mutations may overlap with *WT1* mutations.[45] Functionally, *WTX* is thought to be a classic tumor suppressor gene impacting both the p53 pathway and β-catenin pathways.[48,49]

Other more recent significant discoveries have included the identification of LOH at chromosome 16q (present in 20% of all Wilms' tumors) or 1p (seen in 10% of tumors) as predictors of poor outcome in children with Wilms' tumor.[50–53] Accordingly, current protocols upstage patients with otherwise favorable histology (FH) if they possess LOH at these sites, hoping that more aggressive treatment will result in better outcomes for this subgroup.

Recently, utilizing comparative expressed sequence hybridization (CESH), investigators have discovered that abnormalities in expression of the long arm of chromosome 1q were associated with relapse and worse outcome in a subset of patients with FH Wilms'.[54] A study from the Italian cooperative looked at 77 patients and found that copy number gains at chromosome region 1q21.1–q31.3 were significantly associated with relapse, confirming earlier findings. Therefore, chromosome 1q abnormalities have become a target of interest for staging and risk stratification by the Children's Oncology Group's (COG) Renal Tumor Committee.

Alterations of the *p53* tumor suppressor gene located on chromosome 17p have been noted in approximately 75% of anaplastic tumors, suggesting an important role in the development of anaplasia.[55,56] By acting as a downregulator of cell proliferation and a positive regulator of cellular apoptosis, *p53* is known to play a significant role in tumor suppression. Malkin et al. suggested that the absence of *p53* is an indicator of advanced disease in Wilms' tumor, regardless of the presence of anaplastic changes.[57] Comparative genomic hybridization studies and immunohistochemical analysis have confirmed an association between chromosome 17p (*p53*) abnormalities and tumor aggressiveness.[58,59]

HISTOPATHOLOGY

Wilms' tumor is an embryonal tumor that grows to compress the adjacent normal renal parenchyma, forming a pseudocapsule composed of condensed, atrophic renal tissue. This intrarenal pseudocapsule is an important distinguishing feature. Most tumors are soft and friable, with necrotic or hemorrhagic areas frequently noted. This consistency increases the chance of intraoperative tumor rupture, which can predispose to local tumor recurrence.

Wilms' tumor is characterized by histologic diversity. Classically, a triphasic pattern is seen that includes varying proportions of three cell types: blastemal, stromal, and epithelial (Figure 32.2). Some tumors may only consist of biphasic or even monomorphous patterns. These varied components respond differently to treatment, which can impact outcome.[60] In addition to demonstrating cell types found in a normal-developing kidney, Wilms' tumor often contains tissues such as skeletal muscle, cartilage, and squamous epithelium. These heterotopic cell types probably reflect the primitive developmental potential of the metanephric blastema not seen in

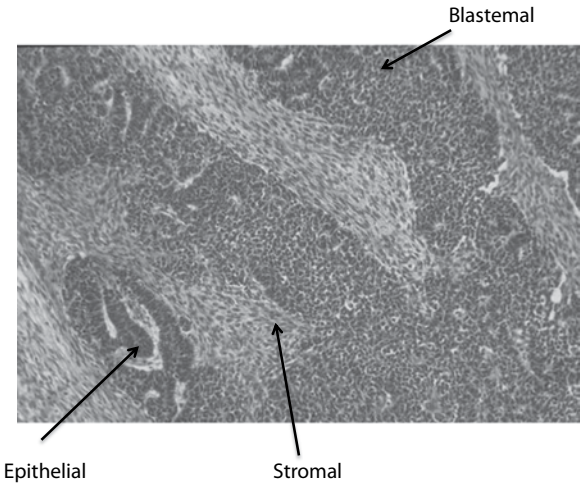

FIGURE 32.2 Triphasic Wilms' tumor.

normal nephrogenesis. Most Wilms' tumors are typically unicentric, but up to 12% may be multicentric unilateral tumors.[9] Extrarenal locations are rare and are thought to arise from displaced metanephric elements or mesonephric remnants.[61,62]

Wilms' tumor is classified as having FH when epithelial, blastemal, or stromal elements are found in the absence of anaplasia.[63] Tumors with large nuclei, abnormal mitotic figures, and hyperchromasia are anaplastic, or *unfavorable*, and are associated with increased rates of relapse and death (Figure 32.3).[63] These unfavorable features were found in approximately 10% of patients, but accounted for almost half of the tumor deaths in early NWTS studies.[64] Anaplasia is rare in the first 2 years of life, but the incidence increases with age at presentation.[65] It is primarily associated with resistance to chemotherapy. A similar incidence of anaplasia has been observed in NWTS studies and in the International Society of Pediatric Oncology (SIOP) study (5.3%).[66] Anaplasia is further classified as focal or diffuse. Focal anaplasia requires that cells with anaplastic nuclear changes be confined to sharply restricted foci within the primary tumor.[67] Diffuse anaplasia is diagnosed when anaplasia is present in more than one portion of the tumor or is found in any extrarenal or metastatic site; it is a harbinger of poor prognosis. When the anaplastic component is completely removed, the outcome is generally excellent.[68] This supports the contention that anaplasia is an indicator of chemoresistance, not inherent aggressiveness of the tumor.

Clear cell sarcoma of the kidney (CCSK) and rhabdoid tumor of the kidney (RTK) were previously grouped as unfavorable histology Wilms' tumors. They are now recognized as separate malignant entities.[69–71]

NRs represent the abnormal persistence into postnatal life of embryonal cells that can involute, sclerose, disappear, or produce a malignancy (Figure 32.4).[72] NRs are seen in 35% of patients with a unilateral Wilms' tumor and nearly 100% with bilateral Wilms'. NRs have been detected in up to 1% of kidneys in infants on postmortem examination; most of these rests undergo involution.[73] It is estimated that less than 1% of NRs will eventually become Wilms' tumor.[74] Two distinct categories of NRs exist, based on the position of these lesions within the kidney. Perilobar nephrogenic rests (PLNRs) are confined to the periphery of the renal lobe, likely developing late. They are seen in 1% of infant autopsies. Intralobar nephrogenic rests (ILNRs) occur within the renal lobe or other sites, including the renal sinus and collecting system. They are associated with an early renal developmental event and are seen less frequently on infant postmortem exam (0.1%). There are biologic differences distinguishing PLNR from ILNR (Table 32.2). ILNR can become cystic and be indistinguishable from renal dysplasia; they are more commonly associated with *WT1* mutations, DDS, and WAGR syndrome. PLNRs are associated with BWS and hemihypertrophy and demonstrate 11p15 abnormalities.

Hyperplastic NRs can produce a renal mass easily mistaken for a small Wilms' tumor.[73] Biopsy of a hyperplastic rest is of little value in distinguishing this lesion from a Wilms' tumor unless the interface between the rest and the normal kidney is sampled.

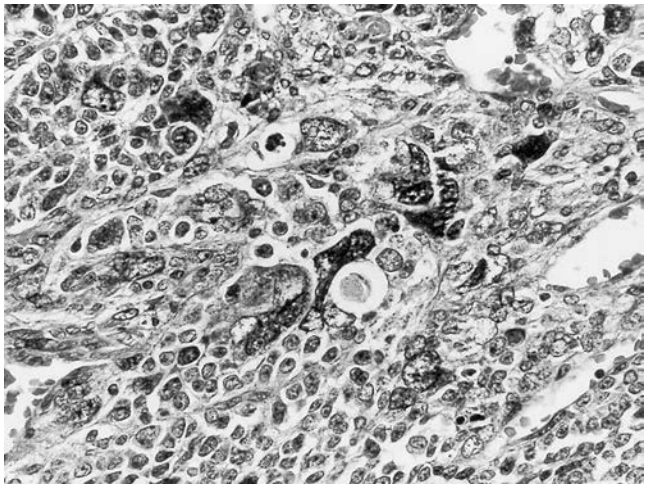

FIGURE 32.3 Anaplastic Wilms' demonstrating large irregulary shaped nuclei.

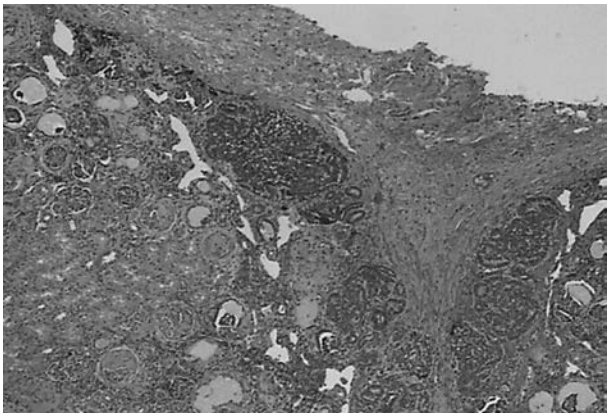

FIGURE 32.4 Perilobar nephrogenic rest composed of blastemal cells just beneath the renal capsule (hematoxylin and eosin, ×40).

TABLE 32.2 Nephrogenic rests and their known associations

	ILNR	*PLNR*
Associated syndromes	WAGR Denys–Drash	BWS, hemihypertrophy Perlman
Median age of Wilms' Tumor development (months)	23	36
Wilms' tumor histology	Stroma/ blastema predominant	Blastemal/epithelial predominant

Wilms' tumor will have a pseudocapsule at the interface, with the normal parenchyma compressing the normal elements; this will be absent in hyperplastic rests.

On imaging, Wilms' tumor will have a spherical shape, whereas hyperplastic rests will be more elliptical or lenticular in shape. Magnetic resonance imaging (MRI) may be of some value in distinguishing between the two lesions.[75]

The presence of multiple or diffuse NRs will lead to the diagnosis of nephroblastomatosis.[76] Nephroblastomatosis can be subclassified according to the rest categories present. Diffuse hyperplastic perilobar nephrogenic rest (DHPLNR) is a particular category in which the majority of the cortical surface of one or both kidneys is composed of hyperplastic NRs. The entire nephrogenic zone is involved, with a thick rind capping the entire kidney (Figure 32.5). These patients are prone to Wilms' tumor development, and bilateral lesions are common. Perlman et al. have reviewed 52 cases of DHPLNRs reported to the NWTS pathology center.[77] Wilms' tumor developed in 23 patients at a median age of 30 months. Of children receiving adjuvant therapy at diagnosis, 52% (17/33) developed a Wilms' tumor. Multiple rests in one kidney usually implies that NRs are present in the other kidney.[73] Children younger than 12 months diagnosed with Wilms' tumor who have NRs have a markedly increased risk of developing contralateral disease.[78] They need regular imaging surveillance to detect contralateral recurrence.[79] The occurrence of metachronous Wilms' tumor in patients previously treated with conventional chemotherapeutic regimens suggests that NRs are not always eradicated.

PRESENTATION, PREOPERATIVE EVALUATION, AND STAGING

Most children with Wilms' tumor present with an asymptomatic abdominal mass. Other signs and symptoms at diagnosis are abdominal pain, gross hematuria, and fever. Occasionally, a child will present with an acute abdomen due to tumor rupture and associated hemorrhage into the peritoneal cavity. Other atypical presentations may result from compression or invasion of adjacent structures (e.g., extension of the tumor into the renal vein and inferior vena cava [IVC]). Varicocele due to gonadal vein obstruction, hepatomegaly due to hepatic vein obstruction, ascites, and congestive heart failure are found in fewer than 10% of patients with intracaval or atrial tumor extension.[80]

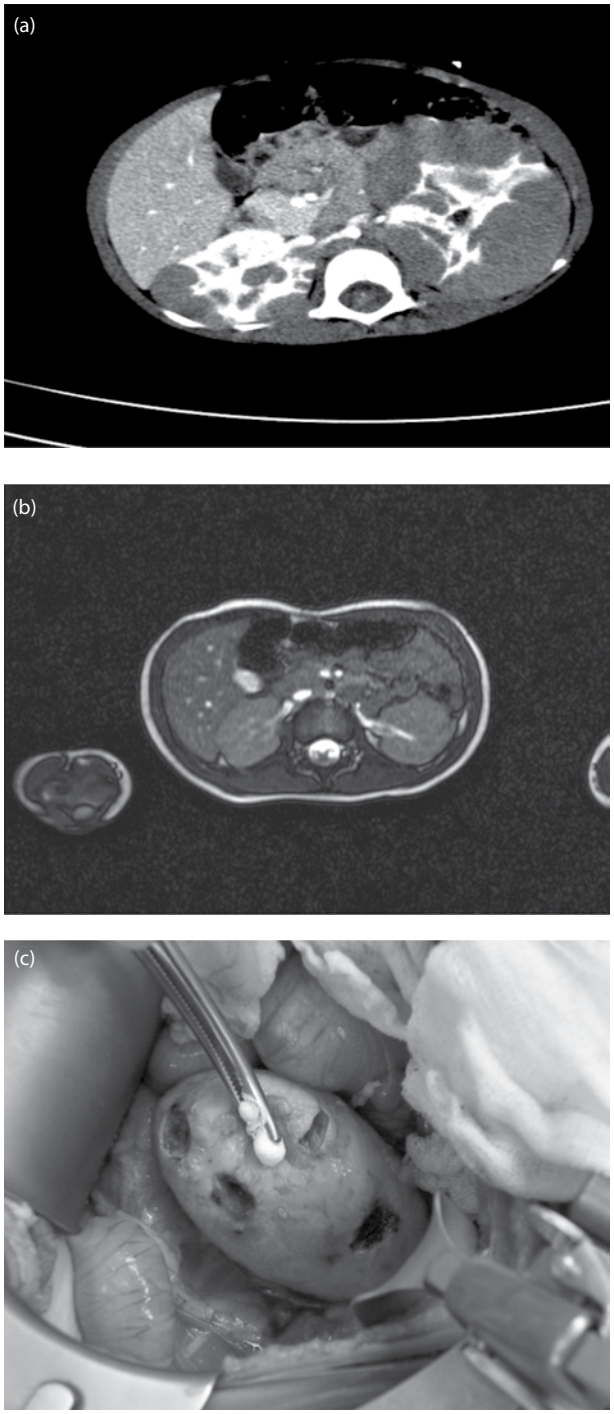

FIGURE 32.5 (a) Pretreatment MRI of bilateral DHPLNR. (b) Postchemotherapy MRI of same patient. (c) Same patient at time of intraoperative biopsy. Note the characteristic "rind" on the surface of the kidney.

Hypertension is present in 25% of cases and has been attributed to elevated plasma renin levels.[81] During the physical examination, it is important to note any physical findings of associated Wilms' tumor syndromes, such as aniridia, hemihypertrophy, and genitourinary anomalies. The preoperative evaluation can generally be completed in 48 hours. Emergent operation is never necessary unless there is evidence of active bleeding or tumor rupture (even

in these rare circumstances, stabilization, volume resuscitation, and blood product replacement should be the first consideration). Laboratory evaluation should include a complete peripheral blood count, platelet count, renal function tests, liver function tests, serum calcium, and urinalysis. Elevation of the serum calcium can occur in children with congenital mesoblastic nephroma (CMN) and RTK. Acquired von Willebrand's disease has been found in 8% of newly diagnosed Wilms' tumor patients.[82]

The preoperative imaging evaluation of children with a solid abdominal mass has evolved over the years. The first study obtained is a renal ultrasound, which can determine if the mass is predominantly solid or cystic. In high-risk children with congenital anomalies or familial syndromes, sonogram may be repeated every 3–4 months for screening. Contrast-enhanced computed tomography (CT) or MRI of the abdomen is obtained next. All the solid renal tumors of childhood have similar radiographic features. However, defining the exact histology is not as important as establishing that there is a solid renal tumor present, which will help the surgeon plan for an operation. Another important role of imaging studies is to establish the presence of a functioning contralateral kidney prior to nephrectomy.[83] More recently, as more nephron-sparing techniques are being adopted, clearly defining local anatomic relationships has become critical for preoperative planning. The radiologist should exclude intracaval tumor extension, which occurs in 4% of Wilms' tumor patients (Figure 32.6).[80] This can usually be excluded on ultrasound, but MRI is the study of choice if extension of tumor into the IVC cannot be excluded by ultrasound.[84]

There is some controversy regarding the utility of preoperative imaging for tumor staging.[79,85,86] Accurate staging of children with Wilms' tumors is essential to define tumor extent prior to initiating treatment, as outcome is highly correlated with stage.[87] However, the staging system used in prior NWTS studies and current COG studies relies on surgical findings and pathologic examination (Table 32.3). Local tumor burden (e.g., regional lymph node involvement) determines the intensity of the chemotherapy regimen and whether a child receives abdominal irradiation. Preoperative CT can certainly identify regional adenopathy, but enlarged benign retroperitoneal lymph nodes are common in children. Correlation between pathologic findings and lymph node evaluation at surgical exploration in Wilms' tumor patients has found high false-positive and false-negative error rates.[88] Detection of extrarenal tumor extension into the perirenal fat and into adjacent structures is also problematic. Most children identified as having possible invasion of the liver on CT are found at the time of surgical exploration to have hepatic compression, rather than hepatic invasion.[89] Therefore, determination of inoperability must be made at surgical exploration. Nonopacification of the kidney on CT may result from tumor obstruction of the collecting system, complete replacement of the renal parenchyma with neoplasm, or intravascular tumor extension.[80,90]

Traditionally, plain chest radiographs were obtained to determine whether pulmonary metastases were present. However, over time most North American institutions began obtaining CT of the chest in the initial evaluation of children with Wilms' tumor. This can detect small lesions missed on chest x-ray (CXR), although the management of such lesions is debated.[91,92] A recent report from COG evaluated event-free survival (EFS) and overall survival (OS) for patients with CT-only pulmonary lesions.[93] Patients with FH and isolated lung lesions found on CXR or chest

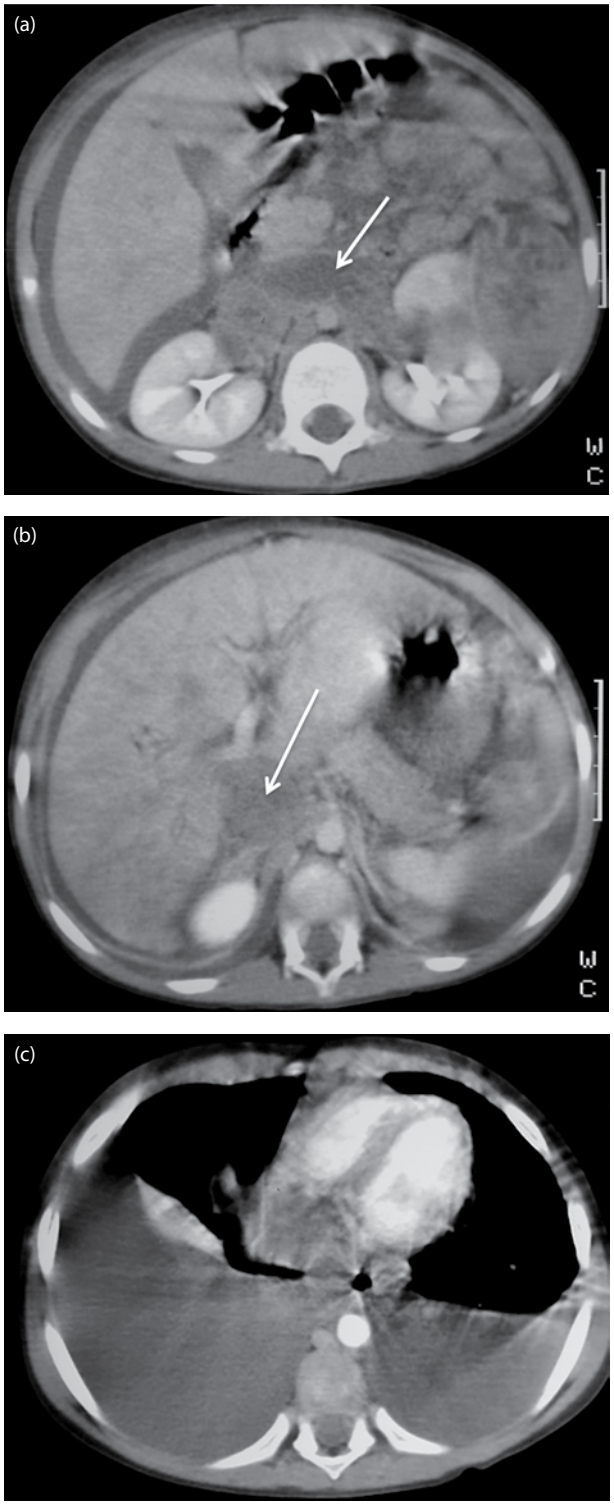

FIGURE 32.6 Renal vein and IVC involvement in a 5-year-old male who presented with shortness of breath and bilateral leg swelling. (a) Left-sided tumor with left renal vein thrombus (arrow). (b) IVC thrombus (arrow). (c) Atrial thrombus.

TABLE 32.3 COG staging system for Wilms' tumor

Stage	Findings
I	The tumor is limited to the kidney and was completely excised. The renal capsule has an intact outer surface. The tumor was not ruptured or biopsied prior to removal (fine-needle aspiration biopsies are excluded from this restriction). The vessels of the renal sinus are not involved. There is no evidence of tumor at or beyond the margins of resection.
II	The tumor extends beyond the kidney, but was completely excised. There may be regional extension of tumor (i.e., penetration of the renal capsule or extensive invasion of the renal sinus). The blood vessels outside the renal parenchyma, including those of the renal sinus, may contain tumor. The tumor was biopsied (except for fine-needle aspiration), or there was spillage of tumor before or during surgery that is confined to the flank, and does not involve the peritoneal surface. There must be no evidence of tumor at or beyond the margins of resection.
III	Residual nonhematogenous tumor is present, and confined to the abdomen. Any one of the following may occur: (1) Lymph nodes within the abdomen or pelvis are found to be involved by tumor (renal hilar, para-aortic, or beyond). (Lymph node involvement in the thorax or other extra-abdominal sites would be a criterion for stage IV.) (2) The tumor has penetrated through the peritoneal surface. (3) Tumor implants are found on the peritoneal surface. (4) Gross or microscopic tumor remains postoperatively (e.g., tumor cells are found at the margin of surgical resection on microscopic examination). (5) The tumor is not completely resectable because of local infiltration into vital structures. (6) Tumor spill not confined to the flank occurred either before or during surgery.
IV	Hematogenous metastases (lung, liver, bone, brain, etc.), or lymph node metastases outside the abdominopelvic region are present.
V	Bilateral renal involvement is present at diagnosis. An attempt should be made to stage each side according to the above criteria on the basis of the extent of disease prior to biopsy or treatment.

CT in NWTS-4 and NWTS-5 were compared with those with CT-only pulmonary findings. Patients with CT-only pulmonary lesions experienced improved EFS if given doxorubicin (DOX) in addition to dactinomycin (AMD) and vincristine (VCR), regardless of whether pulmonary radiation was given. In Europe, where preoperative chest CT is not routine, investigators of SIOP 2001 sought to determine if patients with CT-only pulmonary nodules experience worse outcomes than those patients with localized disease.[94] They found that EFS and OS was worse if pulmonary nodules were seen on CT than if patients had localized disease, but superior to patients who had metastatic disease. Additional imaging studies are helpful under specific conditions. For example, a radionuclide bone scan and x-ray skeletal survey should be obtained postoperatively on all children with CCSK.[95] Brain imaging, using MRI or CT, should be performed.

There is an emerging role for positron emission tomography/computed tomography (PET-CT) in the diagnosis, evaluation, and monitoring of Wilms' tumor.[96,97] A multi-institutional study of 27 patients who had PET-CT performed for suspected disease relapse and progression, and for monitoring of therapy, found that PET-CT was useful for evaluating Wilms' tumor given its metabolic activity.[96] However, pulmonary nodules of <1 cm were not well visualized in this study. A smaller study specifically evaluating the role of fluorodeoxyglucose ($F^{18}FDG$) PET-CT after preoperative chemotherapy found that active Wilms' tumor was still avid, and that higher uptake values were observed in histologically high-risk disease.[97]

The NWTS had previously recommended formal exploration of the contralateral kidney in all children undergoing nephrectomy for presumed unilateral Wilms' tumor. This has been considered necessary to identify lesions that might be missed on preoperative imaging. If lesions are identified intraoperatively, biopsy alone of the lesions is advised and definitive surgical resection is deferred for both kidneys. Review of NWTS-4 patients with BWT found that 7% of lesions were missed on preoperative imaging studies.[98] Most lesions were managed with biopsy alone, yet extended follow-up of the children has not demonstrated any relapses.[99] The majority of these children had nephrectomy of the more involved kidney at diagnosis before exploration of the contralateral kidney. This was also noted in a recent report of NWTS-5 patients.[100] The conclusion of the latest report was that routine exploration is not necessary, provided that preoperative imaging with thin slices on multidetector helical CT scanners or MRI is performed.[99]

SURGERY

The surgeon has an important role in the management of a child with Wilms' tumor. Tumor necrosis, friability, and hemorrhage make these usually large lesions more prone to rupture, increasing morbidity or causing upstaging. Careful removal of the tumor without rupture or spill is essential to decrease the risk of local abdominal relapse.[101] In a retrospective review of 515 patients with favorable histology in NWTS-3 and NWTS-4 who had tumor spillage, 7.3% were found to have recurrent disease.[102] Those who were treated with 10–20 Gy of radiation had lower recurrence rates. Barber et al. evaluated potential preoperative risk factors for intraoperative tumor spillage in a retrospective review of 67 patients from 2000 to 2008.[103] They examined patient age, sex, body weight, tumor capsular thickness, and stage and found the only significant correlation was preoperative tumor volume of >1000 cc. Complete tumor resection also improved patient survival.

Another critical surgical objective is determining tumor stage. A transperitoneal approach is preferred to exclude tumor extension, metastases, or peritoneal seeding. Exploration of the contralateral kidney is no longer mandated prior to nephrectomy if the preoperative CT or MRI demonstrates a normal kidney. If exploration is needed, the colon is reflected and Gerota's fascia opened so that the kidney can be inspected on all surfaces. Any abnormalities of the kidney should be biopsied to exclude Wilms' tumor or NRs. Palpation of the renal vein and IVC should be performed to exclude intravascular tumor

extension prior to vessel ligation. A radical nephrectomy with partial ureterectomy is performed. While a formal lymph node dissection is not required, lymph node sampling is an integral step during surgery for Wilms' tumor.[88] Lymph node metastases (stage III) have an adverse outcome on survival. A recent study looking at patients with stage III disease found that those with lymph node–positive disease faired worse than those who did not have lymph node involvement with 4-year disease-free survival of 73% versus 98%, respectively.[104] The negative impact of LN involvement was further delineated in a study from NWTG-4 and NWTG-5, which showed that positive nodes had worse 5-year EFS, especially in the setting of anaplastic histology.[105] This study also found that the percentage of positive nodes increased as the size of the surgical nodal packet increased. Failure to sample lymph nodes has been identified as a risk factor for local relapse in stage I patients, suggesting that inadequate staging can have significant consequences.[106]

In patients with metastatic disease (most commonly pulmonary metastases), there may be a role for metastasectomy, especially if there is a good response to chemotherapy. In patients who do not respond or experience disease progression, surgical resection metastectomy is unlikely to be helpful.[107,108]

Surgery is not without morbidity and may result in both acute and late complications. A review of NWTS-4 patients undergoing primary nephrectomy found an 11% incidence of surgical complications.[83] The most common complications were hemorrhage and small bowel obstruction. Risk factors associated with increased surgical complications are higher local tumor stage, intravascular extension, en bloc resection of other visceral organs, and incorrect preoperative diagnosis.[83]

TREATMENT AND OUTCOME

The development of effective systemic chemotherapy in the 1960s rapidly changed the outcome and approach to treatment of Wilms' tumor.[109] Randomized trials have been conducted by NWTS, now the COG, as well as SIOP, and the United Kingdom Children's Cancer Study Group (UKCCSG) to determine the appropriate role of available therapeutic modalities in an effort to improve clinical outcomes while minimizing potential side effects and late sequelae. Patients are stratified into different treatment groups based on histopathology and the extent of disease. Despite markedly different initial treatment approaches, outcomes between the major international study groups are quite similar.

National Wilms Tumor Study Group and Children's Oncology Group

The NWTS merged with three other groups in 2000 to form the COG.[110] Initial management of Wilms' tumor has always consisted of up-front nephrectomy, with subsequent management strategy based on histology, surgical staging, and radiologic results. The first three NWTS studies, NWTS-1 (1969–1973), NWTS-2 (1974–1978), and NWTS-3 (1979–1986), showed that postoperative local irradiation was unnecessary for stage I and II FH patients when VCR and AMD were used in combination.[111,112] The addition of DOX to VCR and AMD, in conjunction with radiotherapy, improved EFS for patients with stage III/IV disease. In this series of studies, the staging system was refined as knowledge about histology and other prognostic factors, such as lymph node status, was gained.[87,111–113] The intensity of therapy for the majority of low-risk patients was able to be successfully decreased. This was especially beneficial in limiting the use of the cardiotoxic drug DOX, while still successfully treating patients. There was no statistically significant improvement in survival when cyclophosphamide was added to the three-drug regimen in NWTS-3.

The NWTS-4 (1986–1994) utilized "pulse-intensive" chemotherapy regimens, employing single doses of AMD and DOX, in attempts to limit both treatment toxicity and cost. Pulse-intensive regimens utilized simultaneous administration of agents at less frequent intervals and limited duration to decrease the number of clinic visits, and hence the cost of cancer treatment. NWTS-4 demonstrated that while the administered drug dose–intensity was greater on pulse-intensive regimens, these regimens produce less hematologic toxicity than the standard regimens.[114] Patients treated with pulse-intensive regimens achieved equivalent survival compared with those treated with standard chemotherapy regimens.[100] Treatment with 6 months of chemotherapy was noted to be as effective as treatment with 15 months.

Children with anaplastic Wilms' tumors were randomized in NWTS-3 and NWTS-4 to receive VCR, AMD, and DOX, or those three drugs with the addition of cyclophosphamide. The results were analyzed after the tumors were reclassified using the criteria of Faria et al.[67] There was no difference in outcome between the regimens for children with focal anaplasia, who had a prognosis similar to that for FH patients.[115] For stage II–IV diffuse anaplasia, the addition of cyclophosphamide to the three-drug regimen improved the 4-year relapse-free survival (RFS) rate (27.2% vs. 54.8%).

NWTS-5 (1995–2002) was a single-arm therapeutic trial without any randomization for therapy. Prospective collection of information regarding biologic features of the tumors was part of this study. As a result, collection of banked tumor specimens is available to evaluate new prognostic factors that may be identified in the future. Most importantly, clinical outcome is available for these patient-banked specimens. Based on the results of patients with anaplastic disease in NWTS-3 and NWTS-4, NWTS-5 incorporated cyclophosphamide into the treatment plan for patients with stage II–IV diffuse anaplastic Wilms' tumor.

A central goal of the study was to verify the preliminary finding that LOH for chromosomes 16q and 1p identified patients at increased risk for relapse and death.[51] Among patients with stage I and II FH tumors, the relative risk (RR) of relapse and death was increased for LOH 1p only (RR = 2.2 for relapse; RR = 4.0 for death), for LOH 16q only (RR = 1.9 and RR = 1.4), and for LOH for both regions (RR = 2.9 and RR 4.3) in comparison with patients lacking LOH at either locus.[52] The risks of relapse and death for patients with stage III and IV FH

tumors were increased only when LOH occurred in both regions (RR = 2.4 and RR = 2.7). As a result, LOH for these chromosomal regions can now be used as an independent prognostic factor, together with disease stage, to target intensity of treatment.

A unique aspect of the NWTS-5 trial was that a select group of patients of <2 years of age with stage I FH tumors, weighing <550 g, were managed with surgery alone. This was based on a prior observation of favorable outcomes in a small number of such patients in which postoperative adjuvant therapy had been omitted.[116] A long-term analysis of this cohort revealed a much greater than anticipated salvage rate for the chemotherapy-naive patients who relapsed. Overall, survival between those treated with surgery or chemotherapy were not statistically different despite a higher rate of relapse in those treated with surgery alone (84%) versus those treated with chemotherapy (97%).[117] The current COG protocol, AREN0532, will observe this very low-risk group after surgery alone. Further analysis of this population investigating the effects of body weight and body mass index (BMI) on EFS found no relationship with these factors even when stratified by risk group or age.[118]

All protocols today occur under the auspices of the COG Renal Tumor Committee trials. The current full clinical trials are available through an individual institution's principal investigator. (Table 32.4 shows the current protocol, and Table 32.5 shows the most recently completed studies with survival.) Some highlights from these studies, which include AREN0533, AREN0321, and AREN0534, follow. AREN0533 will investigate patients with stage III or IV FH Wilms' tumor with pulmonary metastases. Patients with pulmonary nodules will be treated with VCR, AMD, and DOX for 6 weeks in the hopes of limiting or eliminating the need for pulmonary irradiation. Chest CT that reveals disappearance of nodules will result in continuation on the three-drug regimen, while incomplete response will be treated with radiation therapy (XRT) in conjunction with AMD, DOX, cyclophosphamide, and etoposide.

Patients with anaplastic Wilms' tumor are being evaluated under COG protocol AREN0321, which hopes to improve clinical outcomes in this high-risk group. Alternating regimens of VCR, etoposide, carboplatin with VCR, DOX, and cyclophosphamide are being given.

Finally, COG has recently opened study protocol AREN0534, which allows for nephron-sparing surgery (NSS) in children with tumor predisposition syndromes and unilateral Wilms' tumor, given the increased risk for renal failure or future bilateral disease.[119,120] The goal is to maximize future renal function by sparing the noncancerous renal parenchyma. On current protocols of COG, the importance of lymph node sampling is stressed, and *all* children with tumor rupture are treated as stage III with more intensive therapy.[110]

TABLE 32.4 Summary of current COG treatment protocol recommendations

Renal tumor	Protocol
FH Wilms' (very low risk/standard risk)	AREN0532
FH Wilms' (standard/higher risk)	AREN0533
Bilateral	AREN0534
Anaplastic Wilms' Clear cell sarcoma Malignant rhabdoid Renal cell carcinoma	AREN0321
Other (low risk)	Follow-on AREN03B2

International Society of Pediatric Oncology

The clinical protocols conducted by SIOP differ from the North American protocols in that therapy is given before surgery, with the goal of reducing the risk of intraoperative rupture or spill by pretreating with chemotherapy.[121] It is also postulated that the neoadjuvant therapy will treat micrometastases, leading to a more favorable stage distribution at the time of surgery.

The first two SIOP studies answered questions with regard to the use of prenephrectomy XRT.[121] The third SIOP study showed that 4 weeks of AMD and VCR was as effective as prenephrectomy XRT in avoiding surgical tumor rupture and increasing the proportion of patients with low-stage disease.[122] SIOP-6, the fourth SIOP study on Wilms' tumor, demonstrated that patients with postnephrectomy stage I disease can safely be treated with 18 weeks of AMD and VCR.[123] Those patients with stage II lymph node–negative disease, however, were shown to have a higher rate of relapse if postoperative abdominal irradiation was omitted. It was concluded that these children require more intensive postnephrectomy chemotherapy, including the use of an anthracycline.[123] Finally, SIOP-6 confirmed the need for a three-drug chemotherapy regimen following nephrectomy for those with more advanced stage disease (i.e., stage II lymph node positive and stage III). The fifth SIOP Wilms' tumor trial, SIOP-9 (1987–1991), evaluated the duration of prenephrectomy chemotherapy. The number of postchemotherapy stage I patients was similar after either 4 or 8 weeks of therapy (64% vs. 62%), and the 2-year EFS was equivalent.[124] Also, there was no significant additional tumor shrinkage benefit after 4 weeks of preoperative chemotherapy.[124] Children with stage II N0 disease were treated with VCR, AMD, and an anthracycline for 27 weeks without XRT, whereas children with stage II N1 and III disease were given the same regimen and abdominal irradiation. The 2-year EFS and OS for stage II N0 was 84% and 88%, and for stages IINI and III it was 71% and 85%, respectively. There were 59 children with stage I–IV tumors who had complete tumor necrosis induced by chemotherapy, and 98% of these children had no evidence of disease at 5 years.[125]

SIOP 93–01 (1993–1999) evaluated a reduction in postoperative therapy for patients with stage I intermediate-risk anaplastic Wilms' tumor.[126] Patients were randomized to receive either 4 or 18 weeks of postoperative chemotherapy with AMD and VCR. Two-year EFS was 91.4% after 4 weeks and 88.8% after 18 weeks of therapy, demonstrating that survival can be maintained while shortening the duration of postnephrectomy therapy. Further retrospective analysis of this study population found that initial tumor volume does impact the risk of finding positive nodes at the time of surgery, while the

TABLE 32.5 Recent completed Wilms' tumor treatment trials and survival

Stage	Histology	Treatment	4-year survival
I	FH of <24 months, tumor weight of <550 g	Surgery only (as part of a clinical trial)	98% OS, 85% RFS
	FH of >24 months, tumor weight of >550 g	Nephrectomy + lymph node sampling followed by regimen EE-4A	98% OS, 94% RFS
	DA	Nephrectomy + lymph node sampling followed by regimen EE-4A and XRT	79% OS, 68% EFS
II	FH	Nephrectomy + lymph node sampling followed by regimen EE-4A	98% OS, 86% RFS
	FA	Nephrectomy + lymph node sampling followed by abdominal XRT and regimen DD-4A	80% OS, 80% EFS
	DA	Nephrectomy + lymph node sampling followed by abdominal XRT and regimen I	82% OS, 83% EFS
III	FH	Nephrectomy + lymph node sampling followed by abdominal XRT and regimen DD-4A	94% OS, 87% RFS
	FA	Nephrectomy + lymph node sampling followed by abdominal XRT and regimen DD-4A	100% OS, 88% RFS
	FA (preoperative)	Preoperative treatment with regimen DD-4A followed by nephrectomy + lymph node sampling and abdominal XRT	71% OS, 71% RFS
	DA	Immediate nephrectomy + lymph node sampling followed by abdominal XRT and regimen I	67% OS, 75% EFS
	DA (preoperative)	Preoperative treatment with regimen I followed by nephrectomy + lymph node sampling and abdominal XRT	53% OS, 46% EFS
IV	FH	Nephrectomy + lymph node sampling, followed by abdominal XRT, bilateral pulmonary XRT, and regimen DD-4A	86% OS, 76% RFS
	FA	Nephrectomy + lymph node sampling, followed by abdominal XRT, bilateral pulmonary XRT, and regimen DD-4A	72% OS, 61% EFS
	DA	Immediate nephrectomy + lymph node sampling followed by abdominal XRT, whole-lung XRT, and regimen I	33% OS, 33% EFS
	DA (preoperative)	Preoperative treatment with regimen I followed by nephrectomy + lymph node sampling, followed by abdominal XRT and whole-lung XRT	44% OS, 31% EFS
V	FH	Bilateral renal biopsies and staging of each kidney followed by preoperative treatment with regimen EE-4A (if disease in both kidneys stage II or less) or regimen DD-4A (if disease in both kidneys greater than stage II), followed by second-look surgery and possibly more chemotherapy and/or XRT	87% OS, 65% EFS
	FA	Bilateral renal biopsies and staging of each kidney followed by preoperative treatment with regimen I, followed by second-look surgery and possibly more chemotherapy and/or XRT	88% OS, 76% EFS
	DA	Bilateral renal biopsies and staging of each kidney followed by preoperative treatment with regimen I, followed by second-look surgery and possibly more chemotherapy and/or XRT	42% OS, 25% EFS

Abbreviations: FA, focal anaplasia; DA, diffuse anaplasia.

response to neoadjuvant chemotherapy, measured as a decrease in tumor volume, did not predict lymph node status at surgery.[127] Thus, tumor shrinkage with preoperative chemotherapy may not be reliably used as a criterion to indicate which patients will require adjuvant radiation. A subgroup analysis of those patients with stage II and III nonanaplastic Wilms' tumor aimed at determining factors associated with prognosis found that stage, tumor volume, and blastemal type histology are the most important prognostic factors.

The current SIOP 2001 study is evaluating risk stratification of patients for treatment based on postchemotherapy histologic findings.[60] SIOP now classifies tumors with complete necrosis as low risk and tumors with diffuse anaplasia and blastemal predominance after chemotherapy as high risk. Intermediate risk includes all other post-chemotherapy histologies.

United Kingdom Children's Cancer Study Group

The UKCCSG has also conducted trials of children with Wilms' tumor.[128–130] The UK approach is to biopsy the tumor prior to treatment. They have noted a 12% incidence of non-Wilms' tumor in patients with the typical features of Wilms' tumor on imaging study.[131] One percent of lesions were benign on biopsy, similar to rates found in SIOP studies.[124] The UKW1 and UKW2 studies evaluated the

single-agent VCR for treatment of stage I FH tumors.[129,132] The OS of 96% compares well with two-drug chemotherapy, but age of >4 years was considered an adverse prognostic factor.[130] The UKCCSG (1986–2001) treated stage I patients up to 16 years of age with immediate tumor resection and 10 weekly doses of VCR alone.[130] The 4-year EFS and OS for patients of >2–4 years old and >4 years were lower using single-agent VCR than those experienced by COG in NWTS-5, which used VCR with AMD.

Preoperative Chemotherapy versus Immediate Nephrectomy

A fundamentally different philosophical approach exists between the pediatric cancer cooperative groups. The NWTS and COG trials have relied on surgical and pathologic staging following up-front nephrectomy. Originally, this was driven by concern that staging information obtained following prenephrectomy chemotherapy may inadequately define the risk of relapse.[123] The value of this approach has been reinforced by the identification of molecular markers predictive of more aggressive disease.[52] On the other hand, preoperative treatment can produce dramatic reduction in the size of the primary tumor, decreasing the morbidity of surgery (Figure 32.7).[133] The specific advantages of this approach include a reduction in intraoperative tumor spill.[128] The SIOP and UK approach continue to use the histologic response of the tumor to preoperative therapy to decide postoperative treatment.

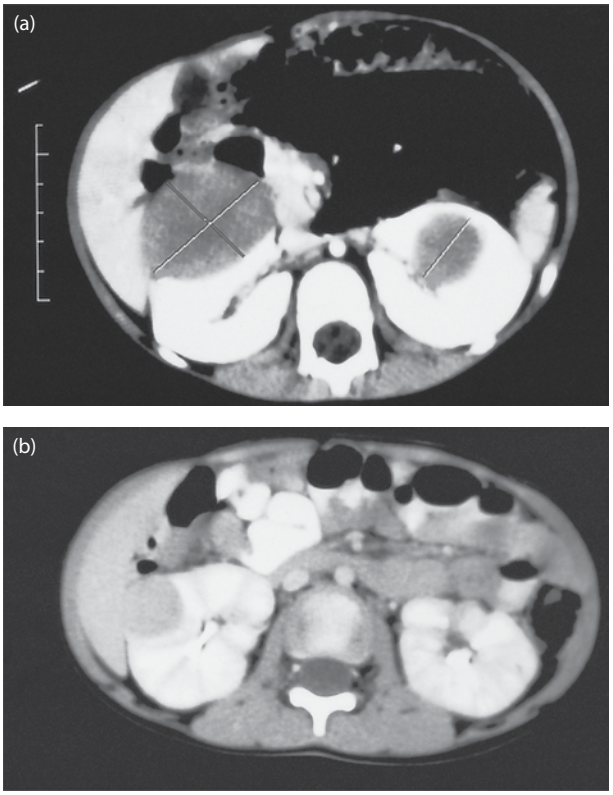

FIGURE 32.7 Computed tomography scan demonstrating bilateral Wilms' tumor: (a) before chemotherapy; (b) 6 weeks after chemotherapy, showing a marked reduction in the size of the masses.

In a departure from the standard up-front surgery approach, the current COG protocol for bilateral tumors, AREN0534, recommends up-front chemotherapy without pretreatment biopsy. Patients eligible for this protocol include those with bilateral tumors, those with tumors in a solitary kidney, and those with predisposing conditions.[134,135]

Both the COG and SIOP tumor staging systems are designed to stratify patients into low-risk and high-risk groups. The goal is to select out high-risk patients for more intense therapy, while minimizing treatment and thus morbidity for low-risk patients. Both groups want to reduce the number of patients receiving irradiation and DOX to avoid the late effects of treatment (see below). Currently, approximately 50% of SIOP patients are treated with an anthracycline and 17% undergo irradiation, whereas approximately 35% of NWTS and COG patients have historically received both therapies.[136–139]

Other indications for up-front chemotherapy in COG protocols include tumors inoperable at surgical exploration, and tumor extension into the IVC above the hepatic veins.[140–143] The latter two conditions are associated with an increased risk for surgical complications if primary nephrectomy is undertaken. Currently, it appears that up to 25% of patients eligible for primary nephrectomy undergo preoperative chemotherapy under COG protocols. It is presumed that these represent cases whereby tumors were large or concurrent metastatic disease existed in the face of a large tumor.

Special Considerations

Ureteral Extension

Wilms' tumor extension into the renal pelvis or even to the level of the bladder and urethra are rare but reported.[144–146] Ritchey et al. performed a thorough review of this subject, analyzing data from multiple NWTS studies, and concluded that the overall incidence was about 2%.[147] Roughly half of these children presented with gross hematuria; however, many with ureteral extension had nonspecific symptoms. Preoperative imaging detected only ~31% of cases, 49% were detected intraoperatively, and some cases were only detected on pathologic examination. The apparent insensitivity of preoperative imaging highlights the importance of intraoperative inspection by the surgeon in order to avoid inadvertently transecting tumor within the ureter. The authors recommended cystoscopy and retrograde studies for all patients presenting with hematuria, hydronephrosis, or a nonfunctioning kidney.[147]

Vascular Extension

Doppler ultrasound had been frequently used as an adjunct to CT for the detection of caval thrombus. A recent analysis of COG patients suggested that Doppler adds little value to this analysis and is not required.[148] For vena cava involvement below the level of the hepatic veins, the caval thrombus can be removed via cavotomy after proximal and distal vascular control is obtained. Generally, the thrombus will be free-floating, but if there is adherence of the thrombus to the caval wall, the thrombus can often be delivered with the passage of a Fogarty or Foley balloon

catheter. If the thrombus extends above the level of the hepatic veins, preoperative chemotherapy can shrink the tumor and thrombus, facilitating complete removal.[140,149] For cases extending into the atria, a combined approach involving cardiac surgeons is required (Figure 32.6). Nephrectomy is accomplished, and the patient is subsequently placed on bypass for clot removal.

Inoperable Tumor

With the exception of the current BWT protocol, current COG protocols continue to advocate for up-front surgery for the primary tumor. Under specific circumstances, however, deferred surgery is allowed. These cases are frequently referred to as "inoperable." Specific circumstances include tumor thrombus extending into the IVC above the level of the hepatics, tumors that involve contiguous structure and would require removal of adjacent organs, tumors that in the surgeon's opinion would expose the patient to unnecessary morbidity or mortality, and large tumors associated with a high risk of spillage, as well as patients with pulmonary compromise due to extensive pulmonary metastasis.[142] A tumor should not be judged inoperable based on imaging studies alone. Preoperative imaging can overestimate local tumor extension, so inoperability should only be determined on surgical exploration. It is also important to remember that the misdiagnosis rate of renal masses after assessment by diagnostic imaging is 5%.[124,131]

If a tumor is found to be unresectable, pretreatment with chemotherapy almost always reduces the bulk of the tumor and renders it resectable.[141,150] Patients who are staged by imaging studies alone are also at risk for understaging.[124] A patient determined to have an inoperable tumor should be considered stage III and treated accordingly.[141] Typically, repeat imaging is performed after 6 weeks of chemotherapy. Experience in SIOP has shown that maximal reduction in tumor volume occurs within the first 8 weeks.[124] After there has been adequate shrinkage of the tumor, definitive resection can be completed.

Partial Nephrectomy in Unilateral Tumors

Reports of successful renal preservation in BWT and, more recently, in unilateral Wilms' has prompted some centers to consider renal-sparing surgery for unilateral tumors (Figure 32.8).[151–154] Proponents of renal-sparing surgery for unilateral tumors will cite concerns about the late occurrence of renal dysfunction in children who have undergone unilateral nephrectomy. There is both clinical and experimental evidence of hyperfiltration damage of remnant nephrons after a loss of renal mass. Following treatment for unilateral Wilms' tumor, some patients develop proteinuria and a decrease in creatinine clearance.[155] Others have pointed to the increase in low-stage chronic kidney disease among survivors of unilateral nephrectomy.[156,157] Interest in this subject has also been sparked by adult literature identifying benefits related to cardiovascular health, bone health, and erectile function in patients undergoing partial nephrectomy as opposed to radical nephrectomy.[158–161] Review of NWTS patients found that the incidence of renal failure in children with unilateral tumors is 0.25%.[139] Most of those patients experiencing clinically significant renal dysfunction had

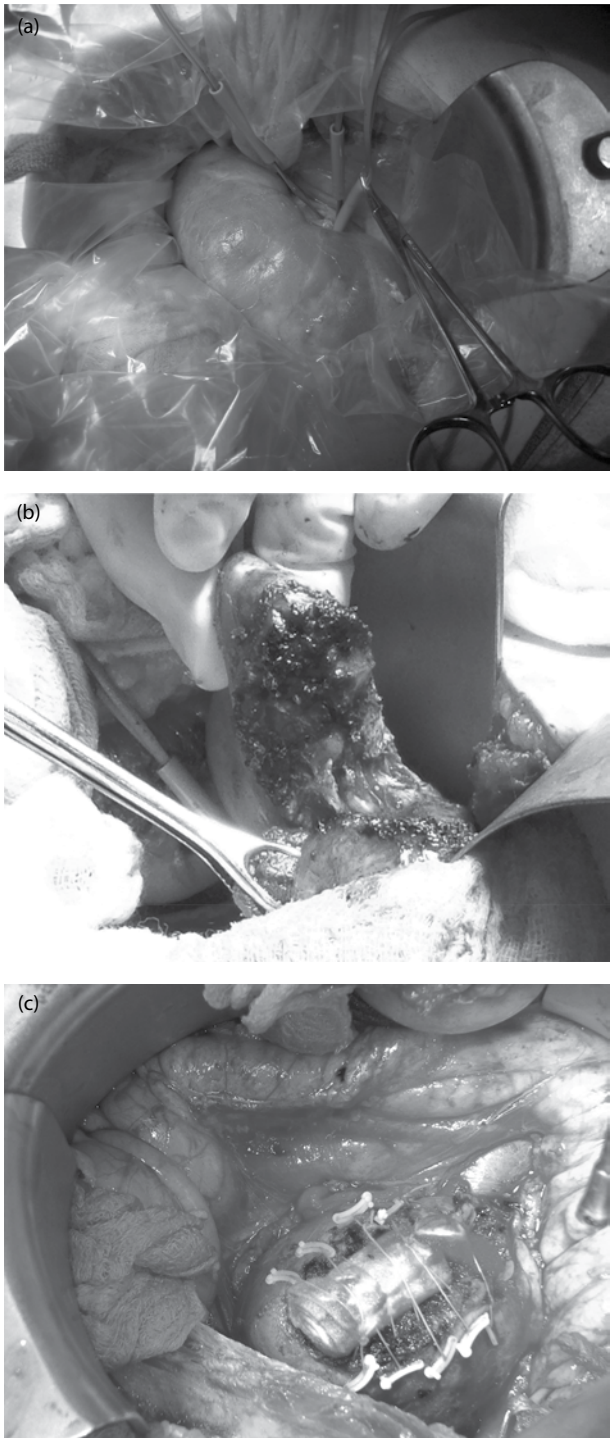

FIGURE 32.8 Intraoperative images of patient undergoing partial nephrectomy for renal mass. (a) Kidney is isolated in impermeable catch drape, and renal vascular has been isolated in preparation for clamping if needed. (b) Partial nephrectomy in progress. (c) Partial nephrectomy completed with gel foam with overlying bolsters.

DDS with intrinsic renal disease, which often progresses to end-stage disease even in the absence of tumor. More recently, other subgroups of patients at increased risk for renal insufficiency have been identified.[136] Patients with the WAGR syndrome have a markedly increased risk of

renal failure. Breslow et al. found a 38% risk of renal failure that occurred at a median of 14 years from diagnosis.[136] They also noted an increased risk for renal failure in children presenting with genitourinary anomalies and Wilms' tumor. This has resulted in current recommendations (AREN0534) that allow for renal-preserving surgery in unilateral syndromic patients at risk for recurrent Wilms' or renal dysfunction. Based on the overall low risk of renal failure in nonsyndromic patients with unilateral tumors, the official COG recommendation remains total nephrectomy.

The issue of cancer control related to partial nephrectomy is another significant consideration surrounded by intense debate. A review of children with BWT enrolled in NWTS-4 found that the incidence of local recurrence was 7.5% following partial nephrectomy and 14% after enucleation.[162] Although OS was comparable, patients with residual disease and recurrences required additional therapy to attain a similar outcome. Previous reports demonstrating poor outcomes for patients experiencing local recurrence have prompted concern regarding the application of partial nephrectomy to unilateral Wilms' patients.[106] However, a recent literature review focused on assessing oncologic outcomes of patients undergoing partial nephrectomy for unilateral Wilms' suggests that oncologic outcomes for selected patients undergoing partial nephrectomy are the same as those for patients undergoing radical nephrectomy.[154] A 2001–2009 SIOP study evaluated the groups' experience with partial nephrectomy for unilateral Wilms'. All patients were pretreated with chemotherapy, and a partial nephrectomy was performed in 91 (3%) of 2800 patients. The overall recurrence rate was 4%, but only one patient experienced local recurrence. The overall and local recurrence rates were comparable to those of the total nephrectomy patients, but the groups were not staged matched. Tumor rupture rates were similar, as were overall and EFS rates. These reports lend credence to the possibility of performing partial nephrectomy in selected unilateral Wilms' patients without compromising cancer outcomes. However, one must consider that in both of these reports a majority of patients had been pretreated with chemotherapy, which is not the current COG standard and can have a profound effect on local control and recurrence.

Owing to the typically large tumor size at presentation, the feasibility and applicability of partial nephrectomy to children with unilateral Wilms' are frequently questioned. A recent analysis performed by the COG looked at this question in very low-risk (<age 2, <550 g) unilateral Wilms' tumors. This population would seemingly be particularly technically amenable to partial nephrectomy as a result of smaller tumor size. Inclusion criteria required preservation of at least one-third of the kidney, in situ procedure performance, and absence of vascular involvement. Disappointingly, partial nephrectomy was deemed technically feasible in only 9% of patients based on radiologic assessment. This study highlights the limited number of eligible patients utilizing the COG up-front surgery approach. Whether this number can be increased by utilizing pretreatment strategies is unclear. In a recent SIOP analysis, only 3% of patients received partial nephrectomy—as of this writing, it is unclear if this implies technical feasibility in only 3% of cases. Conversely, substantial size reduction has been reported using pretreatment chemotherapy.

In summary, while the risk of developing renal failure following treatment appears to be quite low for most children with unilateral Wilms' tumor, continued long-term follow-up of this cohort of children is necessary. While emerging data suggest a potential long-term benefit to renal preservation in cases of solitary renal tumors, the cooperative groups have yet to do a large randomized trial. Finally, within the COG the opportunity to apply renal-sparing surgery to unilateral tumors may be limited due to a philosophical approach that favors up-front surgery.

Bilateral disease

Synchronous bilateral nephroblastoma occurs in about 5% of children with Wilms' tumor, with metachronous lesions developing in only 1% (Figure 32.4).[134,163,164] Therapy of children with BWT is directed toward preservation of renal parenchyma to avoid renal insufficiency.

A review of NWTS patients with BWT found that 9.1% of synchronous bilateral tumors and 18.8% of metachronous bilateral tumors have developed renal failure.[139] The most common etiology for renal failure was the need for bilateral nephrectomy for persistent or recurrent tumor in the remaining kidney after initial nephrectomy.

The initial management, therefore, is chemotherapy. Repeat imaging is done 6 weeks later to assess response of the tumors. Experience in SIOP has shown that maximal shrinkage occurs at about 6–8 weeks of chemotherapy. As noted above, one cannot predict the histology of the tumor by imaging response to the chemotherapy.[60,165] Differentiated tumors may show a poor clinical response to therapy, but have an excellent prognosis if the tumor is completely excised. Tumors with complete necrosis and predominantly regressive changes can also increase in size during therapy.[60] Tumors not responding to therapy require open biopsy to exclude anaplasia. At the time of the second-look procedure, partial nephrectomy or wedge excision of the tumor should be considered, but only if complete tumor resection with negative margins can be obtained, and part of either or both of the kidneys can be salvaged. If the tumors are not amenable to partial resections, patients with persistent viable tumor are then treated with a different chemotherapeutic regimen. The patient should be reassessed after an additional 12 weeks of chemotherapy to determine the feasibility of resection. If it appears that either or both of the kidneys can be salvaged, partial nephrectomies or wedge excisions of the tumors are performed. Radical nephrectomy is performed to remove the kidney with too extensive tumor involvement when only one of two can be preserved. Although rare, bilateral nephrectomies and dialysis may be required if the tumor fails to respond to chemotherapy and radiation therapy. The recommended interval between successful completion of treatment of the Wilms' tumor and renal transplantation varies. Some clinicians advocate a waiting period of 2 years to ensure that the patient does not develop metastatic disease; others have found that a 1-year interval is sufficient.[166] SIOP investigators have noted that late relapses have occurred in patients with BWT more

than 4 years posttreatment and recommended long-term follow-up.[163]

LATE EFFECTS OF TREATMENT

One of the major objectives of the pediatric cancer cooperative groups has been to reduce the intensity of treatment in order to prevent or lower the morbidity of multimodal therapy.[167] It is now well established that each therapeutic modality used in the management of Wilms' tumor can result in both acute and delayed toxicities affecting numerous organ systems. Late effects of cancer therapy are predictable and are based on treatment modalities used, age of patient at treatment, and time elapsed since therapy. Clinicians must be familiar with the spectrum of problems that face these children as they grow into adulthood. Young children are at particularly high risk for growth and development defects given their increased tissue sensitivity. Long-term follow-up of treatment-related complications has been an integral role of the NWTS and COG.

Children treated with radiation and chemotherapy for Wilms' tumor are at increased risk for second malignant neoplasms (SMNs). NWTS investigators reported that 15 years after initial (Wilms' tumor) diagnosis, the cumulative incidence of an SMN is 1.6% and increasing steadily.[168] This is more than eight times the expected incidence. The risk of developing leukemia or lymphoma is greatest in the first 8 years after treatment. The risk of developing a solid tumor continues to increase over time. Most tumors occur in previously irradiated areas, but prior treatment for relapse and use of DOX were also associated with an increased incidence of SMNs. Congestive heart failure is a known complication of treatment with an anthracycline,[169] and the frequency is directly proportional to the cumulative dose received. In addition to the acute cardiotoxicity, reports are surfacing of cardiac failure up to 20 years after treatment.[170] In a preliminary review of patients entered on NWTS-1, NWTS-2, and NWTS-3, the frequency of congestive heart failure was 1.7% among DOX-treated patients. The risk was increased if the patient received whole-lung irradiation. DOX has been shown to be a radiation sensitizer.[168] In light of these findings, all children who undergo treatment with these modalities should undergo periodic reevaluation.

Growth and development disturbances are well-established complications of cancer therapy in children. Spinal irradiation can result in severe reduction in spinal growth, as well as scoliosis.[171] Similarly, chemotherapeutic agents can have a direct effect on chondrocytes, resulting in resistance to endogenous growth hormone and subsequent growth impairment.[172] Hogeboom et al. studied the impact of treatment on stature in Wilms' tumor patients.[173] They concluded that while reductions in stature directly correlated to total radiation dose and age at treatment, currently recommended radiation doses should not result in a clinically significant impact.

Damage to reproductive systems can lead to problems with hormonal dysfunction and/or infertility. The gonads are particularly sensitive to radiation, and gonadal radiation in males can result in temporary azoospermia and hyogonadism.[174] The effect on the testis is dose related, and the prepubertal germ cells also appear to be radiosensitive. In a follow-up of 10 men treated for Wilms' tumor in childhood, oligospermia or azoospermia was found in 8.15. The Leydig cells are more radioresistant than the germ cells, but higher doses can produce damage resulting in inadequate production of testosterone. This can result in delayed sexual maturation. Chemotherapeutic agents can also interfere with testicular function, particularly alkylating agents. Acute toxicity with germ cell depletion occurs in all age groups. Some long-term studies suggested that prepubertal testes are resistant to chronic toxicity.[175] However, recent studies have indicated that prepubertal testes are not protected from chemotherapy-induced damage. One report found that 12 of 19 prepubertal males treated for a variety of solid tumors were sterile as a result of treatment.[176,177]

Female Wilms' tumor patients exposed to radiation are a risk for decreased fertility, intrauterine growth retardation, and spontaneous miscarriage in a dose-dependent fashion. In addition, females who received abdominal radiation have a 12% incidence of premature ovarian failure.[178] Of 16 women who received whole abdominal irradiation, all had evidence of ovarian failure, and 75% were amenorrheic.[179] Chemotherapy-induced damage to the ovaries is most often associated with alkylating agents. A decrease in the number of follicles is seen in prepubertal girls treated with chemotherapy.[180] Premature menopause is a common complication of female childhood cancer survivors, and is usually associated with radiation therapy and/or treatment with alkylating agents. Byrne et al. demonstrated that women receiving alkylating agents were 9.2 times more likely to enter premature menopause.[180,181] Although further studies are needed to assess the extent of the problem, it appears prudent to counsel survivors at risk that a delay in first pregnancy may preclude having children.[182] In the future, cryopreservation and reimplantation of oocytes may be a viable alternative for these patients.

Several studies have addressed the risk of pregnancy in survivors after childhood cancer therapy. As noted above, girls with Wilms' tumor appear to have a higher incidence of Müllerian anomalies, causing some authors to suggest postpubertal level 2 ultrasound evaluation to detect these abnormalities prior to pregnancy.[18] Women with prior abdominal radiation have the greatest potential for adverse pregnancy outcomes. In a study of patients treated for Wilms' tumor, an adverse outcome occurred in 3% among nonirradiated women compared with 30% of women who received abdominal irradiation.[183] Perinatal mortality rates are higher, and infants are more likely to have low birth weights. The potential mutagenic effects of anticancer therapy are of concern. Most studies have found no increase in the incidence of congenital anomalies and no cases of Wilms' tumor in the offspring of survivors.[183,184]

Renal impairment is rare, but possible, in nonsyndromic children undergoing nephrectomy for unilateral disease. Although nephron-sparing techniques are currently being utilized more frequently, most children treated for Wilms' tumor will undergo unilateral nephrectomy as part of the initial treatment. Renal dysfunction

as a late effect of treatment is a particular concern in patients treated for BWT. Sudour et al. found that 20% of bilateral patients treated with multimodality therapy in SIOP 93 experienced impaired renal function; some required hemodialysis or transplant.[185] A review of NWTS patients found that 9.1% of those with synchronous BWT eventually developed renal failure, and the majority of cases were due to second nephrectomy for persistent or recurrent tumor in the remaining kidney after initial nephrectomy.[139] In patients who do not undergo bilateral nephrectomy, impairment of renal function may be related to irradiation, administration of nephrotoxic chemotherapeutic agents, or hyperfiltration of the remaining nephrons. Initially, there is compensatory hypertrophy that develops in this kidney.[186,187] The data are conflicting regarding renal compensatory hypertrophy in patients who receive whole abdominal irradiation. Walker et al. found no difference in renal lengths between patients treated with chemotherapy and radiation versus chemotherapy alone.[187] However, a more recent report used ultrasound to calculate renal lengths and found that patients receiving radiation had poor compensatory growth.[186]

The kidney is sensitive to the effects of radiation. Radiation doses to the kidney should be limited to 12–15 Gy. Mitus and colleagues correlated functional impairment with the renal radiation dose in a review of 100 children treated for Wilms' tumor.[188] The incidence of impaired creatinine clearance was significantly greater for children receiving >12 Gy to the remaining kidney, and all cases of overt renal failure occurred in patients who had received >23 Gy. Clinical signs of radiation nephritis may occur very acutely or begin months or years after therapy is discontinued.[188] Direct radiation nephrotoxicity is the usual cause, with injury to the intrarenal vasculature.

Nephrotoxicity related to chemotherapy is well documented. Studies in children have demonstrated that alkylating agents in particular are associated with renal tubular dysfunction related to drug metabolites.[189] Unfortunately, Mesna has not been protective against these effects. A recent study by Bardi et al. has suggested that high-risk Wilms' patients receiving agents such as cyclophosphamide may be at risk for early, subclinical, renal dysfunction, as evidenced by elevated levels of cystatin C, a measure of glomerular function, and elevated *N*-acetyl-D-glucosaminidase, along with microalbuminuria.[190] The latter are both indicators of proximal tubular dysfunction. The long-term significance of these findings remains to be determined.

The liver may also be subject to long-term negative sequelae of Wilms' tumor therapy. A recent retrospective review of 158 patients from a single institution sought to determine the rate of hepatic veno-occlusive disease (VOD), now known as sinusoidal obstruction syndrome (SOS), that occurs in patients following preoperative chemotherapy with VCR and actinomycin.[191] Liver biopsy was performed after 4 or 8 weeks of chemotherapy, and 45.1% of patients had histologic evidence of VOD; the rate was highest in the group treated according to the SIOP 2001 protocol, where a single larger dose of actinomycin was given in comparison to smaller, repeated dosing.

OTHER RENAL TUMORS OF CHILDHOOD

Cystic Partially Differentiated Nephroblastoma

Cystic partially diffentiated nephroblastoma (CPDN) is a benign, solitary, cystic lesion, thought to be in the spectrum of nephroblastoma. The cysts are lined with blastemal or other immature elements. These lesions should not contain hemorrhage, necrosis, or calcification. Cysts are common in Wilms' tumor and range in size from microscopic to several centimeters in diameter. The majority of these lesions occur in the first year of life.[192] These lesions are indistinguishable radiographically from solitary multilocular cysts, described below. Surgery is curative in almost all patients, with recurrence the result of incomplete resection.[193,194]

Multilocular Cystic Nephroma

Multilocular cystic nephroma is another benign renal lesion in the spectrum of nephroblastoma. Also known as multilocular cyst, it has a bimodal age incidence. This tumor is distinguished by the finding of only *mature* cell types within the septa of the cyst wall, which should be free of any nodularity. Fifty percent of the multilocular cysts reported in the literature have been found in children younger than 4 years; boys predominate in a ratio of 2:1. The second peak incidence occurs in adults and, unlike the pediatric cases, usually in women.[195] Cystic nephromas are commonly found incidentally on radiographic studies, but may present as an abdominal mass found on routine physical examination. Whereas the majority of cases of multilocular cystic nephroma have been unilateral, there are rare reports of bilateral cases.[196] The gross appearance of the tumor is its most distinguishing feature. The cut surfaces reveal a well-circumscribed multilocular tumor composed of cysts ranging from several millimeters to several centimeters in the greatest diameters. The tumor is well encapsulated, compressing the surrounding renal parenchyma. It is cured by nephrectomy, but incomplete excision by partial nephrectomy has resulted in tumor recurrence. If partial nephrectomy is considered, frozen section is indicated to exclude cystic, partially differentiated nephroblastoma.[192]

Congenital Mesoblastic Nephroma

CMN is found virtually exclusively in infants, and is the most common renal tumor in infancy, with a mean age at diagnosis of 2 months. The typical presentation is a newborn with an abdominal mass, but in recent years, a number of cases have been recognized prenatally with polyhydramnios (Figure 32.9).[197–199] Tumor induction is postulated to occur at a time when the multipotent blastema is predominantly stromagenic.[200] The neoplasm is grossly indistinguishable from Wilms' tumor, but is microscopically distinct with two major histologic types: classic and cellular. In a small percentage of patients, these two cell types may coexist in a "mixed pattern." The

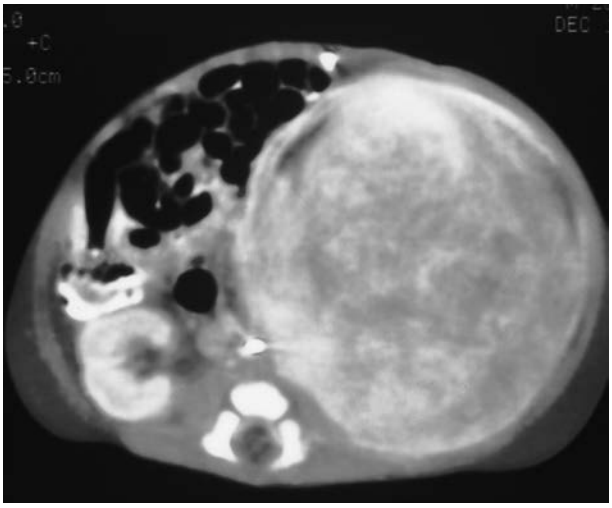

FIGURE 32.9 Computed tomography scan of an infant with congenital mesoblastic nephroma.

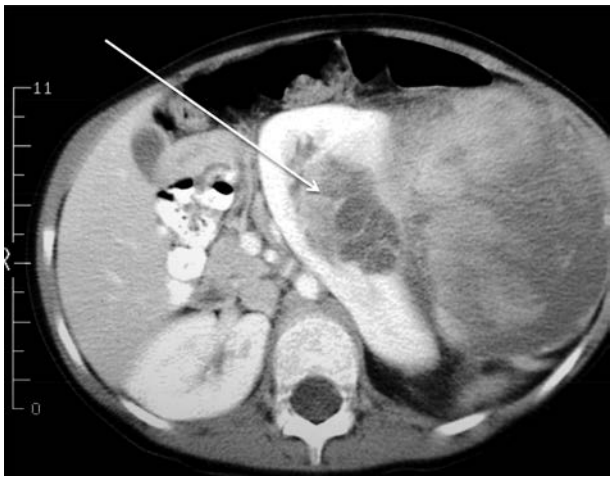

FIGURE 32.10 Image of patient with CCSK. Note the cystic component of the lesion (arrow).

classic subtype is characterized by interlacing sheets of bland spindle cells, and resembles infantile fibromatosis. Nodules of hyaline cartilage, thin-walled vascular spaces, and variable mitotic activity are often seen. The cellular variant has a solid sheetlike growth pattern, plump cells, and large nuclei frequent mitoses.[201–203] Unlike the classic variant, these lesions are well demarcated. This variant is virtually identical histologically to congenital fibrosarcoma. Molecular studies have found a similar translocation in both tumors that fuses the *ETV6* (*TEL*) gene from chromosome 12p13 with the chromosome 15q25 neurotrophin-3 receptor gene, *NTRK3*.[204] Imaging studies cannot reliably distinguish CMN from other renal mass lesions. Abdominal CT shows a heterogeneous solid mass arising from the kidney (Figure 32.6). Complete excision is curative for most patients with CMN.[197] Local recurrence and metastasis can occur, particularly with the cellular variant of CMN.[202,203] The pathology specimen will often identify extension of tumor into the hilar or perirenal soft tissue; therefore, complete surgical resection is important.[201] The risk of recurrence is thought to be less in children under 3 months of age at diagnosis, but metastases have been reported in a few infants.[205] Neither chemotherapy nor radiation therapy is routinely recommended, but consideration for adjuvant treatment should be given to patients with cellular variants that are incompletely resected. There are reports demonstrating the response of both inoperable and recurrent tumors to chemotherapy.[206,207]

Clear Cell Sarcoma of the Kidney

This tumor is also known as the "bone-metastasizing renal tumour of childhood" because of its predilection bony spread.[208] There is also an increased risk of brain metastases with this tumor.[209] CCSK accounts for 3.5% of renal tumors reported to the NWTS (Figure 32.10). This malignant mesenchymal tumor is made up of undifferentiated cells arranged into cords and nests.[69] Nuclei often appear "empty." Microscopically, the tumor subtly invades into surrounding normal parenchyma in sharp contrast to the borders of nephroblastoma. A number of variant patterns, such as myxoid, cellular, and epitheloid, may be present, hindering an immediate diagnosis. Unlike anaplastic Wilms' tumor, even stage I CCSK lesions are associated with increased rates of relapse. There are no reports of children with bilateral CCSK. Studies have demonstrated that the use of DOX is associated with a significant improvement in outcome for these children.[87,210] Patients with CCSK were treated on NWTS-5 with a regimen combining VCR, DOX, cyclophosphamide, and etoposide in an attempt to further improve the survival of this high-risk group. Preliminary analysis shows very promising results except for patients with stage IV disease. Seventy-nine patients with stage I–IV CCSK were treated with cyclophosphamide–etoposide, alternating with VCR– DOX–cyclophosphamide, and there have been 12 relapses, revealing a 77.6% 4-year RFS. Two-thirds of stage IV CCSK patients relapsed. Currently, one of AREN0231's protocol objectives is evaluating outcomes for a modified chemotherapy regimen based on prior results specifically for CCSK patients. Additionally, radiotherapy is being withheld for stage I patients who have done well with chemotherapy alone.

Rhabdoid Tumor of the Kidney

RTK was first identified by NWTS pathologists in 1978.[63] This highly malignant, rare renal neoplasm accounts for 1.6% of renal tumors registered to the NWTS.[211] It derives its name from the resemblance to rhabdomyoblasts, but it is not derived from myogenic cells; the cell of origin is unknown. Infants with RTK often have concurrent brain tumors. It is difficult to ascertain if these are metastases or two distinct primary tumors.[212] A unifying feature of these tumors, at renal or central nervous system sites, is the presence of mutation or deletion of the *INI-1* gene located at chromosome 22q11, which predisposes to the development of rhabdoid tumors.[69,212–214] This tumor is typically seen in infants and very young children, with a median age of 13 months. The prognosis of patients with rhabdoid tumor remains dismal with conventional chemotherapeutic regimens, with more than 80% of children dying within 1 year of diagnosis.[215] In NWTS-5, children with all stages

of rhabdoid tumor were treated with carboplatin, cyclophosphamide, and etoposide; they also received abdominal irradiation. Preliminary results again were poor, with survival ranging from 50% for stage I tumors to 21% for stage IV tumors, and an average survival of 25.8%.

Renal Cell Carcinoma

Only 5% of renal cell carcinomas occur in children.[216] These patients generally present after age 5 years, and it is the most common renal malignancy in the second decade of life.[217] Survival of children with renal cell carcinoma is dependent on the ability to completely resect the tumor. Raney et al. found that all children with stage I lesions survived.[218] Age is also a prognostic factor, with improved survival in children younger than 11 years. In contrast to adults with lymph node–positive disease, recent reports suggested that local lymph node involvement does not predict a poor outcome.[219] Renal cell carcinomas in children also differ in their histologic morphology and molecular characterization.[220] Currently, three main pathologic classifications in children exist: papillary renal cell carcinoma, renal medullary carcinoma, and renal cell carcinomas with clear cell features. There is a higher percentage of *TFE3* (transcription factor micro E3 binding protein) "translocation" carcinomas and "unclassified" carcinomas in the first two decades of life.[220] There is also a lower frequency of clear cell carcinomas and *VHL* (von Hippel–Lindau gene) alterations compared with adults. These tumors do not appear responsive to chemotherapy or radiation therapy. There currently is no unified grading or staging system, nor is there an accepted treatment protocol, for pediatric renal cell carcinoma.

CHAPTER
33

Surgical Approaches for Pediatric and Adolescent Renal Tumors

Victor H. Figueroa and Armando J. Lorenzo

INTRODUCTION

Radical nephrectomy (RN) has traditionally been considered the basis of the surgical treatment of renal tumors in children and adolescents. The majority of the lessons learned about the management of pediatric renal tumors come from procedures to resect Wilms' tumors (WTs) or nephroblastoma. As described in Chapter 32, WT is the most common primary renal tumor in children, with an estimated annual incidence of 8.1 cases per million individuals and approximately 650 new cases in North America per year. It corresponds to 6% of all pediatric tumors and is the second most frequent intra-abdominal solid organ tumor found in children. Surgery alone is not sufficient for most children. In the early part of the last century, the survival rate with RN alone was poor (close to 30%). With the introduction of radiotherapy to the renal fossa in the 1940s, a decrease in local recurrence without a significant impact on the long-term survival was reported. Since then, the survival rate has improved dramatically thanks to the introduction of adjuvant chemotherapy and multimodal management, achieving survival rates greater than 90%.[1–5]

This significant progress in the treatment and understanding of patients with WT is the result of a multidisciplinary approach and multi-institutional cooperative group trials. In North America, patients with WT were managed according to protocols developed by the National Wilms Tumor Study Group (NWTSG) (now the Children's Oncology Group [COG]), which recommend primary nephrectomy with histological diagnostic confirmation for unilateral disease. In Europe, a different strategy is employed. Protocols developed by the International Society of Pediatric Oncology (SIOP) recommend initial treatment with preoperative chemotherapy, after radiographic diagnosis, followed by surgery afterwards. Despite these differences, oncologic outcomes remain comparable and excellent, irrespective of the utilized protocol.[6,7] In both, surgical resection is included and forms an integral part of management, differing mostly on the timing along the treatment course when it is performed.

Investigators have recently focused on reducing treatment morbidity while preserving survival in patients with low-risk tumors, by searching for novel therapies based on stage, histology, and genetic markers to improve outcomes in patients with high-risk disease.[8,9] Currently, therapy has been refined so that children with low-risk tumors may be spared intensive chemotherapy and radiation—with their long-term side effects. In patients with high-risk tumors, research continues to look for better options, including early treatment intensification. In addition, patients with bilateral disease and predisposition syndromes are being considered for nephron-sparing procedures, maximizing long-term renal function even in the setting of high-volume initial disease or high risk for metachronous lesions. Irrespective of the scenario, within the multidisciplinary treatment team the pediatric urologist or surgeon plays a critical role in the diagnosis and staging, and the surgeon's technical skills and judgment direct therapy and can have a clear impact on outcomes.[10,11] Thus, good surgical principles are paramount to adequate management and optimal cure rates.

ANATOMICAL RELATIONSHIPS OF THE KIDNEY

A good understanding of the retroperitoneum, as well as renal vascular anatomy, is important to adequately apply sound surgical principles for RN and partial nephrectomy (PN). The kidneys are located in the lumbar fossa, surrounded by a layer of perinephric fat, which is enveloped by a thin fascial layer (Gerota's fascia), the main anatomical boundary that helps define the area of resection during a RN and helps confine disease processes originating in the kidney.

The *perirenal space* is confined by Gerota's fascia (anteriorly) and Zuckerland's fascia (posteriorly), defining the anterior and posterior pararenal spaces. Recent studies based on perirenal abscess formation and distribution suggest that when large volumes of occupying fluid develop rapidly, the capacity to accommodate it within retroperitoneal spaces may be overwhelmed, resulting in disruption of these fascial planes. Spread may cross the midline (through the retromesenteric interfascial planes) or extend behind the kidney into Zuckerland's fascia, allowing for more extensive compromise of the posterior pararenal space and neighboring regions.[12] This can have clinical relevance and explain tumor spread to the posterior perirenal space in the presence of large or

FIGURE 33.1 Renal vascular anatomy on CT angiogram. Note the location and length of the main right (arrow) and left (arrow) renal arteries. Bilateral accessory renal branches are highlighted with open arrows.

ruptured renal masses, and challenges the perception that fascial layers are infallible robust barriers to neoplastic spread.

Other organs and structures adjacent to the kidneys should be kept in mind, as they are at risk for damage during surgical resection and serve as landmarks to guide dissection when the anatomy is significantly distorted by a large renal mass. These include

Posteriorly: Diaphragm, psoas major, and quadratus lumborum muscles

Anteriorly

Right kidney: Liver, hepatic flexure of the colon, second portion of the duodenum, adrenal gland

Left kidney: Spleen, tail and body of the pancreas, stomach, splenic flexure of the colon, adrenal gland

Renal Vasculature

The renal pedicle classically consists of a single artery and vein, which enter the kidney via the renal hilum. These structures branch from the aorta (just below the superior mesenteric artery) and inferior vena cava (IVC) at the level of the second lumbar vertebra. The vein is anterior to the artery, and the renal pelvis posterior to these vascular structures.

Arterial Blood Supply

The right renal artery leaves the aorta and courses with a caudal slope under the IVC toward the right kidney. The left renal artery has a shorter and more direct course, as it originates almost directly medially to the left kidney (Figure 33.1).

Upon approaching the kidney, at a variable distance from the ostium, the main renal artery splits into segmental branches (commonly apical or upper, middle, lower, and posterior). It is important to remember that these are segmental ("end") arteries, without collateral blood supply to their respective areas of irrigation, and that multiple renal arteries are sometimes encountered, separately perfusing different areas of the kidney (Figure 33.2). Ligation results in ischemia of the corresponding renal segment, which can be of value for selective embolization or control during nephron-sparing surgery, yet can adversely impact survival of important segments of parenchyma in the case of inadvertent damage during dissection. This is in contrast to the venous drainage, which does enjoy collateral drainage and tolerates segmental ligation without much consequence.

The kidney is susceptible to ischemia due to its very active aerobic metabolism. Although experimental studies indicate that a warm ischemia time of up to 30 minutes can be tolerated without significant functional loss, contemporary reports suggest that every minute counts.[13,14] Renal proximal tubular cells appear to be most sensitive, and may be damaged transiently or permanently, depending on the duration and severity of the injury. A focus during PN has been to develop strategies to minimize injury. "Zero ischemia" resection is based on anatomical vascular microdissection of tertiary and higher-order renal arterial branches. Only the tumor, with immediate peritumoral areas, is superselectively devascularized. Arterial

perfusion to the remainder of the parenchyma continues uninterrupted intraoperatively.[15] When a long surgical period of ischemia is expected, external surface cooling or perfusion of the kidneys with cold solution instilled into the renal artery is required. External surface cooling is the most practical and less invasive of the two methods. It is preferable to keep the entire kidney covered with ice for 10–15 minutes after arterial occlusion. Temperatures of 20°C–25°C can be maintained using this method. Studies have shown that hypothermia to this degree provides renal protection for up to 3 hours.[16] Generous preoperative and intraoperative hydration and avoidance of unnecessary renal artery manipulation or traction are additional measures. Administration of mannitol 10–15 minutes prior to arterial occlusion is also thought to be beneficial, as it increases renal plasma flow, decreases intrarenal vascular resistance, minimizes cellular edema, and promotes osmotic diuresis when renal circulation is reestablished.[17,18] When renal ischemia is necessary for surgery, it is preferable to occlude the artery alone since simultaneous occlusion of the artery and vein can produce venous congestion and additional renal damage.[17]

Venous Drainage

Renal venous drainage correlates closely with the arterial supply, yet multiple veins are less common. The right renal vein is shorter than the left and usually has no tributaries. The left renal vein is longer, travels between the aorta and superior mesenteric artery (Figure 33.3), and has a thicker muscular layer. These anatomical characteristics have a special surgical relevance in donor nephrectomy, as the left kidney is usually preferred due to its longer vein. Injuries to the right renal vein may also occur more easily given its thinner wall. Both renal veins enter the IVC on its lateral aspect, at about the same level, an anatomical relationship that is important because large tumors that compress the right renal vein and vena cava may lead to the intraoperative impression that the dissected renal vein is the right one when in reality it represents the left one (Figure 33.4). The left adrenal and gonadal veins are significant branches draining into the left renal vein, and

FIGURE 33.4 Left renal vein (arrow) encountered during dissection of the vena cava (open arrow) for large right renal mass. Due to anatomical distortion, it may be mistaken for the right renal vein and inadvertently ligated.

their presence has important implications for extensive vascular resections. Occlusion of the left renal vein at the level of the IVC is less likely to significantly impair venous drainage of the left kidney since collateral venous drainage can develop via tributaries, in contrast to a similar maneuver conducted on the right. Thus, special caution should be taken when performing dissection to keep adequate venous drainage of the right kidney.

IVC involvement by tumor thrombus has variable clinical repercussions depending on the side as well as the level of involvement. Lower extremity edema, an acquired varicocele, dilated superficial abdominal veins, proteinuria, pulmonary embolism, a right atrial mass, and nonfunction of the involved kidney are all clinical signs suggestive of intravascular tumor extension.[19] Transabdominal or transesophageal color Doppler ultrasonography and magnetic resonance imaging (MRI) are the preferred studies when evaluating for intravascular tumor extension.[20] In circumstances when the thrombus does involve the wall of the IVC, as seen in some cases after neoadjuvant chemotherapy, resection of the involved segment is required (Figure 33.5). Resection of the infrarenal segment of the IVC can sometimes be done relying on the presence of rich collateral circulation stimulated by the obstructing thrombus. With right-sided renal tumors, the suprarenal portion of the IVC may also be removed since venous drainage from the left kidney can occur via the gonadal and adrenal tributaries. Resection should not be performed when collateral venous circulation for the renal vein would be impaired, without alternate drainage.

Collecting System

The renal papillae constitute the first macroscopic structure of the renal collecting system. Each renal segment contains one or more major calyces draining the corresponding portion of the kidney. In total, 8–10 major calyces open into the renal pelvis. An understanding of the calyceal anatomy is required when performing PN to guarantee an adequate repair without compromising urine drainage. Preoperative placement of a ureteral stent may aid with detecting leaks and facilitate a watertight closure (Figure 33.6). Particular attention should be paid to cases of nephron-sparing surgery of tumors located near the hilum, due to the possibility of iatrogenic obstruction of

FIGURE 33.5 Vena cava replacement after removal of suprarenal segment with adherent tumor thrombus.

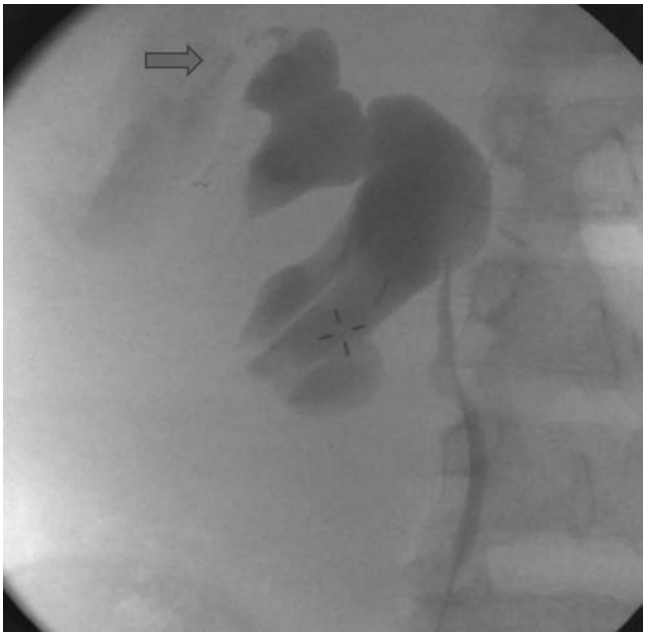

FIGURE 33.6 Extravasation (urine leak, arrow) after PN for small renal mass in patient with predisposition syndrome.

segments of the collecting system during attempted repair of a leak. In addition, the presence of a duplicated system should be kept in mind (Figure 33.7). This has obvious implications in terms of the blood supply to each moiety. The presence of this anatomical variant may allow for resection of part of the kidney (heminephrectomy) without compromising the drainage system of the other moiety.

IMPLICATIONS OF CLINICAL PRESENTATION

Most WT cases are diagnosed incidentally with a palpable abdominal mass (Figure 33.8). Gross hematuria and abdominal pain are less frequent findings at diagnosis. However, the presence of gross hematuria could indicate tumor extension into the collecting system,[21] so-called botryoid extension, a situation that should prompt total ureterectomy. As the tumors tend to be large, a generous incision is often required. In younger children and infants, a transverse abdominal incision may provide greater exposure, while in older patients a classic Chevron-type one is preferred.

Up to 25% of patients present with hypertension secondary to elevated plasma renin levels that resolves after removal of the tumor, 20% of children have hematuria, and 10% have coagulopathy, all findings that have important implications for safe anesthetic delivery and intraoperative management. Fever, anorexia, and weight loss rarely occur; their presence should raise the suspicion of another etiology (such as a neuroblastoma) or widely metastatic disease, both situations that may demand alternative management strategies than up-front nephrectomy. Tumor rupture and bleeding can cause an acute abdomen. In these cases, emergency surgical intervention may be

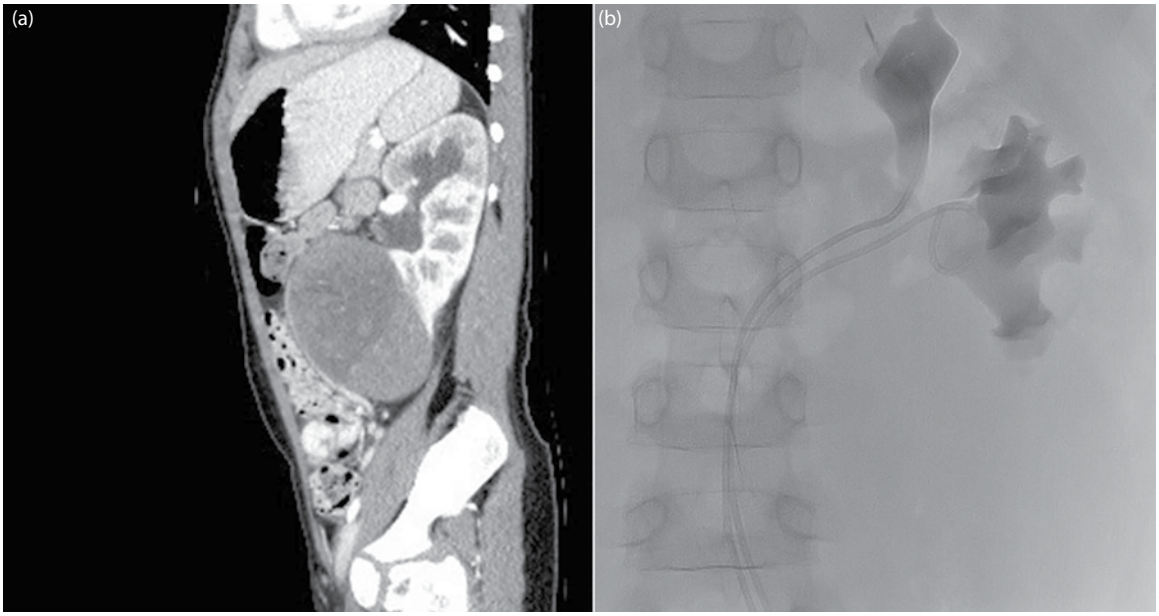

FIGURE 33.7 Lower-pole renal mass (a) on a patient with complete duplication, as documented during retrograde pyelogram and stent placement prior to neoadjuvant chemotherapy (b).

warranted, and the approach should be through a generous incision that allows good exposure and vascular control of the hilum, aorta, and vena cava, such as a large midline incision. Between 5% and 10% of tumors are bilateral, a presentation that can be synchronous or metachronous.[22] Bilateral tumors are more commonly found in children with predisposition syndromes (such as the Beckwith–Wiedemann syndrome); thus, the presence of bilateral masses should raise suspicion for such conditions and demands a thorough evaluation. The incidence of bilateral Wilms' tumor (BWT) demands neoadjuvant chemotherapy prior to surgical intervention[23] (Figure 33.9).

In 13%–28% of children, physical examination reveals congenital anomalies, such as aniridia, genitourinary malformation, hemihypertrophy, or signs of overgrowth.[24,25] Syndromes associated with an increased risk of developing WT include WAGR (aniridia, genitourinary malformation, and mental retardation), Beckwith–Wiedemann, and Denys-Drash syndromes. Other less common ones include isolated hemihypertrophy, Klippel–Trenaunay–Weber syndrome, and Perlman syndrome.[23] In all cases, the possibility of metachronous contralateral lesions should be kept in mind, and surgical management should focus on nephron- and adrenal-sparing procedures (if feasible). In addition, incisions should be fashioned in such a way that they may be used in the future if reinterventions are needed (i.e., new lesion or local recurrence at site of PN).

FIGURE 33.8 WT at presentation as a palpable renal mass.

IMPLICATIONS OF DIAGNOSTIC IMAGING FINDINGS

Any child with an intra-abdominal mass requires axial imaging in order to define the origin of the mass, the presence and involvement of the contralateral kidney, evidence of metastasis or rupture, and the presence of tumor thrombus.[26,27] The differential diagnosis of an intra-abdominal mass is extensive and includes other solid organ tumors, such as hepatoblastoma, neuroblastoma, germ cell tumors, and rhabdomyosarcoma. Abdominal ultrasound with vascular assessment of the renal vein and IVC should be the initial study. A computed tomography (CT) scan of the abdomen and pelvis with oral and intravenous contrast typically demonstrates an intrarenal neoplasm that displaces the collecting system and effaces the interface with the remaining normal renal parenchyma, a finding sometimes referred to as the claw sign (Figure 33.10). It is important to assess both kidneys to rule out bilateral tumors and the possibility of a renal mass in a solitary kidney. Current WT studies mandate radiographic imaging of the chest with CT scan, resulting in a high detection rate of lesions that would have been otherwise missed in the plain chest radiograph (Figure 33.11).[28,29] The presence of widely metastatic disease should raise concerns for pulmonary problems during or after surgery, and—in rare circumstances—favor the use of neoadjuvant chemotherapy

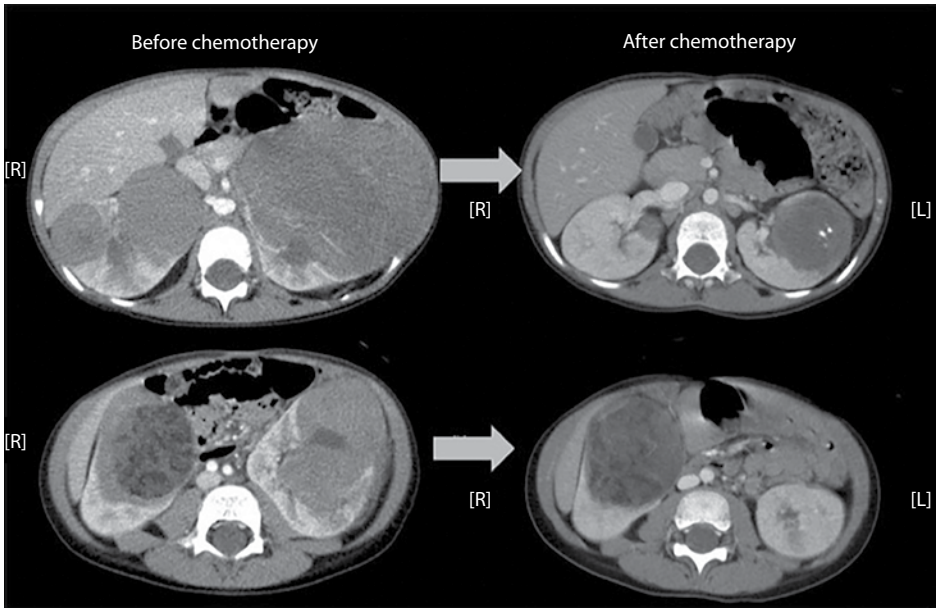

FIGURE 33.9 Response of BWTs to neoadjuvant chemotherapy.

FIGURE 33.10 CT scan findings on a patient with a large renal mass, confirmed as WT on pathology after RN.

before resection. Transabdominal or transesophageal Doppler ultrasound and echocardiography are the best methods to visualize the renal vein, IVC, and atrium in order to rule out vascular extension of the tumor, yet MRI provides exquisite assessment of venous structures and gives additional anatomical detail. Thus, in some centers the latter is the preferred imaging modality, a strategy that also avoids exposure to ionizing radiation. In addition, MRI may also be of value in distinguishing between nephrogenic rest and WT.[30]

Certain investigations are necessary only with specific types of tumors. Renal cell carcinoma (RCC) and clear cell sarcoma can metastasize to bone. Consequently, patients with focalizing musculoskeletal symptomatology should undergo a bone scan and skeletal survey prior to surgery.[31] In addition, brain metastases can occur with both clear cell sarcoma and rhabdoid tumor of the kidney; therefore, a head MRI or CT scan should be performed in these patients and obviously conducted preoperatively in

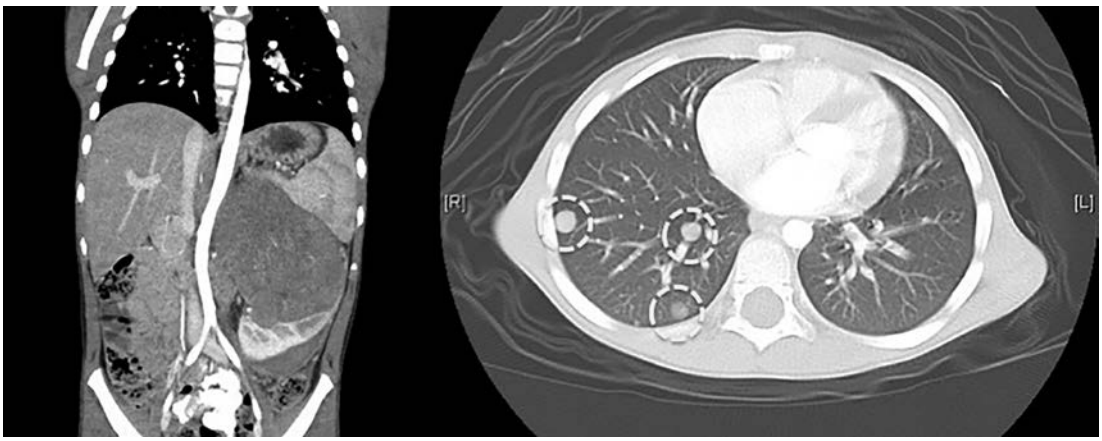

FIGURE 33.11 Pulmonary nodules in a patient with a WT (arrows). Lesions were not seen on admission plain chest x-ray.

any patient with focal neurological symptoms.[32] Although rare, both of these circumstances can have important implications in preparation for surgical management.

APPROACH FOR PATIENTS WITH SUSPECTED WILMS' TUMOR

Patient Preparation

In the absence of a preoperative biopsy, tumors in the first few years of life are approached with the assumption that they represent WTs. Adequate patient preparation and positioning are essential for an optimal surgical outcome. The surgical incision should allow the surgeon to have complete access to the tumor, gain adequate exposure for vascular control, accurately assess the abdomen (for staging purposes), and appropriately deal with potential complications, should they develop. Extension into the thoracic cavity, with a thoracoabdominal incision, is rarely used and is only recommended for large upper-pole tumors.

Placement of IV lines in the lower extremities should be avoided. This is particularly important when clamping of the vena cava is anticipated. Placement of an arterial line is recommended to accurately measure blood pressure in patients with hypertension, large tumors, or vascular involvement. In addition, consideration should be given to placement of an epidural catheter after induction in order to help with postoperative pain control.

Surgical Principles

Complete exploration of the abdomen is recommended, specifically examining for the presence of bloody peritoneal fluid (suggestive of tumor rupture), liver metastasis, and peritoneal seeding. Although WTs can be quite large, they typically displace rather than invade adjacent organs. This feature is key to understanding important principles: radical resection should rarely involve the removal of adjacent organs (except for the adrenal gland or small portions of fascia or muscle), and resectability should be determined in the operating room (and not solely based on imaging studies, with the notable exception of a large tumor thrombus or bilateral tumors).

Although in the past routine exploration of the contralateral kidney was considered mandatory, it is currently not performed or recommended if imaging (CT or MRI) is satisfactory and does not suggest a bilateral process.[10,26,27] Should the radiological evaluation raise suspicion for a possible contralateral synchronous lesion, management should shift to that of bilateral renal masses employing neoadjuvant chemotherapy with or without confirmatory renal biopsy. The implications of this particular aspect of care are not inconsequential, as RN with subsequent management of the contralateral lesion can lead to removal of valuable renal parenchyma, with increased risk for renal insufficiency. Lastly, any evidence of a tumor rupture should be clearly documented due to the increase risk for local recurrence and protocol-driven intensification of therapy (including radiation).[10]

Radical Nephrectomy

The colon is reflected to achieve adequate exposure and access to the respective great vessels (aorta on the left and vena cava on the right). On the left side, division of the splenocolic ligament facilitates this maneuver and avoids excessive traction and possible splenic injury. On the right side, the duodenum is also mobilized in order to avoid injury and provide access to the vena cava and hilum.

Initial ligation of the renal artery and vein should not be pursued if technically difficult, a situation commonly seen in the management of a large renal mass. In contrast to older recommendations, it is preferable to gently dissect and mobilize the kidney first to gain adequate exposure of the hilum. This is of greater importance when addressing a left renal mass, as the superior mesenteric artery can be in close anatomical proximity to the displaced hilum and erroneous ligation can have serious consequences. When the renal vein is exposed and controlled, it should be carefully palpated prior to ligation to rule out extension of the tumor into its wall or the lumen, irrespective of findings on imaging studies.[33] In the presence of a large right renal mass, the cava can be effaced and compressed against the tumor, increasing the risk of ligation by erroneously assuming it to be a dilated gonadal vein. Similarly, the contralateral (left) renal vein may be ligated by mistake. The right renal artery can be dissected either lateral to the vena cava or between the vena cava and aorta. This approach can be helpful with large tumors that extend medially. Tributaries (gonadal, adrenal, and lumbar veins) must be carefully dissected to avoid their inadvertent injury and intraoperative bleeding. In some cases, enlarged perihilar lymph nodes can add difficulty to the identification and exposure of the renal pedicle. In these cases, lymph node sampling before attempting to control the hilum is recommended.

Disruption of the renal capsule (by rupture, spill, or biopsy) upgrades the stage and often demands postoperative radiation. Thus, the kidney and tumor should be removed intact within Gerota's fascia, to ascertain any microscopic evidence of extension into the perinephric fat or positive margins. Similar to the growing body of evidence in adult oncological care, the adrenal gland should not be routinely removed, and can be safely preserved if it is not adherent to the tumor.[34] Ureteral ligation is routinely performed as distally as convenient, but complete resection of the ureter is not necessary except in cases with suspected urothelial extension (by either preoperative imaging studies, gross hematuria, or passage of tumor fragments through the urethra).

Slow, methodical separation of the mass from adjacent organs is almost always feasible and should be done patiently to avoid injury to other structures (such as the spleen, pancreas, liver, colon, and small bowel) or tumor rupture. Rarely is resection of a small portion of the liver, diaphragm, psoas muscle, or tail of pancreas warranted, and it should only be undertaken if it will allow for complete resection without additional operative morbidity. At times, this maneuver can be advantageous, avoiding upstaging due to positive margins and reducing the subsequent need for adjuvant therapy.[23,35] If complete resection is not possible, heroic measures should be avoided and a

tumor biopsy considered in anticipation of reexploration after chemotherapy (which decreases tumor size and stimulates development of a well-defined pseudocapsule around the tumor). Titanium clips are employed as markers for suspicious areas, resection margins, and residual tumor, in order to guide future radiological investigation or radiation planning.[10] Judicious use of clips before vascular control can be of great value, considering that placement of a vascular clamp across structures with clips may lead to suboptimal occlusion and bleeding.

Lymph Node Sampling

The presence of hilar and regional lymph node metastasis is an extremely important factor in staging.[36] Studies have shown that surgeons incorrectly identify histologically positive nodes as clinically negative 4%–11% of the time, and clinically positive nodes are negative up to 40% of the time. Therefore, routine sampling in the hilum and pericaval or para-aortic areas, along with any other suspicious nodes, is mandatory.[37,38] This is a sampling procedure, and not an extended lymph node dissection. Unfortunately, studies have also demonstrated a higher risk of recurrence in children who did not have their node status documented at the time of nephrectomy; thus, this aspect of surgical care should not be overlooked.[37,39]

Intravascular Invasion

Tumor extension into the renal vein, cava, and right atrium presents special surgical challenges.[33,40,41] Thankfully, many of these tumor extensions regress with preoperative chemotherapy, an approach favored in cases of suprahepatic involvement or bulky disease with complete occlusion of the suprarenal vena cava, or in the presence of a large component of an associated clot in the contralateral renal vein or infrarenal cava (Figure 33.12). In patients with shortness of breath, hypoxia, or hemodynamic instability, the possibility of a tumor thrombus embolism should be entertained and appropriately worked up before chemotherapy or surgery.

Tumor invasion into the renal vein and infrahepatic vena cava can be removed en bloc with the kidney with good vascular control and generous mobilization of the liver. Primary resection of a thrombus extending into the hepatics or into the atrium should be avoided.[33,40,41] Even after chemotherapy, adherence to the vein wall may develop or persist; thus, resection is not always straightforward and should be done with cardiovascular surgery backup. Intraoperative transesophageal echography can be of value in monitoring the thrombus during surgery, including any gains by dissection of the kidney and renal artery control, as well as assessing heart function in the setting of a suspected embolism. Control of the renal vein or cava above and below the tumor with vessel loops or vascular clamps is always necessary. Similarly, portal triad vascular flow may need to be temporarily occluded (Pringle maneuver) to decrease blood loss from the liver in selected cases with venotomy extension to or above the hepatic veins. Whenever possible, the tumor thrombus should not be transected, as this may result in residual disease or lead to embolization. After chemotherapy, a desmoplastic-type reaction may fix the thrombus to the vessel wall, making surgical extraction more difficult, and a large venotomy may be required (Figure 33.12). If after preoperative chemotherapy the tumor still extends above the hepatic veins, cardiopulmonary bypass may be needed. The kidney and abdominal tumor thrombus should be mobilized prior to administration of systemic heparin. After placing the child on bypass, the right atrium is opened and the tricuspid valve inspected. The tumor is removed from the heart above and below at the same time to prevent tumor embolism.[10]

FIGURE 33.12 Large renal mass with tumor thrombus extending above the hepatic veins.

Tumor Spillage and Rupture

The resection technique can play an important role in determining subsequent adjuvant therapy.[30,35,36] Studies have consistently shown an increased risk of recurrence in patients with tumor spills or ruptures regardless of the cause, which can adversely impact survival. These events also result in intensification of adjuvant therapy with its associated consequences. Spillage—defined as transgression of the tumor capsule during operative removal, whether accidental, unavoidable, or by design—can be minimized with careful, gentle tumor handling. A spill would also occur if the surgeon transects the renal vein or ureter at the site of tumor extension. Percutaneous or open-needle biopsies are also considered local spillage, unless the peritoneal cavity has been grossly contaminated in the process.

Rupture refers to either the spontaneous or posttraumatic preoperative tumor breach with subsequent dissemination of neoplastic cells into the retroperitoneum and/or the peritoneal cavity (Figure 33.13). The finding of bloody peritoneal fluid is considered a sign of generalized abdominal soilage. When a hematoma is present, it is presumed

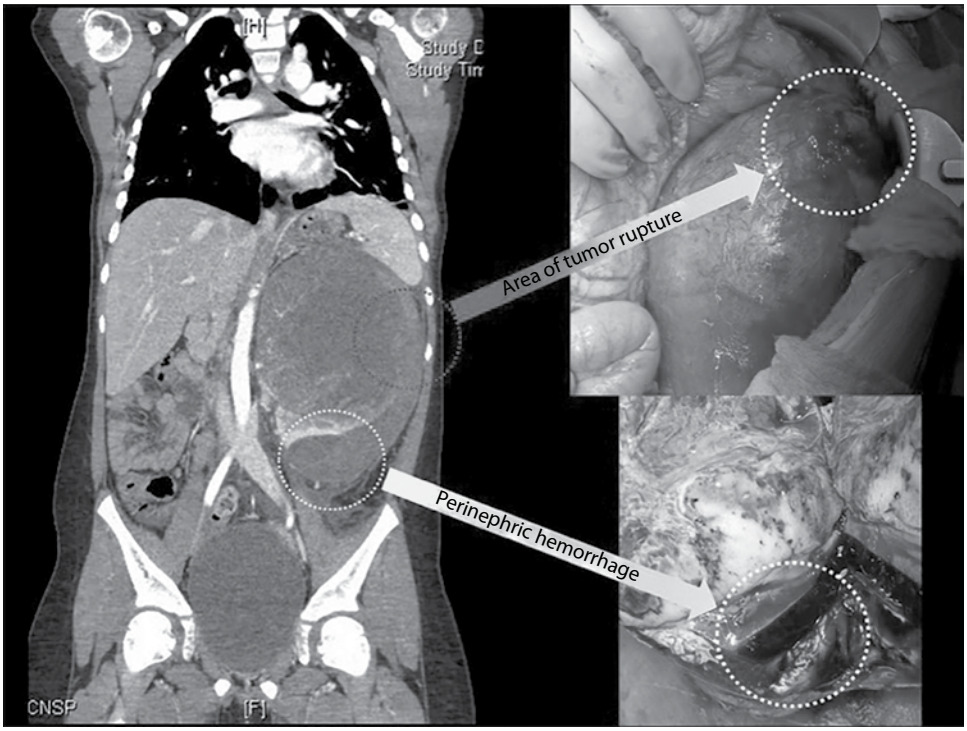

FIGURE 33.13 Renal tumor with preoperative imaging evidence of rupture.

that tumor cells are present in it, and the risk of contamination increases, particularly if the hematoma is entered or disrupted during dissection. Major soilage is also considered when the tumor penetrates the kidney capsule and the overlying peritoneum, with neoplastic tissue surface being in free communication with the peritoneal cavity. Separate, distinct nodules of tumor on the peritoneal or serosal surfaces, at a distance from the primary neoplasm, so-called "satellite implants," are also considered a sign of prior dissemination.[10] At the time of surgery, such lesions should be biopsied or removed, depending on the location, size, and involvement of adjacent structures.

Synchronous Bilateral Tumors and Conditions at Risk for Metachronous Lesions

In children with bilateral tumors (stage V) at the time of diagnosis, survival without early development of renal insufficiency has improved, with a focus on sparing renal parenchyma.[42] Unfortunately, renal failure has been described in 9.1% of these children.[43] Avoiding RN is recommended.[42] Primary excision of large tumor masses should also be discouraged unless absolutely necessary, such as in the case of rupture and persistent bleeding.

After initial chemotherapy, the patient is reassessed with axial imaging studies at 6 weeks. If imaging suggests that PN is feasible, it is reasonable to proceed with surgical exploration; otherwise, the process is repeated at 12 weeks. The goal, whether at week 6 or 12, is to accomplish complete resection of tumor with negative margins while preserving the greatest amount of viable kidney. However, surgery should not be delayed past 12–16 weeks to limit the risk of chemoresistant clonal expansion and avoid futile additive exposure to chemotherapy with little further gains in size reduction. A good response is associated with pathological improvement in terms of size regression, development of a pseudocapsule between normal parenchyma and tumor, and a more favorable consistency. Biopsies remain crucial for patients that do not appear to be responding to chemotherapy, since—aside from anaplastic lesions—tumors with complete necrosis and chemoresistant predominant histology can increase in size during therapy. Despite the apparent poor clinical and radiological response, differentiation of the tumor after chemotherapy has also been reported. Stromal and epithelial predominant tumors are often seen after chemotherapy, with reasonable prognosis as long as the tumor is completely excised.[10,23] In nonresponding tumors, concerns over undiagnosed anaplasia are always present.[44] Anaplastic tumors are less likely to respond to standard chemotherapy, thus making surgical resection more challenging. Due to the prognostic and chemotherapy resistance implications, any surgical procedure in patients with suspected anaplasia must ensure complete resection of the tumor, and complete (radical) nephrectomy is sometimes advocated in these cases.

A similar approach is commonly employed in children with a higher risk of metachronous renal tumors, such as patients with predisposition syndromes (including aniridia and overgrowth syndromes, like Beckwith–Wiedemann syndrome and idiopathic hemihypertrophy[45]). The concept of nephron-sparing procedures is identical to that for cases with synchronous lesions. Nevertheless, lesions are often smaller and not always managed with preoperative chemotherapy due to their size (detected with screening ultrasounds if the predisposition syndrome diagnosis

predates development of the renal neoplasm) and the possibility that the finding may represent a nephrogenic rest and not a WT.

Despite efforts to save functional renal parenchyma, some children will progress or develop end-stage renal disease soon after attempted surgical management of BWT (or renal tumors in a solitary kidney). In these cases, it is recommended to wait 2 years before renal transplantation.[46] When renal transplantation is considered, evaluation should take into account any vascular involvement and radiation fields, to maximize the chances of allograft anastomosis in a favorable location. Similarly, due consideration should be given to remove all native renal tissue prior to transplantation.

Partial Nephrectomy or Nephron-Sparing Resection

Following the successful introduction of nephron-sparing surgical techniques in adults with RCC, the concept has been introduced in the pediatric arena, currently favored in cases of bilateral neoplasms, solitary kidney, poorly functioning contralateral kidney, preoperative renal insufficiency, and predisposition syndromes. This shift has occurred with the aim to reduce the incidence or delay the development of renal insufficiency, which can have important implications in terms of morbidity and mortality during long-term follow-up.[43] Thus, the need for RN should always be questioned in patients with unilateral disease, and attention should be paid to rule out conditions at risk for contralateral tumors (i.e., aniridia, Beckwith–Wiedemann syndrome, and hemihypertrophy[47,48]) before rushing to surgery associated with the removal of valuable functional renal parenchyma.

Technical aspects are key to good surgical and oncological outcomes. Generous pre- and perioperative hydration is useful to optimize renal perfusion and decrease prerenal compromise due to relative volume depletion. In addition, the use of mannitol (given intravenously 5–10 minutes before renal artery occlusion) may help ameliorate ischemic renal damage. Whenever possible, resection should be done without clamping the renal artery (zero ischemia) or with selective occlusion of branches perfusing only the tumor area. In most cases, systemic anticoagulation is not necessary, and may increase the risk of bleeding during or after surgery. Even though laparoscopy or robotic or flank incisions are often favored in adults, pediatric cases are still done through an open transperitoneal approach. After opening Gerota's fascia, the kidney is elevated on its vascular pedicle. The perirenal fat overlying the tumor is left adherent and intact, and removed with the lesion. Use of intraoperative ultrasound is helpful to define small lesions or endophytic tumors, and can help define margins of resection, as well as proximity to large vessels or the collecting system. Once the lesions to be excised are identified, capsular incision limits are outlined with electrocautery. A thin rim of normal-appearing parenchyma should be included. Large vessels are controlled with absorbable sutures as the dissection progresses. Hemostasis along the parenchymal surface is then completed with argon beam coagulation and hemostatic agents (Figure 33.14).

Intrarenal surgery benefits from good hemostasis and a relatively bloodless field, conditions that sometimes

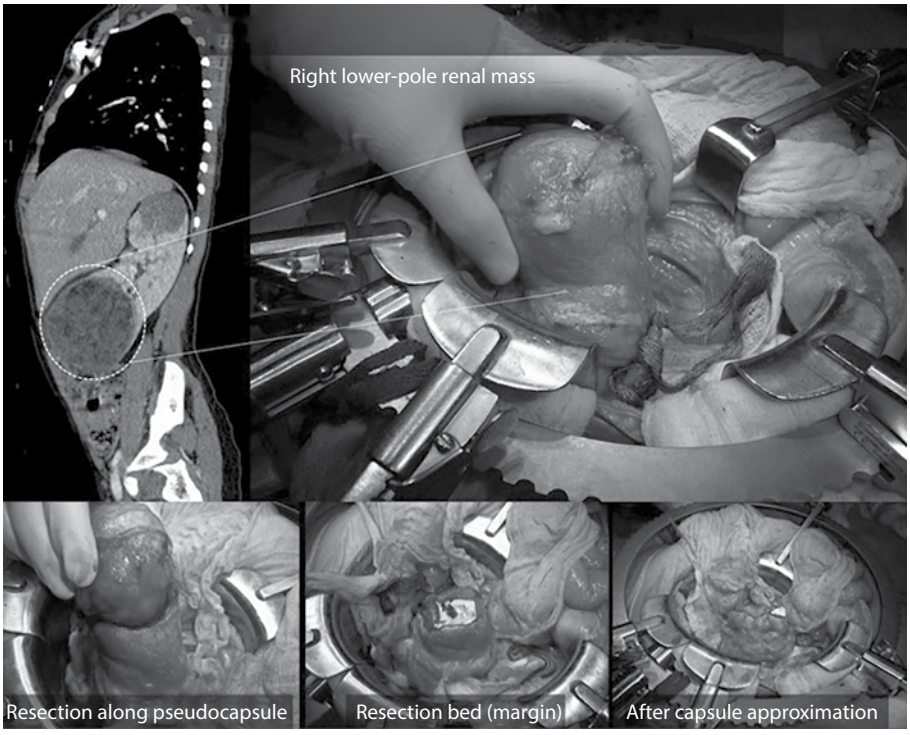

FIGURE 33.14 PN (nephron-sparing surgery) in a patient with bilateral renal masses. Resection of residual large lower-pole mass following neoadjuvant chemotherapy.

demand temporal occlusion of the renal pedicle. Clamping under normothermia provides a reasonable safe period of warm ischemia for approximately 20–30 minutes. If longer time is expected, ischemia tolerance can be prolonged with surface cooling using ice slush, understanding that there is a time-dependent risk of irreversible necrosis. In situ cold perfusion is an alternative that has been used in patients with multifocal BWT.[49] The interval of renal protection is similar to that obtained by surface cooling with slush; however, the arteriotomy and the venotomy used for continuous perfusion increase the risk of subsequent thrombosis. Digital compression of the renal parenchyma proximal to the line of resection often achieves satisfactory hemostasis, obviating the need for vascular occlusion. Irrespective of the technique employed, the renal vascular pedicle should always be encircled with vessel loops to provide rapid access and clamping in the setting of significant or difficult-to-control hemorrhage.[48]

The collecting system may be entered during resection. Identification can be aided by retrograde instillation with methylene blue (via a ureteral stent or by direct puncture into the renal pelvis). Once the opening is defined, it should be closed in a watertight, tension-free fashion with absorbable sutures. The decision to place an indwelling ureteral stent is based on the degree of disruption of the collecting system and the complexity of its closure, with a tendency to favor using one. Additional control can then be obtained by folding the kidney over the cut surface, using Surgicel® or another hematostatic agent over the raw surface. If excessive tension is noted during this maneuver, omentum or Gerota's fascia with perinephric fat can be used to bridge the defect. A closed suction drain is placed near the area of repair and generally removed before patient discharge, at least a day or two after removing the indwelling Foley catheter. Internal stents are removed cystoscopically 2–4 weeks later, taking into account postoperative adjuvant treatment protocols.[50]

Multiple frozen sections of the tumor margins should be obtained to verify that the resection extent is adequate. An additional slice of renal tissue may be resected if the margins are not clear, again with the aid of intraoperative ultrasound.[51] Oftentimes, it is difficult to differentiate resection from enucleation, which involves circumferential dissection along the pseudocapsule surrounding the tumor. This provides an easier plane for blunt dissection, with the advantage of increasing the ability to remove multiple tumors with maximum preservation of normal renal parenchyma and limited bleeding, at the expense of missing tumor penetration past the pseudocapsule.[52] This strategy increases the risk of entering the tumor and creating local spillage, resulting in upstaging.[53] If anaplasia is diagnosed before, during, or after the operation, in absence of clear margins, excision of the whole kidney is favored. As previously mentioned, some argue that anaplasia is an indication for RN irrespective of the margin status, and a relative contraindication for nephron-sparing surgery. This is debatable, yet an understandable approach considering the adverse impact anaplasia has on prognosis.

A baseline ultrasound of the kidney should be obtained within the first 2 weeks postoperatively. A recommended 1-year follow-up includes clinical examination and abdominal ultrasound monthly, chest x-ray every 3 months, and CT or MRI every 6 months.[53] At follow-up, the differential function of each kidney can be assessed by DMSA.[48]

PEDIATRIC RENAL CELL CARCINOMA

Clinical Presentation

RCC is relatively rare in children, representing less than 0.1% of all malignancies and 2%–6% of all renal tumors. It becomes more common in older children and adolescents (mean age 9–10 years).[54,55] Evidence suggests that pediatric RCC may be a different entity from adult counterparts, with distinct morphologic characteristics and unique genetic abnormalities. Childhood RCCs are more frequently papillary[56] and associated with Xp11.2 or TFE3 translocation.[55,57]

Patients often present with gross hematuria, flank pain, and/or a palpable mass, although about 12% of patients are asymptomatic, with the tumor detected incidentally by imaging.[58] RCC can be associated with important predisposition syndromes, such as von Hippel–Lindau, in which the tumors tend to be bilateral, associated with renal cysts, and prone to metachronous recurrences.[59,60] Survival is impacted by stage at presentation and completeness of resection, with an overall survival of 64%–87%.[55,61] More specifically, the 5-year survival is higher than 90% for stage I disease, 85% for stage II, 73% for stage III, and about 14% for stage IV.[62]

Imaging

A CT scan or MRI usually shows a solid renal lesion with variable enhancement. Heterogeneous areas of hemorrhage and necrosis may be present. There is a higher frequency of calcification in RCC (25%) than in WT (9%).[59]

Treatment

Therapeutic strategies for pediatric RCC have been extrapolated from the adult literature. Retrospective and observational data indicate that following adult protocols is reasonable, as doing so provides acceptable morbidity and overall survival.[61] Nephrectomy alone is adequate for stages I and II, with great outcomes with complete resection.[61,63] Also following trends in adult literature, nephron-sparing surgery has been considered for these patients. Cook et al.[64] reported excellent outcomes in patients who underwent nephron-sparing surgery for stage I or II, less than 4 cm RCC with 100% disease-free and overall 5-year survival.

The surgical technique for both RN and PN follows the steps described previously in this chapter. Importantly, though, is the increasing comfort with alternative approaches, such as flank (extraperitoneal) incision or minimally invasive (laparoscopic or robotic) options.

Treatment of metastatic disease is challenging because the tumor, as in adult counterparts, is poorly responsive to radiotherapy and there are limited chemotherapeutic regimens with modest benefit.[55] In very selected patients with obvious metastatic disease, there may be benefit in performing cytoreductive nephrectomy.[65,66] Currently,

part of the standard of care for metastatic RCC in adults involves the use of tyrosine kinase inhibitors (TKIs) and targets of vascular endothelial growth factor receptors, a trend that has expanded into the adolescent and pediatric practice.[55,58,61,67,68]

Laparoscopic Nephrectomy

In the past few decades laparoscopic radical nephrectomy (LN) has become the standard of care for localized renal tumors in adults, when PN is not feasible.[69,70] In children, however, the role of LN for renal masses has not been clearly defined. As WTs usually present with a large, friable palpable mass, offering laparoscopic resection (without preoperative chemotherapy) has been hampered by concerns over tumor rupture. Duarte et al., in 2004, published the first report of LN, showing feasibility and safety after chemotherapy.[71] Following this, several case series have been published, concluding that LN is reasonable, with no short-term adverse oncological results and the advantage of a shorter hospital stay and improved cosmesis.[72,73] Romao et al.[74] presented a series comparing the outcome of LN with RN in the management of renal tumors. Only six patients had preoperative chemotherapy (2 of 13 in the LN group vs. 4 of 32 for RN). They concluded that LN is an alternative to RN in well-selected cases of renal tumors, especially for small lesions or older children. As the age of the patient increases, and they enter adolescence, a stronger case can be made for minimally invasive options, following the aforementioned trends in adult cases (with predominant RCCs). Ultimately, multicentric prospective studies with longer follow-up are mandatory to confirm oncological outcomes similar to those of conventional open RN.

Surgical Technique

The patient is positioned in a semilateral position (30°). A semilunar umbilical incision is performed to gain access to the abdominal cavity following a modified Hasson technique.[75] A 5–10 mm trocar is placed and pneumoperitoneum is obtained using CO_2 to a pressure of 10–12 mm Hg. Using a 30° camera, the peritoneal cavity is examined. Two accessory trocars are placed: the first (10 mm) near the ipsilateral iliac fossa, and the second (5 mm) subcostally at the anterior axillary line. A third (5 mm) additional trocar can be placed near the xyphoid to help with the spleen or liver retraction.

Following similar surgical principles as in open surgery, the colon is mobilized medially to gain access to the retroperitoneum. Carefully, the anterior surface of the kidney is dissected off from the peritoneum layer. The ureter is then identified over the psoas muscle. Using blunt dissection, the ureter is lifted up, developing the posterior plane between the psoas and Gerota's. This maneuver facilitates identification and dissection of the renal hilum. At this point, the renal vessels are bluntly dissected; a suction irrigator is usually helpful for this step. The artery and vein are individually ligated, clipped, or controlled with a laparoscopic vascular stapler. After vascular control has been achieved, dissection of the upper pole is accomplished with sparing of the adrenal, if possible. Following complete mobilization of the kidney, the ureter is clamped and sectioned. Lymph node sampling is then completed; the specimens are placed in a plastic bag introduced through the 10 mm accessory trocar. The intact bag with the kidney and lymph nodes is then removed through a Pfannestiel incision.

CHAPTER
34

Upper Urinary Tract Trauma

Ardavan Akhavan and Paul A. Merguerian

SIMILARITIES AND DIFFERENCES IN EVALUATING PEDIATRIC VERSUS ADULT TRAUMATIC INJURIES

General Comments

Whether the incidence of renal injury following blunt abdominal trauma is increased in the pediatric compared with the adult patient population is controversial.[1–4] Hypothetically, the pediatric kidney is believed to be more susceptible to trauma due to a decrease in the physical renal protective mechanisms found in childhood, namely, a slightly lower renal position in the abdomen, an immature thoracic cage, and weaker abdominal musculature. Statistical evaluations to confirm that children have an increased risk of renal injury have revealed mixed results, and the question remains unresolved.[1–5] Overall, though, children appear to have nearly twice the incidence of renovascular injury than adults.[1] Additionally, preexisting congenital renal abnormalities are found three to five times more often in pediatric patients undergoing a screening CT scan for trauma than in the adult population.[2–4,6] *Classically, patients with a preexisting genitourinary (GU) abnormality present with a history of hematuria disproportionate to the severity of trauma*. In the pediatric population, the most common preexisting GU anomalies found, listed in decreasing frequency, are ureteropelvic junction (UPJ) obstruction, hydroureteronephrosis secondary to reflux, horseshoe kidney, nonobstructing–nonrefluxing hydronephrosis or hydroureteronephrosis, and primary obstructing megaureter.[2–4]

Traumatic-Induced Hematuria

In children, hematuria is unreliable in determining the extent of renal injury; some studies have failed to find any evidence of either gross or microscopic hematuria in up to 70% of children sustaining renal injuries grade 2 or higher. (For grading of renal injuries, see Table 34.1.) Microscopic hematuria has been reported to have a sensitivity and specificity of only 59% and 14%, respectively; the positive predictive value of gross hematuria has been found to be as low as 18%.[7] In essence, posttraumatic hematuria cannot be used as the sole determinant in deciding whether to begin the workup for renal injury.[8,9]

Indications for Imaging the Genitourinary Tract Following Trauma

In the adult, radiographic assessment of the GU tract is recommended following all penetrating trauma, as well as blunt trauma victims that fit one of the following criteria:

1. A significant deceleration (motor vehicle accident [MVA], fall from >15 feet) or high-velocity injury (strike to the back or flank with a high-velocity foreign object, i.e., football helmet, baseball bat, etc.)
2. Significant external trauma resulting in fractures of the thoracic bony structures, spine, pelvis, and femur; bruising of the torso or perineum; and/or signs of peritoneal irritation
3. Gross hematuria
4. Microscopic hematuria (>50 red blood cells per high-power field) associated with shock (systolic blood pressure less than 90 mmHg)[4,10–13]

Clinicians debate about whether the adult screening criteria outlined above apply to children.[7,8,11,14–18] This controversy is based on three separate concerns. First, hypotension in children is not a reliable indicator of the severity of injury. *Children often have normal blood pressure in spite of significant blood loss*. In children, serial hemoglobin determination is a better assessment of blood loss than hypotension.[15] Second, there is no consensus opinion in the literature regarding the definition of an associated injury in the child. For example, pediatric trauma clinicians have not established whether an isolated closed-head injury indicates the need for a screening abdominal computerized tomogram (CT).[8] Finally, there is no standard definition of a deceleration or high-velocity injury, with some authors neglecting to include the latter criteria in their list of indications for abdominal three-dimensional imaging. Despite these discrepancies, though, Santucci and colleagues determined that adult screening criteria are still useful in children and should be used to work up children for renal injury following trauma.[11]

RADIOGRAPHIC AND ENDOSCOPIC ASSESSMENT AND TREATMENT OF GENITOURINARY INJURIES

Abdominal and Pelvic CT and Single-Shot IVP

The patient's hemodynamic stability determines whether, when, and occasionally what type of imaging studies should be done. *In the clinically stable patient, a triphasic abdominal and pelvic CT scan (precontrast study, followed by a study immediately after injection of contrast and then a 15- to 20-minute delayed study) is the most sensitive method for diagnosis and classification of GU trauma*. See Table 34.1 for classification of renal trauma.[4,8,9,11,12,16,17]

In the clinically unstable patient, a single-phase CT scan is frequently obtained with the images taken immediately following injection of contrast. This test is beneficial in determining renal perfusion and the presence of major renal fractures, but it is unable to accurately determine the presence of urinary extravasation and will miss the majority of isolated ureteral injuries.[2,19,20] In the unstable patient requiring emergent laparotomy with no preoperative imaging studies, once the patient is stabilized in the operating room, a one-shot intravenous pyelogram (IVP) (2 mL/kg intravenous bolus of contrast) with the x-ray taken 10–15 minutes following injection of contrast may be beneficial in determining a normally functioning contralateral kidney if unilateral nephrectomy is a consideration.[21] As an alternative to the single-shot IVP, a CT can be delayed until after the patient is resuscitated and stabilized; if necessary, definitive surgical repair of GU injury can often be deferred for 12–24 hours, as long as the patient's condition permits it.[4,22]

Indications and Use of Arteriography

As many as 25% of grade 3 and 4 renal trauma managed by nonoperative protocols will require angiography and selective angioinfarction of bleeding vessels for persistent or delayed renal hemorrhage.[23,24] Clinical signs of persistent bleeding are hematuria associated with blood clots in the voided or catheterized bladder and a falling serial hemoglobin. Orthostatic blood pressure alterations are a late finding in the pediatric population.[4,23,25–27] Delayed hemorrhage classically develops 10–14 days postinjury, but may occur up to 1 month later. Delayed hemorrhage usually arises from the development of arteriovenous (AV) or pseudoaneurysm malformations.[4,25–27] Unlike AV malformations arising from a renal biopsy, AV malformations following renal fractures rarely, if ever, resolve spontaneously. Nearly all require active intervention.[4,25–27]

Superselective angiographic embolization of isolated renal artery branches for persistent or delayed hemorrhage has a success rate approaching 80%. This is the preferred treatment method for persistent or delayed bleeding, with surgical exploration reserved for angioembolization failure.[4,25–28] Occasionally, angiographic embolization is used to treat persistent urinary fistulas. In this clinical scenario, a functionally transected renal fragment following a high-grade renal injury is completely separated from the renal collecting system, and a persistent urinary fistula develops despite management by a double-J stent and/or a percutaneous nephrostomy tube. In these unusual patients, selective angiographic embolization can be performed to resolve the urinary fistula by necrosing the isolated functional renal fragment.[4,29]

Postembolization syndrome (fever, flank pain, and an adynamic ileus) is a well-recognized and self-limiting condition that occurs after angiographic embolization. Symptoms usually resolve by the fifth postembolization day.[4,30–33] Bacterial seeding of either the necrotic renal tissue or the hematoma from the angiographic intervention must be ruled out in patients with postembolization fever. It is therefore mandatory to obtain blood and urine cultures if a febrile response develops postembolization. In this setting, the clinician should consider a repeat CT scan with possible aspiration and culture of the hematoma or urinoma if symptoms persist for 5 or more days after embolization.[4,33]

Indications and Use of Retrograde Pyelography and Percutaneous Drainage

In patients with a history of trauma, two indications exist for performing retrograde pyelography. First, it can be

TABLE 34.1 Grading of renal injuries

Grade of renal injury	Description
1	Renal contusion or subcapsular hematoma
2	Nonexpanding perirenal hematoma, <1 cm parenchymal laceration, no urinary extravasation, all renal fragments viable
3	Nonexpanding perirenal hematoma, >1 cm parenchymal laceration, no urinary extravasation, renal fragments may be viable or devitalized
4	Laceration extending into the collecting system with urinary extravasation—renal fragments may be viable or devitalized, or injury to the main renal vasculature with contained hemorrhage
5	Completely shattered kidney—by definition multiple major lacerations of >1 cm associated with multiple devitalized fragments, or injury to the main renal vasculature with uncontrolled hemorrhage, renal hilar avulsion

used to rule out the presence of a partial or total ureteral disruption; second, it can aid in the placement of a double-J ureteral stent for the management of a symptomatic urinoma.[2–6,19,28,34–36] Most posttraumatic urinomas are symptomatic. Approximately three-fourths of urinomas resolve spontaneously.[4,34,37–39] *Persistence of the urine collection may be associated with persistent flank pain, adynamic ileus, and/or low-grade temperature, necessitating either percutaneous or endoscopic intervention.*[34] Cannon and colleagues determined that conservative management is more likely to fail in patients with no contrast in the ipsilateral ureter, those with a large separation of the upper and lower poles, children with multiple areas of extravasation, and patients with blood transfusion requirements.[40] Although percutaneous drainage and internal stenting are both efficacious, the major advantages to internal drainage include improvements in quality of life during convalescence, specifically avoidance of external catheter care, and the reduced risk of inadvertent tube dislodgment.[4,34,37,41] A disadvantage of internal drainage is that stent placement and removal requires general anesthesia in the child. In addition, smaller ureteral stents (4–5 French) placed in young children can become blocked with debris and blood clots from the dissolving hematoma. Percutaneous nephrostomy tubes should be considered in the following three scenarios: (1) after failure of endoscopic intervention, (2) when managing unstable patients who may not tolerate general anesthesia, and (3) when managing patients at risk for stent obstruction due to debris or hematoma.[34,37]

Indications and Use of DMSA and Follow-Up Radiographic Imaging Following Renal Trauma

Follow-up imaging is typically unnecessary for grade 1 and 2 renal injuries, unless the clinical scenario suggests progressive pathology, as indicated by unrelenting hypertension, fever, dropping hemoglobin, hemodynamic instability, worsening flank pain, progressing renal failure, or persistent hematuria. In patients with grade 3, 4, or 5 renal injuries, we recommend that a repeat CT scan with delayed images be obtained 2–3 days after the traumatic insult. This study assesses the extent of the hematoma or urinoma and functions as a baseline evaluation in case delayed hemorrhage occurs.[4,6] Additional repeat CT scans may be considered depending on the clinical scenario.[6] We also recommend that a 3-month follow-up CT scan be performed in all grade 3–5 renal injuries. This latter study is used to verify resolution of a perinephric hematoma or urinoma and to define the anatomic configuration of the residual functioning renal parenchyma.[9] The nature of follow-up imaging, though, is controversial; other authors have reported successful outcomes using only ultrasonography on children following blunt renal trauma after initial staging, reserving CT scanning for selected patients with clinical symptoms or sonographic findings suggestive of progressive pathology.[42]

Nuclear renal scanning using dimercaptosuccinic acid (DMSA) allows the physician to determine renal cortical function and differential renal function. Serial DMSA scans have revealed that little, if any, renal parenchyma recovers function after 7 days postinjury; therefore, a DMSA scan obtained more than 1 week after the injury provides a valid estimate of subsequent renal function.[43,44] We suggest that all patients with grade 3 injuries with devitalized fragments, all patients with grade 4 and 5 injuries, and all patients with persistent posttraumatic hypertension be evaluated with a quantitative radionuclide scintography, preferably DMSA, at least 1 week following the trauma.[4,43] Provided the serum creatinine is normal, a differential renal function exceeding 30% suggests satisfactory function that would prevent renal failure in the event that the uninjured kidney is lost.[4,39,44]

EFFECT OF ETIOLOGY ON THE MANAGEMENT OF TRAUMATIC GU INJURIES

Blunt versus Penetrating Genitourinary Trauma

The etiology of the traumatic injury plays an important role in determining the management of the patient. In North America, blunt trauma, usually due to high-velocity or deceleration injury, causes 90% of renal injuries in children. Fewer than 2% of children with blunt trauma require radiographic or surgical intervention.[4,6,9,38] Approximately 10% of traumatic pediatric renal injuries are due to penetrating trauma. In the presence of penetrating trauma, the physician should immediately triage the patient into one of two groups depending on the source of the penetrating trauma: either a stab or low-velocity penetrating wound group or a high-velocity penetrating wound group.[4,6,9] Although penetrating trauma results in the risk of wound contamination by outside material, several studies have shown that a selective nonoperative approach to the management of patients with a stab wound and, in very select cases, low-velocity gunshot wounds can be safely implemented.[4,25,45,46] *In hemodynamically stable patients with a penetrating wound posterior to the anterior axillary line, intravenous antibiotics are initiated and a screening triphasic abdominal and pelvic CT is obtained.* In these patients, surgical exploration or laparoscopy is indicated for persistent blood loss, the presence of air in the peritoneum, signs of developing peritonitis, or radiographic findings consistent with a ureteral injury.[4,25,46–49]

Gunshot wounds to the trunk are associated with a GU injury approximately 15% of the time.[47] In patients with GU trauma secondary to a gunshot wound, the kidney is the site of injury in approximately 60% of the patients, the bladder in 20%, the urethra in 5%, and the ureter in 2%; 13% will have two or more GU injuries.[47,50] If a GU structure is traumatically damaged due to a gunshot wound, the likelihood of associated organ injury is approximately 90%.[23,47,50] While the majority of blunt renal trauma and the majority of penetrating renal trauma from stab wounds are amenable to complete radiographic staging and nonoperative management, gunshot wounds to the abdomen often result in a hemodynamically unstable patient with multiple associated organ injuries requiring urgent

TABLE 34.2 Consensus recommendations for management of renal trauma

Clinical findings and/or grade of renal injury	Recommended treatment
Grade 1 or 2 renal injury irrespective of traumatic etiology[a]	Nonoperative
Isolated grade 3 or 4 and hemodynamically stable grade 5 renal injuries	Nonoperative
Uncontrollable renal hemorrhage/vascular instability (usually grade 4 vascular or the vast majority of grade 5 injuries)	Absolute requirement for surgical intervention
Persistent or delayed hemorrhage not responding to angiographic embolization	Absolute requirement for surgical intervention
Expanding pulsatile retroperitoneal mass found on surgical exploration for coexisting intra-abdominal injuries	Absolute requirement for surgical intervention (verify contralateral renal function prior to exploration)
Penetrating trauma, inadequate preoperative radiographic staging due to vascular instability of patient, retroperitoneal hemorrhage found on exploration	Retroperitoneal (renal) exploration strongly recommended (verify contralateral renal function)
Blunt trauma; inadequate preoperative radiographic staging due to vascular instability of patient; coexisting intra-abdominal injuries, especially stomach, duodenum, pancreas, and colon; retroperitoneal hemorrhage found on exploration	Retroperitoneal (renal) exploration recommended (verify contralateral renal function)
Blunt trauma; radiographic screening studies reveal grade 3, 4, or 5 renal injury; coexisting intra-abdominal injuries, especially stomach, duodenum, pancreas, and colon	Retroperitoneal (renal) exploration recommended

[a] Assuming adequate radiographic staging and no absolute indication for exploration.

laparotomy.[45] The need for emergent surgery excludes the ability to adequately stage the renal injury.[23,24,47] If the patients with a gunshot wound can undergo adequate radiographic staging, isolated grade 1 or 2 renal injuries can be managed successfully with a nonoperative approach with minimal complications (Table 34.2).[44]

Gunshot wounds caused by high-velocity missiles (>350 m/s) deserve special consideration. The kinetic energy of a high-velocity bullet creates a surrounding energy wave 30–40 times the missile diameter. In addition, the missile will frequently yaw or tumble during penetration. The combination of blast injury and missile tumbling results in extensive damage to the surrounding tissues at a large distance from its path.[6] With high-velocity gunshot wounds to the torso, radiographic and/or surgical evaluation at the time of the assault may not reveal the presence of a GU injury. In some patients with a high-velocity injury, the renal pelvis and/or ureter will appear intact or perhaps only slightly contused at the time of the radiographic examination and/or surgical exploration. As the high-velocity blast injury matures, necrosis of the ureter or portions of the renal pelvis may develop. The extent of the GU injury often comes to attention days later, as urinary extravasation develops due to delayed necrosis.[4,51,52]

MANAGEMENT OF RENAL TRAUMA

Multiple studies have stated that the nephrectomy rate in patients with traumatic renal injuries is higher with surgical exploration than with nonoperative management.[39,46,53–56] These reports suggest that hemorrhage from the severely injured kidney is tamponaded by the intact Gerota's fascia. Surgical exploration in these cases disrupts the fascia, resulting in uncontrollable renal bleeding and the need for emergent nephrectomy. This reasoning is controversial. With the enhanced ability of the CT scan, we are now more accurately staging renal injuries. With the development and application of trauma-related severity scores, the need for emergent nephrectomy during renal exploration has seemed to be related more to the severity of the initial renal injury, and multiple coexisting injuries and related intraoperative hemodynamic instability, rather than to disruption of Gerota's fascia. Nephrectomy in this situation is performed for expediency to save the hypothermic, coagulopathic, and clinically unstable patient.[4,37,57–60]

Due to this controversy, three different concepts have been suggested to best determine the management of coexisting intra-abdominal trauma and grade 3 or higher renal injuries:

1. Observation unless an absolute indication for renal exploration exists, regardless of the mechanism of injury.[39,46,51]
2. Renal exploration and renorrhaphy of a grade 3 or higher renal injury. This should be completed if a laparotomy is to be performed for a coexisting intra-abdominal injury. If renal exploration is performed, we recommend that control of the renal vessels medial to Gerota's fascia be obtained before renal exploration.[4,6,37,61] In this setting, control of the renal vessels prior to opening Gerota's fascia may prevent life-threatening hemorrhage. With passage of time, even the need for vascular control before renal exploration has become controversial, with some studies revealing the incidence of nephrectomy being equivalent whether or not prior vascular control is used.[4,6,58,61]
3. Exclusion of renal exploration in patients with concurrent intra-abdominal injuries, provided the trauma surgeon separates the enteric injury from the urinary tract injury with omentum or other alternative tissue and places perioperative drains. It is hypothesized that the separation of the enteric or pancreatic injury from the GU injury, along with the placement of perioperative drains, will prevent breakdown of enteric repairs

by leaking urine and/or help prevent the development of urinary tract complications by removal of excess contaminating bacteria or pancreatic enzymes away from the site of the GU injury.[6,37,57,62,63]

The current recommendations for operative intervention are based on three findings: the hemodynamic stability of the patient, an accurate radiographic staging of the renal trauma, and the presence of associated organ injury.[4,6,23,34,37] Absolute indications for renal exploration include life-threatening hemorrhage from a renal source (usually grade 4 vascular and the majority of grade 5 renal injuries), a pulsatile expanding retroperitoneal hematoma found during emergent laparotomy, and persistent or delayed renal bleeding refractory to angioinfarction.[4,6] It is also strongly recommended that patients with penetrating trauma found to have a retroperitoneal hematoma in the absence of adequate preoperative imaging be explored once contralateral renal function is verified by an intraoperative single-shot IVP.[4,6]

The ideal candidate for nonoperative management is the hemodynamically stable patient sustaining either blunt or penetrating trauma and grade 1 or 2 renal injury, with or without associated intra-abdominal injuries. GU complications in this subset of patients are minimal.[4,6,23] In patients with isolated grade 3 or 4 renal injuries, angiographic, endoscopic, or percutaneous intervention is required in up to 55% of them. Intervention is necessary for delayed bleeding in approximately 25%, and for symptomatic urinomas in approximately 25%. Surgical exploration to control complications not amenable to nonoperative techniques will develop in approximately 5%. In essence, conservative management of isolated grade 3 or 4 renal injuries will avoid approximately 95% of open surgical intervention.[4,6,9,23,34,37,62,64]

Contemporary series are plagued with small cohorts of children with higher-grade injuries; however, when pooling data together, it is evident that conservative approaches toward blunt renal trauma have resulted in high renal preservation rates.[28,35,36,45,64–72] Table 34.3 lists contemporary series of children with blunt grade 4 and 5 renal injuries managed conservatively. Of the 144 children with grade 4 trauma, there is a 96% renal preservation

rate. Fifteen percent underwent open surgery, consisting of partial nephrectomy, renorrhaphy, or pyeloplasty, and 14% were primarily managed with minimally invasive procedures, such as ureteral stenting, nephrostomy, or angioablation. Of the 72 children with grade 5 trauma, we tabulated a 64% renal preservation rate, with 22% of patients requiring an open repair and 11% needing endoscopic or percutaneous intervention. These renal preservation rates, though, are likely overestimates, as Keller et al. reported significant renal scarring volume loss in the majority of children following conservative management of grade 4 and 5 trauma.[39]

The recommendations for treating a patient with a history of blunt abdominal trauma who has either inadequate radiographic staging and a nonexpanding and nonpulsatile retroperitoneal hematoma found on surgical exploration, or a known grade 3 or higher renal injury undergoing laparotomy for associated intra-abdominal trauma are more controversial. In these situations, the urologist should be aware of the relationship between the associated organ injury and the severity of the renal injury, and how these two factors relate to GU morbidity. For example, if a colonic injury and a retroperitoneal hematoma are simultaneously present, approximately 10% of patients will be found to have a grade 1 or 2 renal injury, and 90% will have a grade 3 or higher renal injury.[4,6,23] In addition, if a colonic or pancreatic injury is concurrently present with devitalized renal tissue, nonoperative management of the renal injury is associated with a three- to fourfold higher incidence of complications compared with renal exploration and renorrhaphy. In addition, renal exploration in these latter patients does not appear to result in increased risk of nephrectomy.[9,37,57,59] Knowledge of these facts has resulted in the consensus that *patients with a known grade 3 or higher renal injury undergoing exploratory laparotomy for multiorgan injury induced by blunt trauma should undergo renal exploration with renorrhaphy and the placement of retroperitoneal drains*. It is also accepted that patients undergoing emergent laparotomy without adequate preoperative radiographic studies who are found to have colonic or pancreatic injuries and a coexisting retroperitoneal hematoma should have a single-shot IVP obtained to verify contralateral renal function and proceed with renal exploration (Table 34.2).[4,6,9]

Nonoperative Therapy for Renal Trauma

Nonoperative therapy consists of bed rest, close monitoring of the vital signs and urine output, serial abdominal examinations, serial hemoglobin and hematocrit determinations, and transfusion as indicated. In the patient with a grade 3 or higher renal injury, massive blood loss and vascular instability may rapidly appear. The patient managed in this fashion should have blood immediately available. Repeat CT imaging of the kidney 2–3 days following trauma is recommended in patients with grade 3–5 renal injuries. CT imaging should be obtained earlier if prompted by clinical indications (see the "Indications and Use of DMSA and Follow-Up Radiographic Imaging Following Renal Trauma" section). If the child remains hemodynamically stable with or without transfusions and CT verifies a stable or resolving urinoma and/or hematoma, observation can continue. If the child becomes hemodynamically unstable or continues to have a falling hemoglobin or hematocrit despite transfusions, renal angiography with selective angioinfarction of the bleeding site should be attempted prior to formal surgical repair. If the patient with a urinoma complains of chronic or increasing flank pain, or has a persistent low-grade fever and/or a persistent ileus, consideration for endoscopic or percutaneous management of the urinoma is required. The patient may be allowed to walk as soon as gross hematuria has resolved. Resumption of strenuous physical activity is prohibited for 6 weeks.[4,6,9,23,24]

Due to the risk of wound contamination, we recommend intravenous broad-spectrum antibiotics in patients with a renal injury secondary to penetrating trauma on a nonoperative protocol. In renal injuries following blunt trauma, antibiotics may be considered if a large retroperitoneal hematoma or urinary extravasation is present. In this latter situation, the presence of an indwelling urethral catheter and/or multiple intravascular catheters may cause bacterial colonization of the urine or blood and may hypothetically result in an infected hematoma or urinoma.[4,6,9,23,24]

Operative Intervention for Renal Trauma

Renal salvage by renorrhaphy or partial nephrectomy requires complete exposure of the injured kidney, debridement of nonviable tissue, suture ligation of bleeding arterial vessels, and repair of collecting system injury. Defects in the renal parenchyma may be closed primarily with renal capsule. For larger defects, we prefer the placement of small pieces of Gelfoam wrapped in Surgicel directly into the parenchymal defect and closure of the renal capsule defect with woven polyglycolic acid mesh. Alternatively, perinephric fat, omentum, or thrombin-soaked Gelfoam may be used to pack the parenchymal defect. A watertight closure of the collecting system is not always possible and may be inadvisable. If the renal pelvis or ureter is closed with tension, tissue ischemia and delayed resolution of urinary leakage may occur. If a major violation of the urinary drainage system is present, placement of intraoperative ureteral stents and/or a nephrostomy tube should be considered. Adequate drainage of the perinephric area following repair is vital. In the presence of concurrent stomach, duodenal, pancreatic, and colonic injuries, interposition of omentum or peritoneum between the site of the major renal injury and the site of the coexisting intra-abdominal injury is usually necessary. Nephrectomy should be considered in irreparable grade 4 or 5 renal injuries and in hemodynamically unstable patients with multiorgan trauma.[4,6]

RENAL VASCULAR INJURIES

The kidney is an end organ; only rarely is collateral blood flow sufficient to maintain renal function if a segmental or main renal artery is damaged. In a patient sustaining renal arterial trauma, the clinical triad of decreased or absent renal arterial blood flow, inadequate collateral blood flow, and warm ischemia time almost invariably results in the loss of renal function.[4,6] *Therefore, no attempt to repair injuries to segmental renal vessels should be considered,*

and repair of the traumatically injured main renal artery is rarely indicated.[36] In essence, reconstruction of the main renal artery following trauma should only be considered in patients that are hemodynamically stable with an injury to a solitary kidney or in patients with bilateral renal injuries; otherwise, nephrectomy is the most expeditious and least moribund treatment. The infrequent exception to this rule is the presence of an incomplete renal arterial injury where perfusion to the kidney has been maintained by flow of blood either through the partially occluded main renal artery or via collateral vessels.[4,6]

Renal artery thrombosis is rare, occurring in as low as 0.1% of patients presenting with blunt abdominal trauma.[73] The injury is typically associated with acceleration–deceleration injuries, resulting in subintimal dissection and vascular thrombosis. Vascular compression by the vertebrae can also propagate intimal trauma, resulting in thrombosis. Hemodynamically stable patients without concomitant injuries necessitating exploration may be managed with arteriography and endovascular stenting.[74] Successful revascularization is dependent on ischemia time, with success rates dropping off dramatically after 2–3 hours; however, durable recovery of kidney function has been demonstrated following endoscopic revascularization after up to 1 week of ischemia following traumatic renal artery occlusion.[75] Endovascular stenting has also been utilized successfully in the management of penetrating renal artery trauma in children.[76] Unfortunately, the evidence for endovascular stenting as management for renal artery thrombosis or hemorrhage in children is limited to small series and case reports.

TRAUMATIC-INDUCED RENAL VASCULAR HYPERTENSION

The most common causes of posttraumatic renal hypertention are renal ischemia from segmental artery occlusion, main renal artery occlusion with intact peripheral blood flow to the kidney, a traumatically induced AV malformation, and compression of the renal parenchyma by hematoma or fibrosis (the Page kidney model). The presence of hypertension immediately following the traumatic insult may be secondary to pain; however, persistent hypertension 30 days postinjury could be due to a renal source, and the diagnosis of traumatically induced renovascular hypertension should be considered. The incidence of traumatically induced hypertension after renal injury is reported to be around 6% in contemporary grade 4 or 5 pediatric renal trauma series.[28,35,64–67,70,72]

Hypertension from renovascular trauma will usually develop within 36 months of injury.[4,6] If sustained hypertension develops, evaluation with a DMSA scan to determine differential renal function and radiographic studies (MRI or CT angiography) should be performed to rule out the development of an AV fistula. Hypertension related to an AV malformation should initially be treated with angiographic embolization. If consideration for surgical intervention is entertained, renal vein renin sampling for split renin ratios should be considered. The latter is especially helpful in the presence of segmental renal scarring where partial nephrectomy is a consideration for surgical management. The most common clinical finding in posttraumatic-induced hypertension; however, a small poorly functioning kidney (<30% differential renal function) is also associated with scarring. Most authorities believe that a differential renal function of <30% would not prevent the onset of renal failure in the event that the uninjured kidney is lost.[4,6,39,44] Nephrectomy or partial nephrectomy is therefore the treatment of choice for posttraumatic hypertension.[28] Rarely is renal revascularization of any benefit since hypertension is almost invariably produced by the production of increased renin from intrarenal or subcapsular fibrosis. Surgical treatment of hypertension by decortication of subcapsular fibrosis in patients with a Page kidney–induced hypertension has been published; however, the long-term results of this surgical treatment modality are extremely controversial.[4,6]

URETEROPELVIC JUNCTION DISRUPTION

If the screening CT evaluation reveals the presence of medial and perirenal contrast extravasation with no visualization of the ipsilateral distal ureter on delayed images, the diagnosis of either a large laceration of the renal pelvis or an avulsion of the UPJ is entertained and mandates further investigation with either a retrograde pyelogram or surgical exploration.[4,6,19] *Disruption of the UPJ is most commonly caused by acceleration–deceleration injuries (fall from >15 feet) or by sudden extreme hyperextension of the trunk (pedestrian–vehicle collision or patient thrown from the vehicle during a motor vehicle accident).* The mechanism of injury is due to a sudden displacement of the more mobile kidney associated with a relatively fixed ureter, with force vectors from the traumatic impact interacting at the UPJ.[2,3,19]

Although some may suggest that a large extrarenal pelvis or a congenital UPJ obstruction renders the patient more susceptible to disruption of the UPJ, this is controversial. The vast majority of patients with a congenital UPJ or congenital hydronephrosis with a traumatic injury will be found to have a rupture of the renal pelvis or a major laceration through a thinned renal cortex, not a UPJ disruption.[2,3,5,19] Generally, a laceration of an enlarged renal pelvis will appear as an isolated renal injury, whereas a UPJ disruption tends to occur in association with life-threatening injuries. The majority of patients sustaining a UPJ disruption will present with vascular instability, requiring emergent laparotomy, with the patient unable to undergo preoperative imaging. *Up to 30% of patients with a UPJ disruption will have a completely normal urinalysis, without any degree of hematuria.* In the patients undergoing exploratory laparotomy for coexisting intra-abdominal injury, exploration rarely reveals a retroperitoneal hematoma. Due to the frequent association of this injury with life-threatening trauma, inadequate preoperative radiographic staging studies, and the absence of a retroperitoneal hematoma, the diagnosis of a UPJ disruption is delayed for >36 hours in more than 50% of patients. Patients will eventually come to attention due to persistent postoperative fever, flank pain, ileus, or sepsis.[2,3,19,20,36,66,67]

Three classic findings on a triphasic CT scan are associated with UPJ disruption: (1) good renal contrast excretion with extravasation around the upper ureter into the medial perirenal space, (2) absence of parenchymal lacerations and intact renal calices, and (3) nonvisualization of the ipsilateral ureter. When a diagnosis of a possible disruption of the UPJ is entertained, careful evaluation of the delayed CT images is necessary. This diagnosis may be difficult even if suspected. Specifically, the severely injured patient usually has a history of volume depletion; contrast excretion due to the coexistence of hypovolemia, acute tubular necrosis, or renal contusion may be minimal. To definitively rule out the presence of a UPJ disruption, it is necessary to confirm the presence of contrast material in both distal ureters. This can be especially difficult in patients where this injury may be associated with a grade 3 renal injury, where contrast material may be preferentially accumulating in the retroperitoneum. If the results of the CT scan remain inconclusive, a retrograde pyelogram should be performed.[2–4,6,19,20]

In children with preexisting hydronephrosis from a UPJ obstruction, the site of injury is frequently a major laceration through a thinned renal cortex (grade 3 renal injury) or a laceration of the renal pelvis, not disruption of the UPJ. These patients should have a retrograde pyelogram to confirm continuity of the UPJ, and if not suspicious for disruption, it can then be safely managed with either a percutaneous nephrostomy or double-J stent placement with delayed pyeloplasty performed after stabilization of the patient.[3,5,34,36,63,72]

In patients with UPJ disruption, the delay in diagnosis may last up to 3 months following the injury and may significantly increase the risk of nephrectomy.[5,19,20] In the clinically stable patient where the diagnosis is made within 5 days of the trauma, we prefer to proceed to surgical repair with debridement of any devitalized ureteral tissue, spatulation, and reanastomosis of the ureter over a stent, with concurrent placement of an intraoperative nephrostomy tube and retroperitoneal drain. Since the area of ureteral necrosis may extend for 2–3 cm, mobilization and downward displacement of the kidney may be necessary to obtain a tension-free ureteral anastomosis.[19,20] In patients with a delayed diagnosis of a UPJ disruption 6 or more days posttrauma, we prefer to place a nephrostomy tube and allow the injury to stabilize over 6–8 weeks. Differential renal function is then obtained via DMSA scan and the length of the ureteral injury ascertained by a combined anterograde and retrograde pyelogram. The combination of percent renal function and the length of the ureteral defect will allow the surgeon to make the proper surgical planning. Surgical alternatives in this situation include a primary ureteroureterostomy, an ileal ureter, autotransplantation, and nephrectomy (indicated if the split renal function is <30% in the presence of a normal serum creatinine and renal clearance).[4,6,19,20,36]

ACTIVITY LIMITATIONS IN CHILDREN WITH SOLITARY KIDNEYS

Children with solitary kidneys warrant special attention. The American Academy of Pediatrics revised their activity recommendations for children in 2001, recommending no restrictions for noncontact sports, and conditional participation in contact activities. The recommendations stop short of fully endorsing full-contact sports, but advise informed caution and individual assessment of the potential risks associated with exposing a solitary kidney to potential trauma.[77] To evaluate this further, we tabulated the causes of high-grade renal trauma, as reported by contemporary renal trauma series published over the past 12 years.[28,36,64,65,67,70,72,78] Of the 146 reported cases of grade 4 or 5 renal trauma, causes included motor vehicle accidents (42%), falls (37%), pedestrian–vehicle collisions (10%), blunt torso trauma (4%), bicycle accidents (4%), contact sports (3%), sled accidents (2%), abuse (1%), skateboards (1%), and all-terrain vehicle accidents (1%). Given that the overall nephrectomy rate in grade 4 or 5 renal trauma patients in these series was 12%, the risk of being rendered anephric by participation in contact sports is exceedingly low. It would stand to reason that children with solitary kidneys participating in contact sports would be more likely to lose their remaining kidney from the car ride to football practice than by the practice itself.

Johnson et al. evaluated 6 years of data from the National Pediatric Trauma Registry.[79] Of 813 renal injuries, renal loss occurred in 28 children, 75% of which were due to motor vehicle accidents, falls, and pedestrian–vehicle collisions. A total of seven nephrectomies were performed; they were associated with sledding, skiing, rollerblading, jet skiing, and horseback riding. No high-grade renal injuries or renal losses were due to contact sports.

We recommend that patients with solitary kidneys be counseled on the risk of high-grade renal trauma with high-speed recreational activities, and be encouraged to wear safety belts, when possible. Participation in contact sports should not be discouraged due to the presence of a solitary kidney.

CHAPTER 35

The Ureter

Martin Kaefer

GENERAL

The goal of this chapter is to provide an overview of the embryology, general physiology, and molecular mechanisms responsible for normal ureteral development and function. The pathophysiology of the most common pathological abnormalities to afflict the ureter are thereafter described. Processes that affect the ureter are ultimately important because of their impact on kidney physiology. The reader is directed to chapters that specifically focus on alterations in renal function secondary to infection, ureteral obstruction, and vesicoureteral reflux (VUR) for more details on this subject.

EMBRYOLOGY AND ANATOMY

During the fourth week of gestation, the development of the ureter begins as an outpouching of the mesonephric duct, termed the ureteric bud (Figure 35.1). The development of this structure is heavily influenced by molecular factors released from the mesodermal tissue mass, which is destined to become the renal parenchyma (i.e., the metanephric blastema). At 28 days, the ureter consists of an epithelial tube surrounded by loose mesenchymal cells. Transient luminal obstruction ensues with subsequent recanalization during the seventh week of gestation.[1,2] It appears that this recanalization process begins in the midureter and extends in a bidirectional manner both cranially and caudally. It has been suggested that angiotensin, exerting its affect through the angiotensin II receptor (AT_2), may play a role in this recanalization process.[3] Chwalle's membrane, a two-layered cell structure, transiently divides the early ureteric bud from the urogenital sinus.[4] Subsequent dissolution of this membrane results in unimpeded flow of urine from the kidney into the bladder.

The first signs of ureteral muscularization are seen at 12 weeks of gestation. Smooth muscle differentiation is first noted at the ureterovesical junction (UVJ) and then ascends cranially toward the upper collecting system.[5] With time, these fibers, which are initially randomly arranged in the wall of the ureter, become more numerous and assume a more specific orientation.[6] The epithelium attains a transitional configuration by 14 weeks. Once fully developed, the muscular wall of the ureter is characterized as having an inner longitudinal, middle circular, and outer longitudinal layer. As the ureter penetrates the bladder, its muscular layers disperse. The outer layer melds into the detrusor in the upper part of the hiatus to form Waldeyer's sheath, which attaches the ureter to the bladder and is in continuity with the deep trigone.[7] As the ureter makes its transition to an intramural location, the muscle fibers take on a primarily longitudinal orientation.[8] The longitudinal muscle fibers spread out to form the borders of the superficial trigone.

Proper development and spatial orientation of the ureter as it combines with the bladder are dependent on a number of molecular factors. The renin–angiotensin system appears to play a major role in ureteral development. AT_2 is expressed in high concentration by the mesenchymal cells that are positioned adjacent to the ureteric bud at early developmental stages. The fact that expression of this receptor markedly decreases after birth supports the contention that AT_2 might play an important role in ureteral development.[9] Mice in whom the AT_2 gene has been knocked out demonstrate a high incidence of congenital anomalies of the urinary tract, including VUR, UVJ obstruction, and megaureter.[10] These structural anomalies may result from delayed apoptosis of the mesenchymal cells surrounding the ureteric bud. The clinical relevance of these experimental findings has been underscored by the identification of a select group of patients with mutations at this locus who possess a syndrome that includes ureteropelvic junction obstruction and megaureter.[11]

Proper spatial orientation of the ureter is likely dependent on genes responsible for cell specification and body segmentation. The PAX family of genes has been extensively studied in this regard.[12] These genes appear to play a role in the interplay between the ureter and the developing kidney.[13] PAX mutations have been implicated in syndromes with VUR and renal anomalies and are inherited in an autosomal dominant manner.[14] However, to date mutations neither in the PAX genes nor in other genes involving body segmentation have been demonstrated to any significant degree in patients with familial VUR.[15]

URETERAL PHYSIOLOGY

Function of the Ureter

The function of the ureter is to effectively transport urine from the renal pelvis to the bladder in a unidirectional

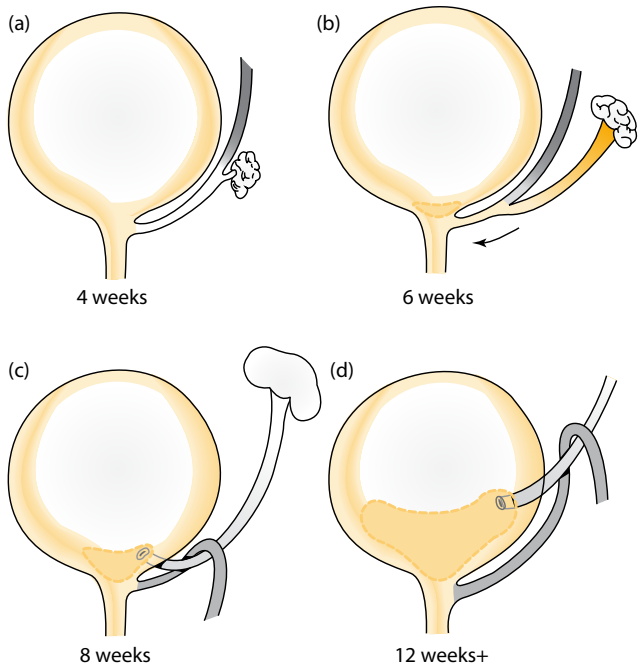

FIGURE 35.1 Embryology of ureter and trigone. The ureteral bud develops into the ureter and induces the metanephric blastema to differentiate and become the kidney. The common excretory duct (segment of mesonephric duct caudal to the ureteric bud) is absorbed into the bladder and becomes the deep trigone.

fashion. Coordinated antegrade movement of urine is initiated by pacemaker sites located in the renal pelvis and proximal ureter.[16–18] This electrical stimulus propagates caudally and, in so doing, gives rise to peristaltic activity of the ureteral musculature. Under healthy normal conditions, peristaltic contractions occur between two and six times per minute and advance down the ureters at a rate of between 2 and 6 mL/second.[19,20] The following section describes how events at the cellular level are translated into achieving this goal.

Electrical Excitation: Muscular Contraction

Unlike their skeletal muscle counterparts that receive a discrete stimulus from a motor end plate, smooth muscle cells of the ureter lack discrete neuromuscular junctions and depend on initiation of an action potential from pacemaker cells located in the renal pelvis and upper ureter. The ureter also receives neurologic input from numerous sources. Spontaneous electrical activity initiated by the pacemaker is in itself adequate to propagate electrical activity and induce coordinated peristaltic muscular activity. Evidence to support this contention includes the persistence of peristalsis after renal transplantation or denervation.[21,22] Individual muscle cells allow propagation of electrical activity through tight areas of cell-to-cell contact termed intermediate junctions.[23–25]

The parasympathetic and sympathetic nervous systems, as well as peptidergic substances (e.g., tachykinins, substance P, and neurokinin A) and nitric oxide, appear to have as their primary role the ability to modify ureteral contraction that has been initiated by the pacemaker unit.[26–28] Neuropeptides influence muscle activity via second messengers, including cAMP, cGMP, Ca^{2+}, inositol, 1,4,5-trisphosphate (IP_3), and diacylglycerol (DG). Upon binding of the specific effecter molecule to the cell receptor, the generation of these second messengers mediates the functional response through a process that frequently involves a cascade of protein phosphorylation. Release of these neurotransmitters is unlikely to exert the dominant force responsible for peristalsis. Physiologic support for this contention comes from the fact that treatment with specific neuropeptide antagonists (e.g., atropine in the case of the parasympathetic nervous system) often has little or no clinically significant effect on ureteral function.[29]

The smooth muscle cell is the structural element responsible for the effective mechanical transport of urine through the ureter. As in skeletal muscle, actin and myosin act as the two primary structural proteins that serve to provide active deformation of the cell during contraction and relaxation. Actin is bound to attachment plaques on the cell surface, which serve as an anchor point against which it can exert force on the cell membrane. Any process that results in a significant increase in Ca^{2+} in the region of the contractile proteins favors the development of a contraction. The phosphorylation of myosin is a key step in the contractile process. Phosphorylation of the myosin light chain allows actin to activate myosin Mg^{2+}-ATPase activity, leading to hydrolysis of ATP and the development of smooth muscle tension or shortening.

Function of the Ureterovesical Junction

The function of the ureterovesical junction is to facilitate the unidirectional, antegrade flow of urine from the ureter into the bladder. A number of passive and active factors play a role in maintaining this mechanism.

Facilitation of Antegrade Flow

After the urine bolus has progressed to the level of the UVJ, it is propelled into the bladder across the intramural ureteral segment. This process is facilitated by retraction of the ureter in a superolateral direction, in keeping with its primarily longitudinally oriented muscle. As a result, the resistance at the UVJ is lowered, facilitating antegrade fluid transport.[30]

Prevention of Retrograde Flow

Sampson was the first to propose a passive valvular mechanism created by the obliquity of the ureters as the ureter courses through the bladder wall, a mechanism that he named "ureteral lock."[31] Paquin demonstrated that in normal subjects (i.e., children without VUR), a 5:1 ratio of tunnel length to ureteral diameter existed.[32] In creating reflux by resecting the roof of the submucosal ureter in a pig model, Ransley and Risdon gave further support to the concept that ureteral tunnel length is of importance in maintaining a competent UVJ.[33]

In order for this passive mechanism to work successfully, the ureter must have an adequate muscle backing against which it can be compressed during bladder filling. In addition, the distal end of the ureter must be adequately anchored to the base of the bladder so that with filling, it

does not migrate laterally and experience a shortening of tunnel length. The importance of adequate muscle backing is supported by the increased incidence of VUR in patients with periureteral diverticuli. The passive mechanism for maintaining unidirectional urine flow across the UVJ is depicted in Figure 35.2.

The traditional concept of the ureterovesical antireflux mechanism consisted solely of this passive flap valve mechanism. However, a number of investigators have noted sufficient anatomic and physiological evidence to point to an active sphincteric mechanism.[34] The active valve function of the human ureter is thought to consist of a "vesicoureteral sphincter" that contracts in response to bladder contraction and relaxes after contraction of the external urethral sphincter.[35] Although an anatomically defined circumferential sphincter has not been identified, it has been postulated that a "physiological sphincter" exists.[36,37] During micturition, the longitudinal muscles of the UVJ are postulated to provide this "active" component by closing the meatus and submucosal tunnel. The alteration in ureteral jet pattern seen in patients with VUR has been cited by some investigators as evidence for this sphincteric mechanism.[38] Tanagho et al. demonstrated that prolonged electrical stimulation or administration of intravenous epinephrine can cause resistance to flow as contraction of the longitudinal muscle (which makes up part of the trigone) draws the orifice inferomedially.[8] The importance of trigonal attachment in maintaining an active valvular mechanism may vary from species to species. Hannan and Stephens, in excising the muscular component of the canine trigone, failed to demonstrate a significant increase in VUR in their model and concluded that the trigone did not play a major role in the function of the UVJ in this species.[39]

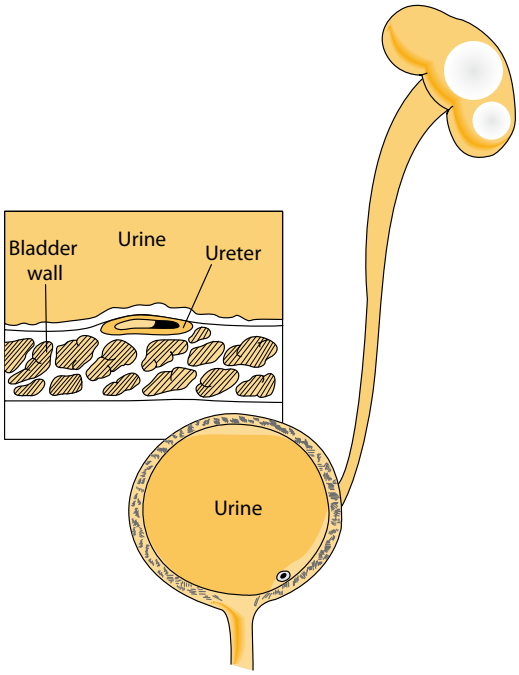

FIGURE 35.2 Flap valve mechanism: Urine compresses the ureter between the bladder mucosa and the bladder wall muscle, thus creating a flap valve mechanism that prevents reflux.

Synopsis of Urine Transport from Renal Pelvis to Bladder

A graphical representation of the process of urine transport from the renal pelvis to the bladder, as described by Griffiths and Notschaele, is shown in Figure 35.3.[40] The process begins when the production of urine results in a rise in the renal pelvic pressure. Urine is subsequently propelled into the upper ureter, which is initially in a collapsed state. A contraction wave originates in the most proximal portion of the ureter and moves the bolus of urine in front of it in a caudad direction. For efficient urine transport, the ureteral wall must completely coapt during the propagation of a urine bolus down the ureter.[41] The bolus that is pushed in front of the contraction wave lies almost entirely in a passive, noncontracting part of the ureter.[42] The resting pressure within the ureter, 0–5 cm H_2O, is similar to the intravesical pressure of the nondistended bladder. Peristaltic waves elevate this pressure to between 20 and 80 cm H_2O.[43] If the intraureteral pressure exceeds the intravesical pressure, urine will proceed into the bladder.

FACTORS INFLUENCING URETERAL FUNCTION

Many factors affect ureteral function. These typically are appreciated in the presence of either ureteral obstruction or VUR, both of which are described in the subsequent section. However, at times these factors may occur in the absence of these two major maladies. For example, ureteral dilatation may occur in the absence of obstruction

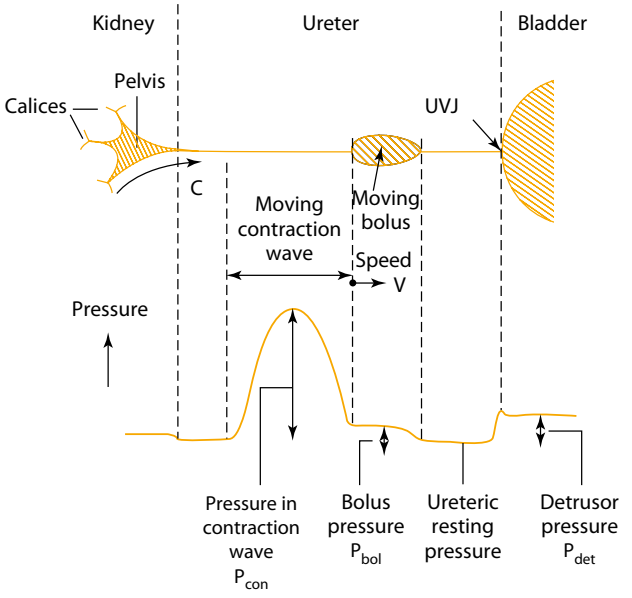

FIGURE 35.3 Schematic representation of a single bolus or urine in the ureter moving away from the renal pelvis and toward the bladder. Arrow C indicates the direction of bolus transport. The corresponding distribution of pressure within the urinary tract is shown in the lower tracing. (Adapted from Griffiths D, Notschaele C. *Neurourol Urodyn* 1983;2:155–6.)

or VUR in patients with high urine output secondary to diabetes insipidus.[44]

Ureteral Dilatation

Ureteral dilatation occurs due to either too much fluid entering or too little fluid exiting the ureter per unit time. Factors that influence the egress of urine from the ureter range from infection to high intravesical pressure to anatomic obstruction of the ureter. An increase in ureteral dimensions in and of itself adversely affects antegrade urine flow. As described by the Laplace equation, dilatation alters intraluminal pressure.

$$\text{Pressure} = \text{Tension} \times \text{Wall Thickness/Radius}$$

By increasing the luminal size (i.e., radius), the intraluminal pressure is diminished, decreasing the force propelling urine in a forward direction.[45]

Urine Volume

Hydration status and the ability of the kidney to concentrate urine affect the volume of urine transported per unit time through the ureters. Urinary concentrating ability is the first aspect of renal function to be affected in the presence of obstruction.[46] Evidence also exists that in the presence of VUR, the concentrating ability is altered.[47] With increasing urine flow rates, the initial response of the ureter is to increase peristaltic frequency. After the maximal frequency is achieved, further increases in urine transport occur by means of increases in bolus volume.[48,49] Eventually, the boluses coalesce and the ureter becomes filled with a continuous column of fluid.

Infection

Infection within the upper urinary tract may adversely affect urine transport. Experimentally induced pyelonephritis in a primate model has been associated with decreased peristaltic activity.[50] In vitro studies have shown that bacteria and *Escherichia coli* endotoxin can inhibit ureteral peristaltic activity.[51,52] Other investigators have not been able to suppress ureteral activity with endotoxin but have noted that growth media from *E. coli*, *Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* do inhibit ureteral contractility. These investigators suggested that the inhibition of peristaltic activity is due to an exotoxin.[53] In humans, irregular peristaltic contractions and alterations in the ureteral jet have been recorded with infection.[38,43] Ureteral dilatation has also been reported to result from retroperitoneal inflammatory processes, which presumably exert their effect via the transudation of bacterial endotoxins or inflammatory mediators.[54]

Ureteral Histology

Alterations in ureteral histology are likely to have a significant impact on ureteral function. Lee and colleagues evaluated the histology of obstructed and refluxing megaureters and identified marked differences between the two groups. The authors found that refluxing megaureters had a twofold increase in the tissue matrix ratio of collagen to smooth muscle when compared with patients with primary obstructed megaureter and controls. This was due to not only an increase in collagen, but also decreased amounts of smooth muscle in the refluxing ureters.[55] The same group of investigators subsequently demonstrated that there was a greater contribution of type III collagen in the refluxing megaureter, and felt that this may play a role in the pathophysiology of the disease.[56] Because type III collagen is a less distensible fiber, it may cause an intrinsically stiffer ureter and play a role in the lower surgical success in the reimplantation of refluxing megaureters.[57,58] The histology of the refluxing ureter associated with prune belly syndrome likewise exhibits significant histological alteration. Ureters frequently are found to have a scarcity of muscle bundles among dense connective tissue.[59]

PATHOLOGIC PROCESSES AFFECTING URETERAL FUNCTION

The two primary pathophysiologic conditions that affect the pediatric ureter include obstruction and VUR. As mentioned in the previous section, infection can itself alter ureteral function. Often, two or three of these conditions may coexist in one patient, as, for example, in the child with posterior urethral valves who suffers from the common combination of bladder dysfunction, VUR, and urinary tract infection.[60]

Ureteral Obstruction

Well-known anatomic causes of ureteral obstruction that result in a compromise of the ureteral lumen include ureterocele, ureteral ectopia, and urinary lithiasis. In contrast, the classic example of a functional obstruction is the primary obstructed megaureter, in which there exists an adynamic segment of distal ureter with adequate ureteral diameter (Figure 35.4).[61] Apart from anatomic or functional obstruction at the UVJ itself, the relationship between ureteral intraluminal pressure and intravesical pressure is important in determining the efficacy of urine passage across the UVJ into the bladder. The ureter has been shown to decompensate when intravesical pressure approaches 40 cm H_2O.[62]

The effects of ureteral obstruction on renal function are numerous and complex. Molecular mediators, including eisocanoids, nitric oxide, endothelin, and the renin–angiotensin system, dramatically affect blood flow and subsequent urine output.[63–66]

After the onset of obstruction, a backup of urine occurs within the urinary collecting system, along with an associated increase in baseline ureteral pressure and an increase in ureteral length and width.[67,68] A transient increase in the amplitude and frequency of the peristaltic contraction waves accompanies these initial dimensional and pressure changes.[69] With time, as the ureter fills with urine, the peristaltic contraction waves become smaller and are unable to coapt the ureteral wall. Urine transport then becomes dependent on hydrostatic forces generated by the kidney.[67]

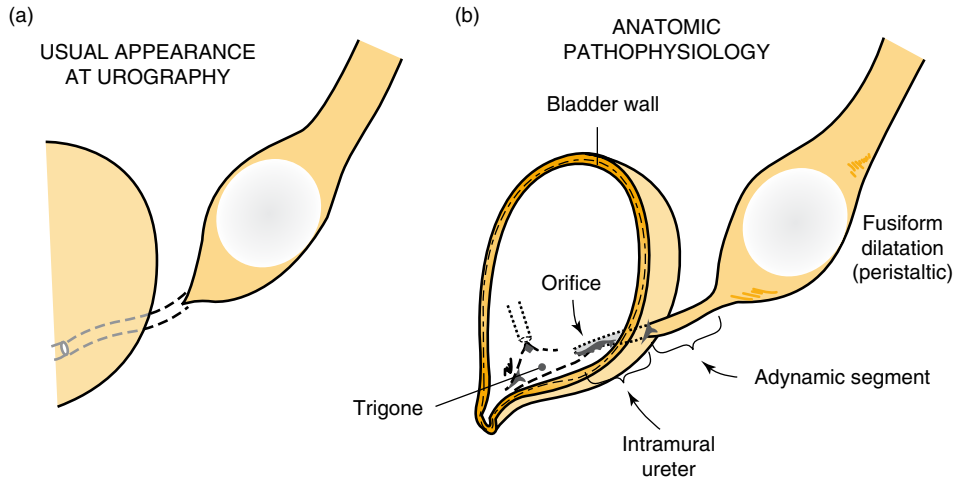

FIGURE 35.4 (a) Graphic representation of a primary obstructed megaureter. Ureteral dilatation begins above the UVJ, usually a few millimeters or more above the bladder, just proximal to an adynamic distal segment of the ureter. (b) Characteristic appearance of the distal portion of a primary obstructed megaureter.

Within a few hours of the onset of obstruction, the intraluminal baseline ureteral pressure increases substantially. With time, the ureter experiences muscular hypertrophy and a greater ability to generate contractile forces.[70,71] Nevertheless, the simultaneous increase in ureteral diameter decreases the ability of the ureters to generate intraluminal pressure, as predicted by the law of Laplace. After ureteral dilatation has occurred, intraureteral pressure declines to a level only slightly higher than the normal baseline pressure. The decrease in ureteral pressure can also be attributed to changes in intrarenal hemodynamics, such as a reduction in renal blood flow, with resultant decreases in the glomerular filtration rate and intratubular hydrostatic pressure.[72,73] Fluid reabsorption into the venous and lymphatic systems (pyelovenous and pyelolymphatic backflow) may also play a role in the reduction in baseline ureteral intraluminal pressure.[74]

Under conditions of obstruction, the hierarchical order of the ureteral pacemakers may also be altered.[75,76] When these alternate pacemakers fire, electrical activity and subsequent peristalsis can propagate both caudally and cranially from the site at which it is initiated. This lack of coordination affects the efficiency of urine transport and contributes to upper tract dilatation.

From a therapeutic standpoint, it is important to understand why a tapered megaureter repair may be beneficial once the obstructive element has been removed. The effect of ureteral diameter on the ability to generate effective peristaltic contractions provides the rationale for ureteral tapering in the patient with an increased ureteral size.[77] Although tapering does not alter muscle thickness and the ability of the ureteral fibers to contract, the decrease in radius, according to the Laplace relation, would result in higher intraluminal pressures and a resultant improvement in antegrade urine transport.

Vesicoureteral Reflux

VUR, the retrograde flow of urine across the UVJ, is the most common problem of the ureter treated by the pediatric urologist.[78] The high incidence of sibling VUR supports a genetic basis for this disorder. Factors that have been implicated in the development of VUR include (1) anatomic and functional abnormalities of the UVJ, (2) inordinately high intravesical pressures, and (3) impaired ureteral function.

Genetics of Reflux

Very strong evidence exists to support a genetic component to VUR.[79,80] Although autosomal recessive, x-linked, and polygenic modes of transmission have been supported by various authors in the past, the majority of data suggest an autosomal dominant pattern of inheritance with variable penetrance.[81] Supporting data include an approximate 50% incidence of sibling reflux in the first 2 years of life and a high incidence of parent-to-child transmission.[80,82] Perhaps most suggestive of autosomal dominant transmission is the incidence of sibling reflux found in multiple-gestation births. Kaefer et al. demonstrated reflux in 80% of identical twins and 35% of fraternal twins.[83] The incidence for groups of twins less than age 18 months was 100% for identical twins and 50% for fraternal twins. Despite such a strong genetic component, it still remains unclear as to which of the factors contributing to reflux is primarily affected (i.e., anatomic properties of UVJ, bladder properties, or impaired ureteral function).

Anatomic Abnormalities of the UVJ

As outlined in the previous section on normal ureteral function, unidirectional flow of urine across the UVJ appears to depend on both passive and active components. In comparing the anatomy of children with and without VUR, Paquin demonstrated that there was a significant difference in the ratio of ureteral tunnel length to orifice diameter between the two groups. Whereas the patients with reflux had a ratio of 1.4:1, children not exhibiting reflux had a significantly longer intravesical tunnel with an average length-to-width ratio of 5:1.[32] Hutch estimated the average intravesical ureter length to be 0.5 cm in neonates and 1.3 cm in adults.[84] Although the 5:1 ratio sets the standard for reimplantation surgery, many pediatric

urologists feel that achieving such a long intravesical tunnel may not be absolutely necessary to obviate reflux.

Lateral displacement of the ureteral orifice is a result of the ureteric bud originating on the mesonephric duct at a point more caudal than normal. As a result, the period during which the orifice undergoes migration is prolonged. As predicted by Stephens, the orifice will eventually assume a position on the trigone that is more lateral than usual. The ureter will have a submucosal course that is short and almost perpendicular to the bladder wall, thus failing to meet the anatomic requirements needed for proper functioning of the flap valve mechanism.[85,86] The degree of reflux correlates with the degree of laterality and inversely with the length of the submucosal ureter (Figure 35.5). Spontaneous resolution of reflux in children is in part explained by the growth of the bladder, during which the submucosal tunnel elongates.[85]

Proper formation of the trigone is also believed to be necessary to provide adequate muscular support of the ureters. A more caudal takeoff of the ureteric bud from the mesonephric duct results in a shorter common excretory duct. As a result, its contribution to the development of the trigone is decreased, resulting in poor muscularization. The importance of adequate muscular backing is underscored by the rare female patient with bilateral single-system ectopic ureters. When reimplanting a ureter in these children, special attention must be taken to achieve very long tunnel length due to absent trigonal musculature and poor detrusor muscularization, both of which result in poor posterior support for the reimplanted ureter. If special care is not taken to achieve a greater than normal ureteral tunnel length, these patients are prone to postoperative reflux.[87] Focal absence of adequate muscle backing in the form of a periureteral diverticulum can also contribute to VUR due to poor muscle backing and poor attachment of the ureter to the trigonal muscle complex.[88]

Alterations in the active valvular mechanism may also occur and result in or contribute to the expression of the reflux phenotype. From an embryologic standpoint, a more caudal takeoff of the ureteric bud from the mesonephric duct and the earlier absorption into the bladder would allow less time for the common mesenchyme to accumulate around the developing ureteric bud. One would therefore anticipate that the intramural ureter may be deficient in musculature. As a result, the orifice can be patulous or gaping.

Recent histologic evaluation of the distal ureters in children with VUR has suggested that there may be dysplasia, atrophy, and architectural derangement of smooth muscle fibers.[89] In addition, there appears to be altered extracellular matrix deposition and a decrease in intramural nerve supply.[90] This combination of factors, by affecting the muscle layer of the intramural ureters, may alter the active valvular mechanism deemed by many to contribute to the function of the UVJ. The fact that many children outgrow their VUR suggests that even if histological alterations of the intravesical ureters are contributing to the presence of VUR, they play only a partial role in the reflux phenotype.

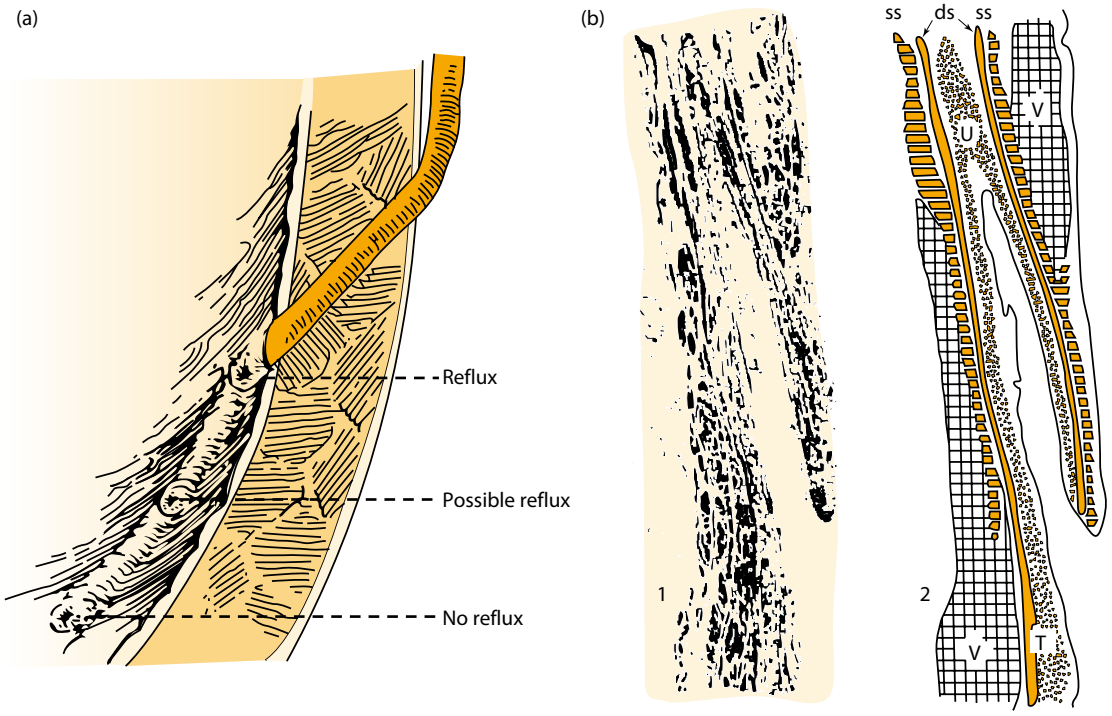

FIGURE 35.5 (a) The refluxing UVJ has an inadequate length of intravesical submucosal ureter. Some orifices with marginal submucosal tunnels may reflux intermittently. (b) UVJ in longitudinal section: 1, photomicrograph; 2, diagrammatic representation. The ureteral muscularis (U) is surrounded by superficial (ss) and deep (ds) periureteral sheaths, which extend in the roof of the submucosal segment and continue beyond the orifice into the trigonal muscle (T). The relationship of superficial sheath to the vesical muscularis (V) is clearly seen. Transverse fascicles in the superior lip of the ureteral orifice belong to the superficial and deep sheaths. No true space separates ureter from bladder. ([a] Adapted from Glenn J., ed., *Urologic Surgery*, 2nd edn., Harper & Row, New York, 1975; [b] Adapted from Elbadawi A. *J Urol* 1972;107:224–9.)

Intravesical Pressure

As mentioned earlier in this chapter, intravesical pressure must be lower than the pressure generated by the ureter in order for there to be adequate transport of urine in an antegrade direction. In the presence of increased intravesical pressure, secondary reflux can occur.[62] Failure to maintain a low intravesical pressure also results in an increase in the incidence of VUR. This is commonly referred to as secondary reflux. The most common anatomic cause of secondary VUR is posterior urethral valves, in which approximately 50% of boys are affected.[91,92] However, functional causes of increased intravesical pressure, including detrusor sphincter dyssynergia in patients with neuropathic bladder dysfunction secondary to myelomeningocele, are far more common.[93]

Transient urodynamic abnormalities have also been identified in neurologically normal children who present with urinary tract infections and reflux in the first year of life. One study identified abnormalities, including detrusor hyperreflexia and elevated filling pressures, in 97% of boys and 77% of girls who presented in infancy with reflux.[94,95] Intravesical pressures in boys were found to be higher than in girls, a finding confirmed by other investigators.[96,97] This finding may account for gender differences in the degree of reflux. In older children, bladder dysfunction is typically an acquired phenomenon resulting from abnormal voiding patterns in neurologically normal children.[98,99]

The normal UVJ is extremely resistant to reflux, even in the face of very high intravesical pressures that occur with normal voiding. However, if intravesical pressures remain chronically elevated, the antireflux mechanism can be overcome. McGuire et al. demonstrated that if intravesical pressures exceed 40 cm H_2O, the incidence of reflux and renal injury increases.[62] The development of reflux further reduces the efficiency of bladder emptying, leading to further increases in intravesical pressures and yet further damage to the upper urinary tract.[100]

Impaired Ureteral Function

Although an abnormality of the UVJ is the primary etiologic factor in most cases of VUR, evidence exists that decreased ureteral peristalsis can be a contributory factor. This may explain why a normal ureter may not reflux even when reimplanted into a bladder without a submucosal tunnel, or why a defunctionalized refluxing ureter may cease to reflux when a proximal diversion is taken down.[101–103] Tanagho's observation that VUR may temporarily cease after ureteral electric stimulation further supports this possibility.[104]

Even the mildest forms of VUR may be associated with a decreased frequency of ureteral peristalsis.[105] Although this may offer further evidence that decreased peristaltic activity is a possible etiologic factor in the development of reflux, an alternative interpretation is that the decreased peristaltic activity reflects changes in ureteral or renal function resulting from the reflux. Finally, the success rate of antireflux procedures is lower with poorly functioning dilated ureters. Although this may be related to technical factors, decreased peristaltic activity may be another reason for the lower success rate in this condition. Bladder infections and the accompanying inflammation may also contribute to reflux by decreasing the compliance of both the bladder and intramural ureter, elevating intravesical pressures, and distorting and weakening the UVJ.[106–108] In some patients, reflux appears to occur only during episodes of acute cystitis and resolves once the infection has been adequately treated and the inflammatory response has resolved.[109]

CHAPTER 36

Ureteral Development

Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

Ureteral development from the ureteral bud is closely associated with the distal end of the mesonephric duct, also known as the Wolffian duct. As described in Chapter 20, the mesonephric duct bends ventrally as it enters the cloaca. In the fifth week, there is an outpouching (the ureteral bud) from the dorsal medial aspect of the bend.[1] This is the beginning of the ureter. As originally shown by Grobstein, signals from the metanephric blastema induce elongation of the ureteric bud and invasion of the blastema by the ureteral bud.[2] Evidence in both mice and humans is helping to explain the mechanisms by which this occurs, but our understanding is still incomplete. The renin–angiotensin system (RAS), which in postnatal life regulates blood pressure, is a key factor in the development of the ureteral bud and subsequent branching of the ureter to produce the renal pelvis and the calyces.[3] Angiotensin I is converted to angiotensin II by the angiotensin-converting enzyme (ACE). Angiotensin II acts via AT_1R and AT_2R (angiotensin receptors) to induce the production of the glial-derived neurotrophic factor (GDNF) in the metanephric blastema. GDNF in turn acts on the tip of the ureteral bud via interaction with the ret (rearranged during transfection) receptor tyrosine kinase and Gfralpha1 (glial cell line–derived neurotrophic factor receptor alpha) to cause cell proliferation, elongation of the ureter, invasion of the metanephric blastema, and eventual branching of the ureter.[4] The entire length of the Wolffian duct can respond to GDNF. Consequently, regulation of the site of GDNF activity is critical to the production of normally situated ureteral orifices.[5] The distal end of the mesonephric duct inferior to the ureteral bud opening forms the common excretory duct. The trigone has been thought to be formed by integrating the upper portions of the common excretory ducts and a small portion of the mesonephric ducts just superior to the ureteral bud into the bladder base (Figure 36.1). Studies by Tanaka et al. have cast doubt on this theory and have suggested that the trigone is formed from endoderm rather than mesoderm.[6] Ultimately, with expansion and absorption of the common excretory duct into the trigone or its loss due to apoptosis and replacement by endoderm, ureteral and Wolffian duct orifices become separated from each other.

In mice, mutations that result in the absence of GDNF, Ret, or Gfralpha1 cause bilateral renal aplasia due to a failure of the ureteric bud to grow.[7] The development of ureteral atresia is thought to be due to relative or total ischemia that might occur with the migration of the developing kidney as it changes and reestablishes regional blood supply to the ureter. This theory is based on experimental studies on intestinal atresia.[8] It may be extrapolated to explain ureteral stenosis and postnatal involution of multicystic dysplastic kidneys.

Complete or partial ureteral duplication (or triplication) can occur if multiple ureteral buds develop, or if the ureteral bud divides before meeting the metanephrogenic mass. In this instance, if one bud met the center of the metanephrogenic mass and the other a pole of degenerating metanephric tissue, the former would develop normally, whereas the latter might be dysplastic (Figure 36.2). This seems to explain the high association of dysplasia with ureteral ectopia,[9] although these ureters are also often obstructed.

PAX2 (paired box gene 2) is a positive regulator of GDNF, while Spry1 (sprout gene1) and Bmp4 (bone morphogenic protein 4) are inhibitors of GDNF. A delay or absence in RET signaling can produce ectopic ureters, while mutations in genes from Bmp4 and components of the RAS cascade can produce vesicoureteral reflux. Other factors involved in ectopic budding of the ureteral bud are fibroblast growth factors 7 and 10 and their receptor FGFR2. These observations confirm the observations of Mackie and Stephens that abnormal ureteral bud position induces renal dysplasia.[5]

Ureteral ectopy occurs when the orifice is located in a location other than the normal orthotopic corner of the trigone. These orifices can be within the bladder, urethra, vas, or vagina. Ureteral ectopy is four times more common with duplicated systems than with single ureteral systems.

Ureteral obstructions occur primarily at the ureteropelvic and ureterovesical junctions but can also occur in the pelvis where the ureter crosses over the iliac vessels. These obstructions are usually intrinsic in nature, and the area in question is often of normal caliber but abnormally fibrous histologically, perhaps reflecting a localized vascular accident sometime during development (Figure 36.3). The elongating ureter is formed only of epithelial cells, but muscle is induced to form from the surrounding mesenchyme by Shh (Sonic hedgehog) signals.[10] One might speculate that abnormalities in this signaling could produce obstructions, such as ureteropelvic junction obstructions and obstructive or nonobstructive megaureter.

CHAPTER
37

The Imaging of Vesicoureteral Reflux and Ureteral Disease

David A. Diamond, Jeanne S. Chow, and Frederick D. Grant

INTRODUCTION: THE IMAGING OF REFLUX AND URETERAL DISEASE

This chapter discusses the imaging techniques used in evaluating vesicoureteral reflux and ureteral diseases. Different imaging modalities are described with specific clinical scenarios to highlight the uses of each modality. Practice patterns may vary from institution to institution.

IMAGING VESICOURETERAL REFLUX

Voiding cystourethrography (VCUG), radionuclide cystography (RNC), and sonocystography demonstrate the presence or absence of vesicoureteral reflux. While VCUG is a fluoroscopic examination and RNC is a nuclear medicine study, studies are performed similarly and expose the patient to ionizing radiation. Sonocystography is performed with ultrasound and exposes the child to no ionizing radiation.

During VCUG, dilute water-soluble contrast is instilled into the bladder through a sterile urethral catheter by gravity under fluoroscopic guidance. Spot images of the abdomen, early filling views of the bladder, oblique images of the bladder to view the ureterovesical junctions (UVJs), oblique views of the urethra (especially important in boys), and postvoid images of the abdomen are standard. Additional views to show other abnormalities may be necessary (Figure 37.1a–f).

In infants, a cyclic study is performed, where the bladder is refilled with contrast after the infant voids around the catheter to increase the sensitivity of the study.[1] Otherwise, the bladder is filled to the predicted capacity to maximize the likelihood for finding reflux. Bladder capacity can be calculated by the two following sets of equations:[2,3]

- Under a year of age:

$$\text{Bladder capacity (mL)} = \text{Weight in kg} \times 7$$

- Older than a year of age:

$$\text{Bladder capacity (oz.)} = (\text{Age in years} + 2) \times 30$$

The relationship of normal bladder capacity and age in children has been found to follow a nonlinear curve[4] and can be determined for two age groups:

- For children under 2 years of age:

$$2 \times \text{Age (years)} + 2 = \text{Capacity in oz.}$$

- For children over 2 years of age:

$$\text{Age in years}/2 + 6 = \text{Capacity in oz.}$$

Direct RNC uses the instillation of radiolabeled fluid into the urinary bladder to demonstrate vesicoureteral reflux. Like in VCUG, a urethral catheter is inserted after the patient voids and the perineum has been prepped. The usual radiotracer is [^{99m}Tc]-sodium pertechnetate, but if there is a history of bladder augmentation with gastric or intestinal mucosa, then ^{99m}Tc-labeled sulfur colloid is preferred to limit mucosal absorption of free pertechnetate. Although some guidelines[5] suggest a weight-based radiopharmaceutical dose, the currently recommended tracer dose is 0.5–1.0 mCi[6] to ensure adequate sensitivity of the study.

Using a gamma camera, dynamic images are acquired in the posterior projection. A radiopharmaceutical is administered aseptically into the bladder and followed by warm saline infused by gravity flow. Infusion is continued until the end of the filling phase, indicated by slowing or stopping of flow, or the infused volume reaches a bladder volume appropriate for age. If the patient has not begun to void spontaneously, he or she is urged to void. Dynamic imaging should continue during voiding, as many cases of reflux will be identified only during the voiding phase. Some patients may be unable to void while supine, and it may help to have them sit upright (preferably while still imaging) or sit on a toilet or commode. Vesicoureteral reflux identified by RNC is typically graded on a 3-point scale (Figure 37.2).[7] A postvoid image of the kidneys and bladder may be helpful to demonstrate reflux that occurs during delayed voiding. In patients with demonstrated reflux, a postvoid image is useful for identifying postvoid retention of the tracer in the renal collecting system, which may suggest some degree of ureteral obstruction superimposed on the vesicoureteral reflux. Some guidelines suggest completely emptying the bladder through a urethral catheter to minimize radiation exposure from the tracer retained in the bladder.[5] Although a cyclic study can be performed with RNC, the yield of

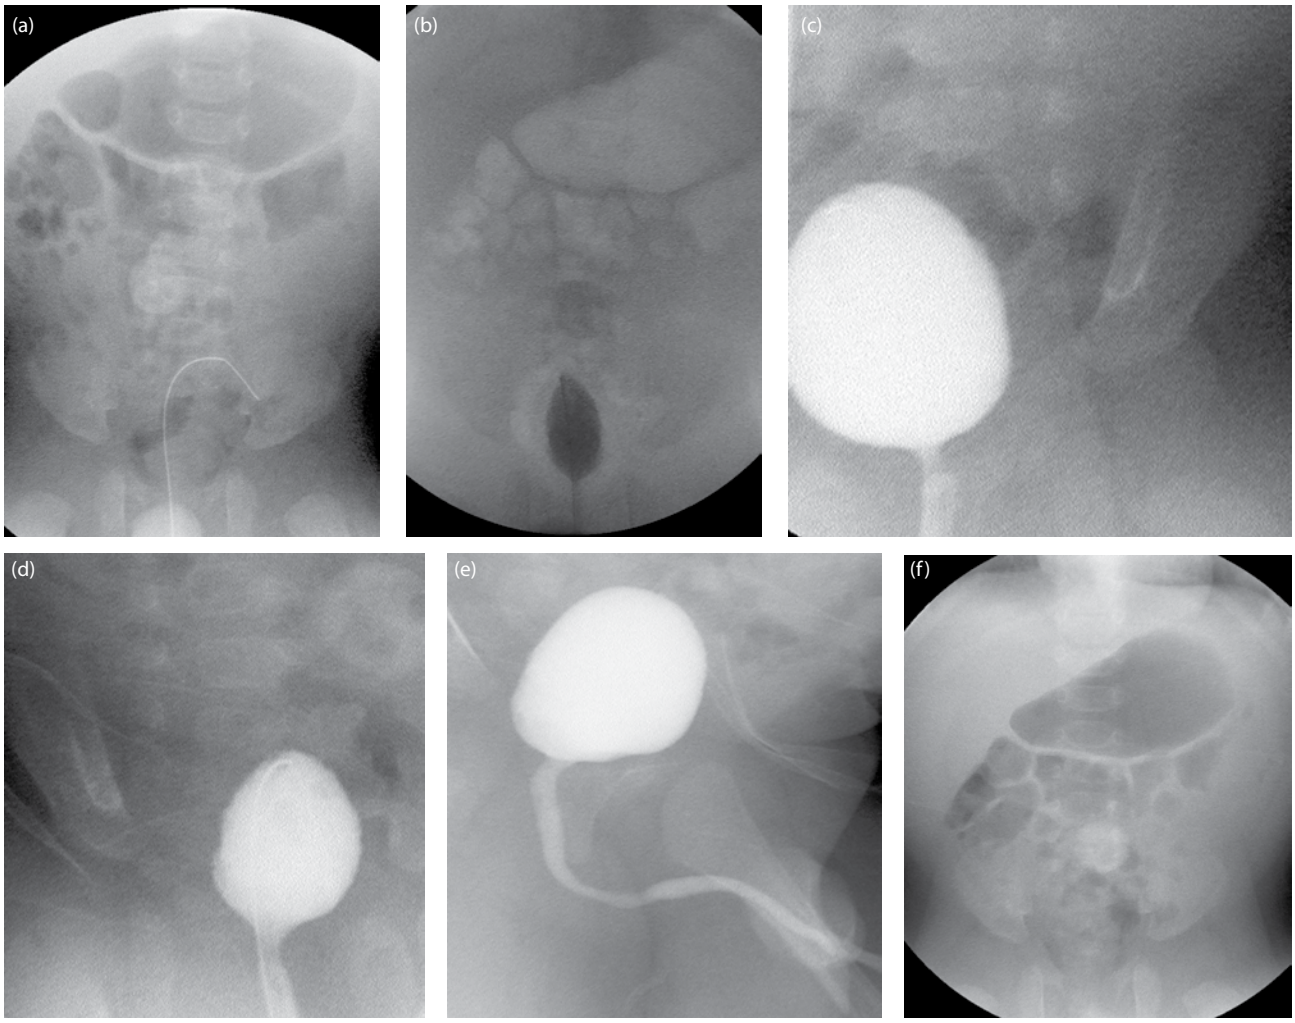

FIGURE 37.1 Standard images from normal VCUG in a boy include (a) a scout film of the abdomen and pelvis, (b) an early filling view of the bladder, (c and d) bilateral oblique views to visualize the UVJs, (e) an oblique view of the male urethra, and (f) a postprocedure image of the abdomen and pelvis.

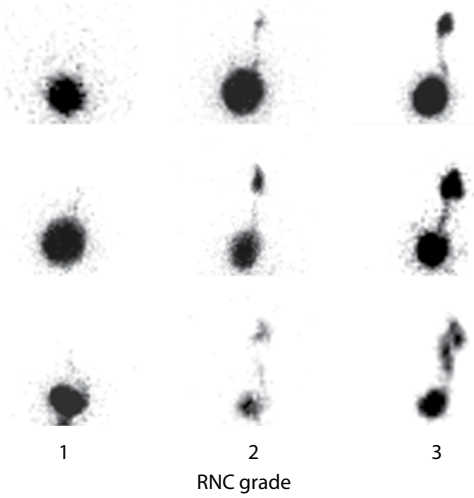

FIGURE 37.2 RNC grading. When diagnosed by RNC, the severity of vesicoureteral reflux is graded on a 3-point scale: grade 1, reflux only into the ureter; grade 2, reflux into the renal collecting system; and grade 3, reflux into a tortuous ureter or dilated renal collecting system.

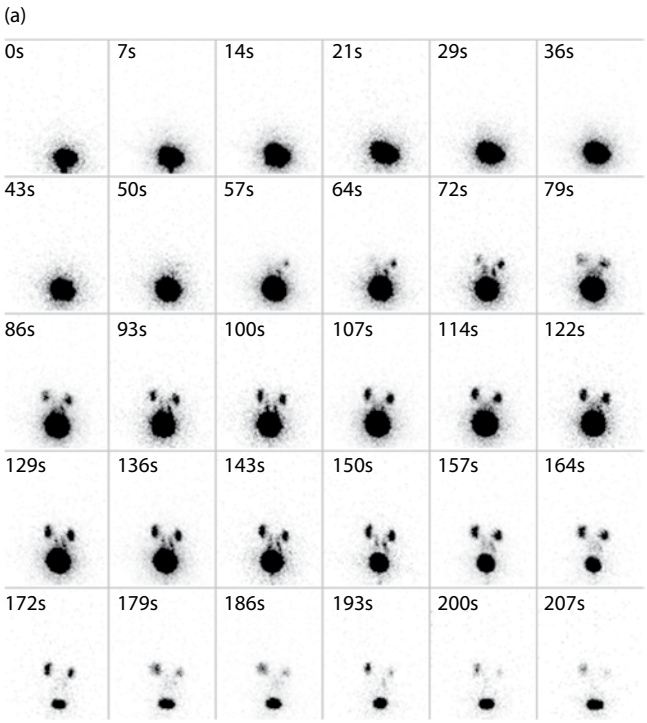
repeated infusion is quite low, possibly due to the high sensitivity of the study for subtle reflux.

Bladder volumes and pressures can be recorded during the performance of RNC.[5,8,9] The patient should void before the study, and the residual urine volume can be measured at the time of catheter insertion. The volume of infusate provides an estimate of bladder volume, and the void volume also can be measured. At our institution, a single-head gamma camera installed in the urology suite allows RNC to be performed during urodynamic studies, thereby preventing the need for the patient to undergo a second urethral catheterization.

Both VCUG and RNC expose the patient to low doses of ionizing radiation, and all studies should be performed in accordance with the ALARA (as low as reasonably achievable) principle. Traditional VCUG exposes the patient to 100 times the radiation of RNC. In the past two decades, low-dose fluoroscopy techniques, including digital fluoroscopy and pulse fluoroscopy, have decreased radiation dose to the patient[10–14] while still providing diagnostic quality images.[15–17] Gonadal shielding and careful image coning also substantially decrease patient radiation

exposure. In our department, modern low-dose fluoroscopic methods have reduced the radiation dose of VCUG to approximately eight times that of RNC,[18] but doses vary from hospital to hospital.

The decision to perform RNC or VCUG on a patient suspected to have reflux depends on the patient, clinical indication, and referring physician. When VCUG and RNC are compared, VCUG provides greater anatomical detail at the expense of a higher radiation dose than RNC (Figure 37.3a and b). VCUG allows evaluation of the bladder wall, UVJ (in patients with reflux), intrarenal reflux, and male urethra (Figure 37.4). RNC may be more sensitive for subtle reflux, but does not provide the anatomic detail provided by VCUG. Therefore, in our institution VCUG is typically performed for the initial evaluation of males and young children or infants with well-documented pyelonephritis; patients with neurogenic bladder; patients with duplex kidneys (Figure 37.5) and



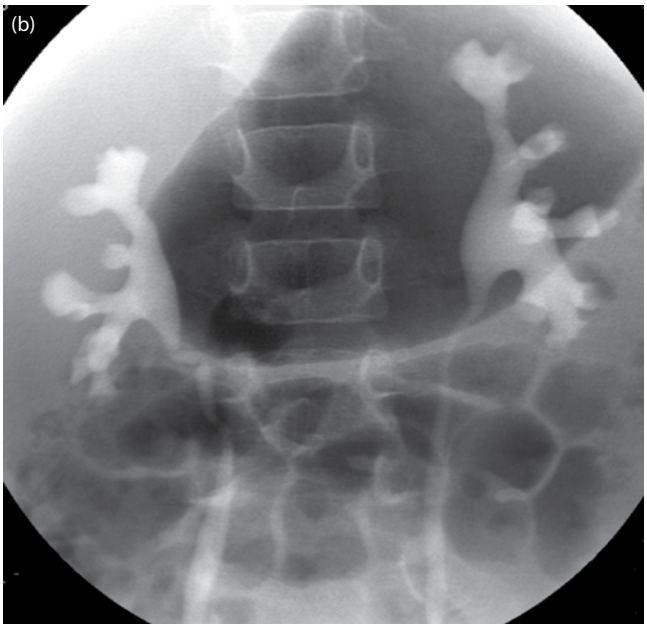


FIGURE 37.3 (a) Multiple images from a radionuclide cystogram demonstrate bilateral grade 2 reflux. (b) A single image from VCUG demonstrates bilateral grade 2 or 3 reflux.

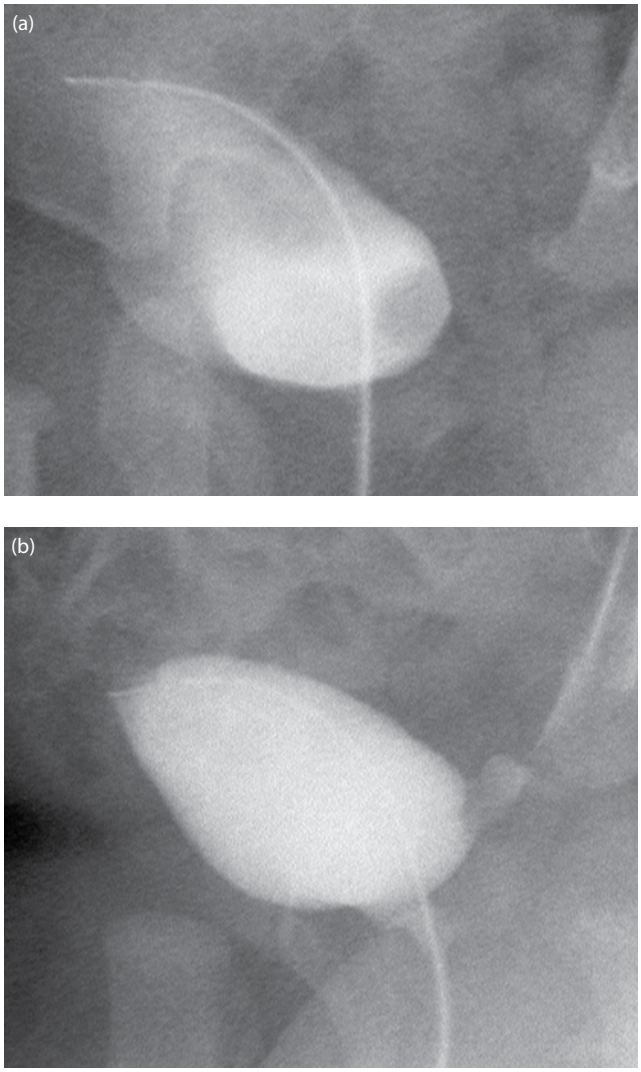

FIGURE 37.6 Oblique VCUG images of showing a left ureterocele (a) that everts (b).

dilatation of the upper or lower pole, or both; and patients suspected to have a ureterocele (Figure 37.6a and b).

RNC is performed for the follow-up of patients in whom reflux has been identified by VCUG, after antireflux surgery, and may be used in the initial evaluation of older girls. In siblings of children with reflux, the prevalence of reflux may be as high as 50%. Until recently, these siblings were screened for reflux, usually by RNC. This practice has recently come into question, partly on economic grounds,[19] and the clinical utility of screening siblings for reflux is an unresolved issue.

During sonocystography, the bladder is infused with an ultrasound contrast agent, and reflux is assessed by the sonographic appearance of contrast within the kidneys and ureters. The grading system is similar to that for VCUG.[20] Sonocystography is more sensitive[21] and accurate in detecting reflux[22–24] and provides similar anatomic detail of the bladder, ureters, and urethra as VCUG.[25,26] It is indicated in the first-time evaluation of reflux in girls and follow-up reflux after VCUG in boys and girls[27] and screening in high-risk patients. Transperineal ultrasound during voiding can detect posterior urethral valves[28] and is used to evaluate the urethra confidently.[29] At the time of this publication, ultrasound contrast agents were not approved by the U.S. Food and Drug Administration (FDA) for sonocystography, thus limiting its use there.

Cystography for assessing reflux can be stressful for the patient and family and is ideally performed by an experienced clinician in an environment comfortable for the patient, family, and healthcare provider. When parents and children are also well informed, prepared, and reassured, the discomfort of the examination is compared to that of an immunization, and thus no sedation is necessary.[30] Trained technologists and child life specialists are very helpful in preparing, educating, and reassuring parents and patients.[31] It can be helpful if a technologist, nurse, or child life specialist speaks with a parent by telephone a few days before the scheduled study. In the rare circumstances when sedation is required, midazolam and nitrous oxide can be used without decreasing the reliability of the examination.[32–35]

Patients who are suspected to have reflux because of a well-documented case of pyelonephritis should receive prophylactic antibiotics until the examination, and antibiotics should be continued if reflux is found.[36] Use of prophylactic antibiotics for prenatal hydronephrosis or a family history of reflux is controversial. Patients with prior allergies to intravenous contrast do not have allergies to intravesical contrast; thus, no premedication is required.

Renal Cortical Scintigraphy

Renal cortical scintigraphy uses the radiopharmaceutical ^{99m}Tc–dimercaptosuccinic acid (DMSA) to provide functional images of the renal cortex.[37] After intravenous administration, ^{99m}Tc-DMSA is taken up by cells in the proximal renal tubule, with little ^{99m}Tc-DMSA excreted into the renal collecting system. After 3–4 hours, most administered tracers will have cleared from the systemic circulation and accumulated in the renal cortex. The North American consensus guidelines[6] recommend an administered dose of ^{99m}Tc-DMSA of 1.85 MBq/kg (0.05 mCi/kg), with a minimum dose of 18.5 MBq (1.0 mCi).

Planar images (acquired in the posterior projection) permit localization of both kidneys and assessment of renal size and configuration. Images acquired in the posterior and oblique projections with a pinhole collimator can provide more detail about renal cortical structure and will provide greater sensitivity for identifying scars and other defects in the renal cortex. Single-photon emission computed tomography (SPECT) improves both the sensitivity and specificity for identifying defects in the renal cortex. In children less than 1 year of age, small patient size usually limits the utility of SPECT for imaging the renal cortex. Infants may have persistent fetal lobation, which an inexperienced interpreter may confuse with renal scarring. SPECT also offers the possibility of quantitative assessment of the functional renal volume.[38]

In patients with acute pyelonephritis, renal cortical imaging will demonstrate diminished DMSA uptake in the involved regions of the renal cortex. However, the use

of DMSA in the setting of acute infection will have little utility if all febrile urinary tract infections are treated in a similar manner. Renal cortical scintigraphy has greater utility when used for the evaluation of postinfection renal scarring. With successful therapy of pyelonephritis, long-term damage to the renal cortex can be averted, and this will be demonstrated by resolution of the cortical defects identified by cortical scintigraphy. Typically, scintigraphic defects will resolve within 3–6 months of an infection.[39] However, one study showed additional resolution for up to 3 years after treatment of an acute infection.[40] Scintigraphic defects will not resolve when there is persistent postinfection scarring. In one recent systematic review,[41] among children with an initial episode of febrile urinary tract infection, 57% were reported to have abnormalities on an acute DMSA scan and 15% were reported to have persistent abnormalities consistent with cortical scarring on a follow-up DMSA scan performed at least 5 months after the first scan. Patients with reflux were at higher risk for developing pyelonephritis and were more likely to develop renal scarring.

In patients with the diagnosis of reflux, DMSA cortical scintigraphy can be useful to assess for renal cortical scarring. Patients with both reflux and renal scarring may be at greater risk of additional scarring,[42] and the presence of scarring may support earlier surgical intervention to correct the reflux. No studies have adequately compared the accuracy of DMSA SPECT and state-of-the-art ultrasound in the evaluation of renal cortical scarring.

The standard approach for the evaluation of an initial febrile urinary infection[36] has been referred to as the "bottom-up" approach. That is, patients presenting with a febrile urinary infection are evaluated for reflux, which can be treated medically or surgically. In some patients, renal imaging, with either ultrasound or renal cortical scintigraphy, can be used to assess the risk of renal scarring. Critics of this approach point out that it will miss the small subset of children that may develop renal scarring in the absence of diagnosed reflux, and that many children with reflux will never develop renal scarring.[43] In response to these concerns, a "top-down" approach has been proposed, and has seen greater adoption in Europe than the United States.[44,45] This approach is based on the principle that abnormal DMSA cortical scintigraphy during an acute urinary infection identifies kidneys at risk for subsequent renal scarring. In the absence of a renal cortical defect, a patient with an acute febrile urinary infection will receive antibiotic therapy, but will undergo no further evaluation. Only patients with a renal cortical defect are evaluated for reflux. Critics of the top-down approach point out that a patient will not undergo evaluation for reflux until renal damage may already have developed. Also, implementation of the top-down approach requires DMSA cortical scintigraphy to be performed within 72 hours of the onset of acute urinary tract infection symptoms, which can be inconvenient and disruptive for the patient and family. The appropriate evaluation and management of children with a febrile urinary tract infection remains controversial[36,46,47] and is unlikely to be settled without rigorous studies assessing risk and outcome to provide evidence-based recommendations.[48]

IMAGING OF URETERAL DISEASES

Ultrasound

Introduction

Ultrasound is typically the first study selected in evaluating potential ureteral disease in children because it is noninvasive, rarely requires sedation, and emits no ionizing radiation. Whereas the normal-caliber ureter is not routinely visualized on ultrasound, even a mildly dilated ureter is readily imaged with contemporary equipment. This makes ultrasound an ideal modality for following anatomical abnormalities or pathological processes that result in hydronephrosis and hydroureter. Other than ideally having a bladder fully distended with urine to evaluate the bladder and distal ureters, no patient preparation is necessary.

The diagnostic quality of the ultrasound depends on the ability of the sonographer and sonologist, the machinery, and the use of new techniques and software. Imagers trained to work with children often employ special tricks when scanning children, such as prone imaging or scanning while the patient is being cradled by a caretaker, to obtain the best images.

The newest ultrasound machines offer a variety of methods that improve image quality over conventional imaging. For example, spatial compound imaging, or simply compound imaging, is a method that obtains information from several different angles of insonation and combines them to produce a single image. Harmonic imaging exploits nonlinear propagation of sound waves to form a more focused ultrasound beam that is less susceptible to reverberation artifacts. Ultrasounds are also able to acquire a volume of information, which can be translated into three-dimensional images and four-dimensional movies.[49]

The kidneys and bladder are easily visualized by ultrasound. Viewing the kidneys in the supine and prone positions increases the likelihood of visualizing the entire kidney, which can be partially obscured by bowel gas. A normal ureter is usually collapsed, and not typically visualized by ultrasound. A peristalsing ureter containing urine, measuring up to 3.5 mm in diameter, is normal. Dilated ureters are easiest to visualize near the ureteropelvic junction (UPJ) and behind a full bladder near the UVJ. The midureter is often hidden by bowel when imaged from the supine approach, and coronal imaging through the retroperitoneum can be helpful. A nonobstructed collecting system may be dilated due to a full bladder and should be reevaluated after the bladder is emptied.

Hydroureter is typically implied by seeing proximal and distal ureteral dilatation even when the midureter is obscured by bowel gas. Hydroureter may be due to reflux or obstruction, or both. The degree of distal ureteral dilatation in patients with reflux predicts a high grade of reflux.[50] In patients with acute obstruction, the absence of a ureteral jet or asymmetry in ureteral jet frequency in the bladder correlates highly with high-grade ureteral obstruction.[51]

Prenatal Hydronephrosis

The finding of hydronephrosis is made on 1 in 200 routine prenatal ultrasounds. Postnatally, ultrasound will confirm the majority of these cases to be mild, without hydroureter, allowing them to be followed sequentially with serial ultrasounds until resolution has been documented. If the postnatal ultrasound demonstrates moderate (characterized by calyceal dilatation) or severe (characterized by parenchymal thinning) hydronephrosis, further diagnostic studies are indicated. These would include VCUG to rule out reflux and magnetic resonance urography (MRU) or a mercaptoacetyltriglycine (MAG-3) renal scan to exclude a UPJ or UVJ obstruction. Hydroureter with any degree of hydronephrosis mandates further evaluation for reflux with VCUG (Figure 37.7a and b).

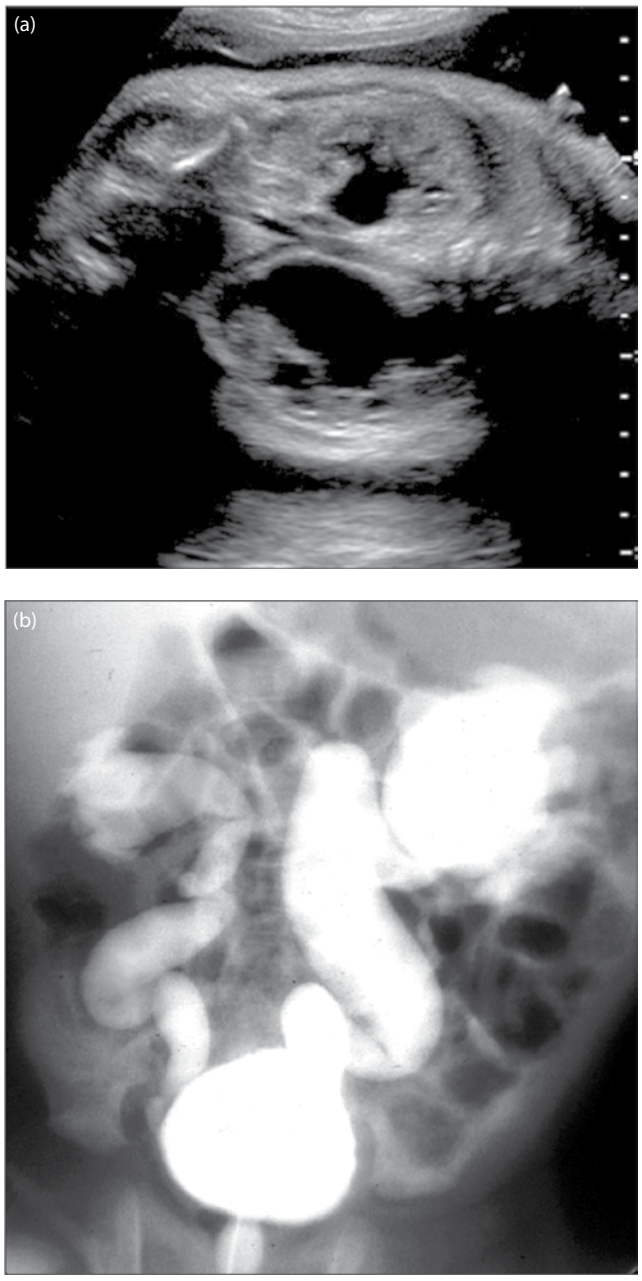

FIGURE 37.7 (a) Prenatal ultrasound showing bilateral hydronephrotic kidneys in the coronal plane. (b) VCUG demonstrates bilateral high-grade vesicoureteral reflux.

Duplex Systems

A duplex collecting system may present prenatally, especially if there is associated hydronephrosis. Hydronephrosis of the upper pole and ureter is typically associated with distal ureteral obstruction due to an ectopic ureter or ectopic ureterocele. Ultrasound views of the bladder enable one to make this distinction. A ureterocele is visualized as a fine septum within the bladder, while an ectopic ureter courses beneath the full thickness of the bladder wall in the transverse view. Lower-pole hydronephrosis is typically due to reflux or UPJ obstruction. Therefore, VCUG and MRU or a MAG-3 renogram is needed for further evaluation of lower-pole hydronephrosis (Figure 37.8a–c).

Postoperative Assessment

In patients undergoing either pyeloplasty for UPJ obstruction or transurethral incision of an obstructing ectopic ureterocele, ultrasound is an ideal modality for postoperative confirmation of the relief of ureteral obstruction. Ultrasound is a nondefinitive study for ruling out postoperative reflux, as it can miss up to 75% of cases of reflux.

Renal Calculi

Ultrasound is an excellent initial study for the assessment of renal colic in the child. Initially, it is important to rule out a congenital obstructive lesion of the ureter at either the UPJ or UVJ. Next, an attempt is made to identify a stone within the ureter, which typically produces distinct shadowing and hydroureteronephrosis proximally. Additional calculi may be imaged within the kidney, and a stone may coexist with a congenital obstructive lesion or alternatively mimic one, if lodged at the UPJ or UVJ. Occasionally, a perinephric urinoma can be imaged in conjunction with an obstructing calculus. Evaluation for a renal stone requires meticulous and thorough imaging, which includes carefully following the entire course of the renal pelvis and ureter (Figure 37.9).

Not only is ultrasound capable of imaging renal and ureteral calculi, but in the form of extracorporeal shock wave lithotripsy (ESWL) with ultrasound guidance, it can also be used to fragment calculi, thereby allowing them to be cleared naturally by the urinary tract. The effectiveness of any surgical treatment for stone clearance may be accurately assessed by ultrasound, and ultrasound may be used for long-term surveillance of stone formers.

Ectopic Ureter

The evaluation of a female patient who is continually wet must include consideration of an ectopic ureter. Ultrasound remains the first imaging evaluation for making this diagnosis, as it may show findings that indicate a (sometimes subtle) dysplastic upper pole or solitary ectopic dysplastic kidney. Traditionally, intravenous pyelography (IVP) was used to evaluate a patient with a suspected ectopic ureter, but this has been essentially replaced by computed tomography urography (CTU) and MRU. These techniques

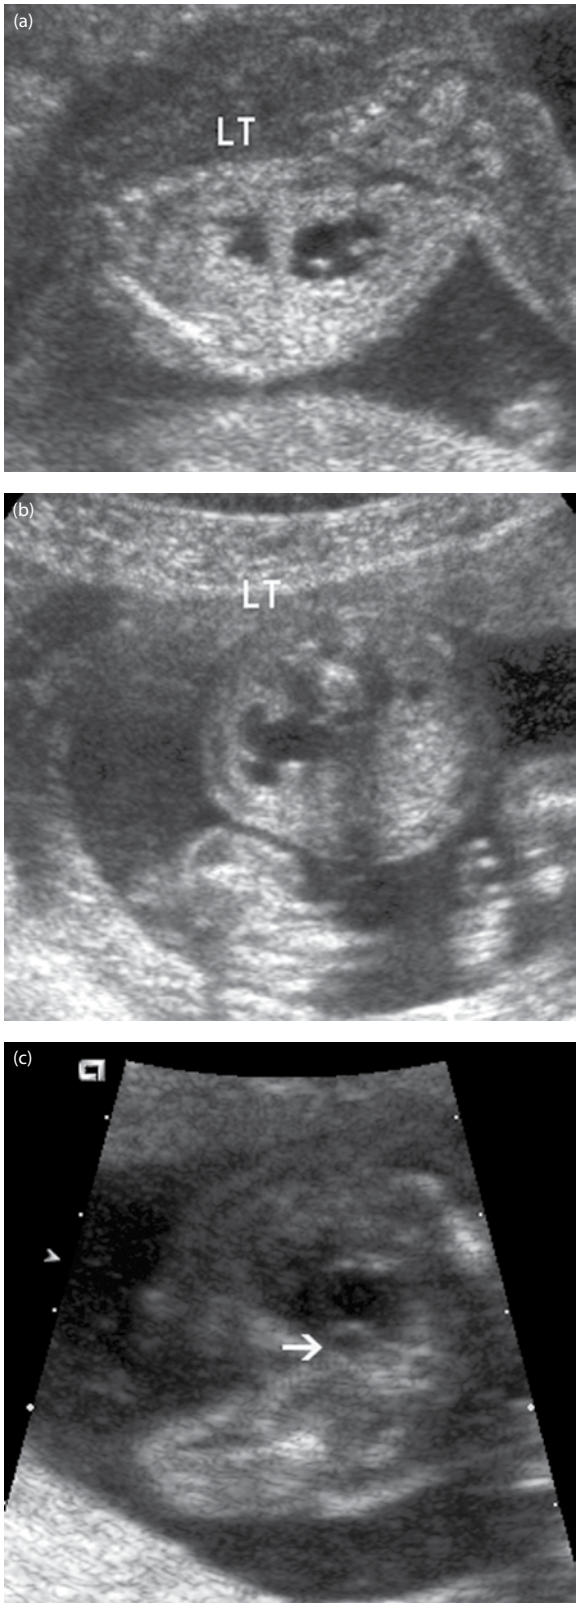

FIGURE 37.8 Fetal ultrasound showing sagittal (a) and axial (b) images of the left kidney with upper- and lower-pole hydroureteronephrosis. (c) Transverse view of the fetal bladder showing a ureterocele (arrow). After the patient was born, imaging studies showed a left duplex kidney with an upper-pole obstructed ureter ending in a ureterocele and lower-pole reflux (imaging studies not shown).

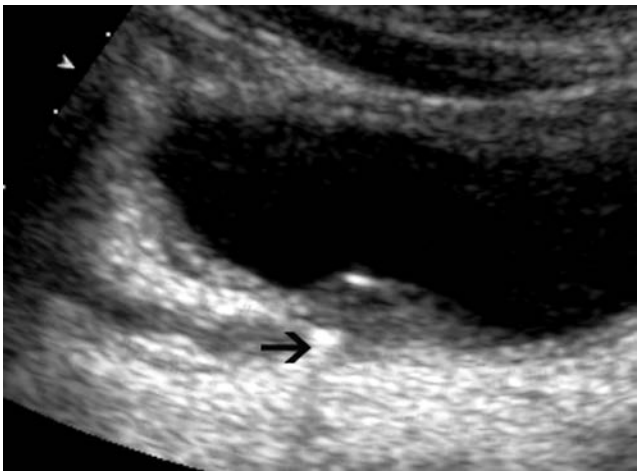

FIGURE 37.9 Distal ureteral stone. A sagittal ultrasound of the bladder demonstrates a small distal ureteral calculus (arrow) with mild hydroureter and edema at the UVJ.

better show the dysplastic upper pole and the degree of function, and may also show the site of ectopic ureteral insertion. With MRU, the benefit of nonionizing radiation study must be weighed against the potential need for sedation and higher cost (Figure 37.10).

Primary Megaureter versus Ectopic Ureter

IVP is no longer routinely performed in all cases of hydroureteronephrosis. A combination of ultrasound, MAG-3 renal scan, and MRU are useful in diagnosing and characterizing UVJ obstruction and distinguishing a primary

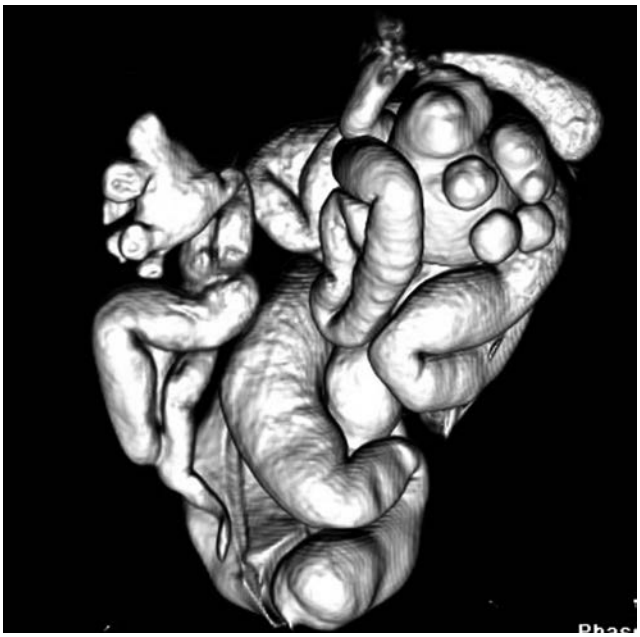

FIGURE 37.10 Magnetic resonance shaded rendering image of a urinary tract patient with prenatal hydronephrosis who was found to have severe bilateral hydroureteronephrosis postnatally. On the right, there is a UVJ obstruction of a bifid ureter. There is complete ureteral duplication on the left, with the upper-pole ureter inserting ectopically.

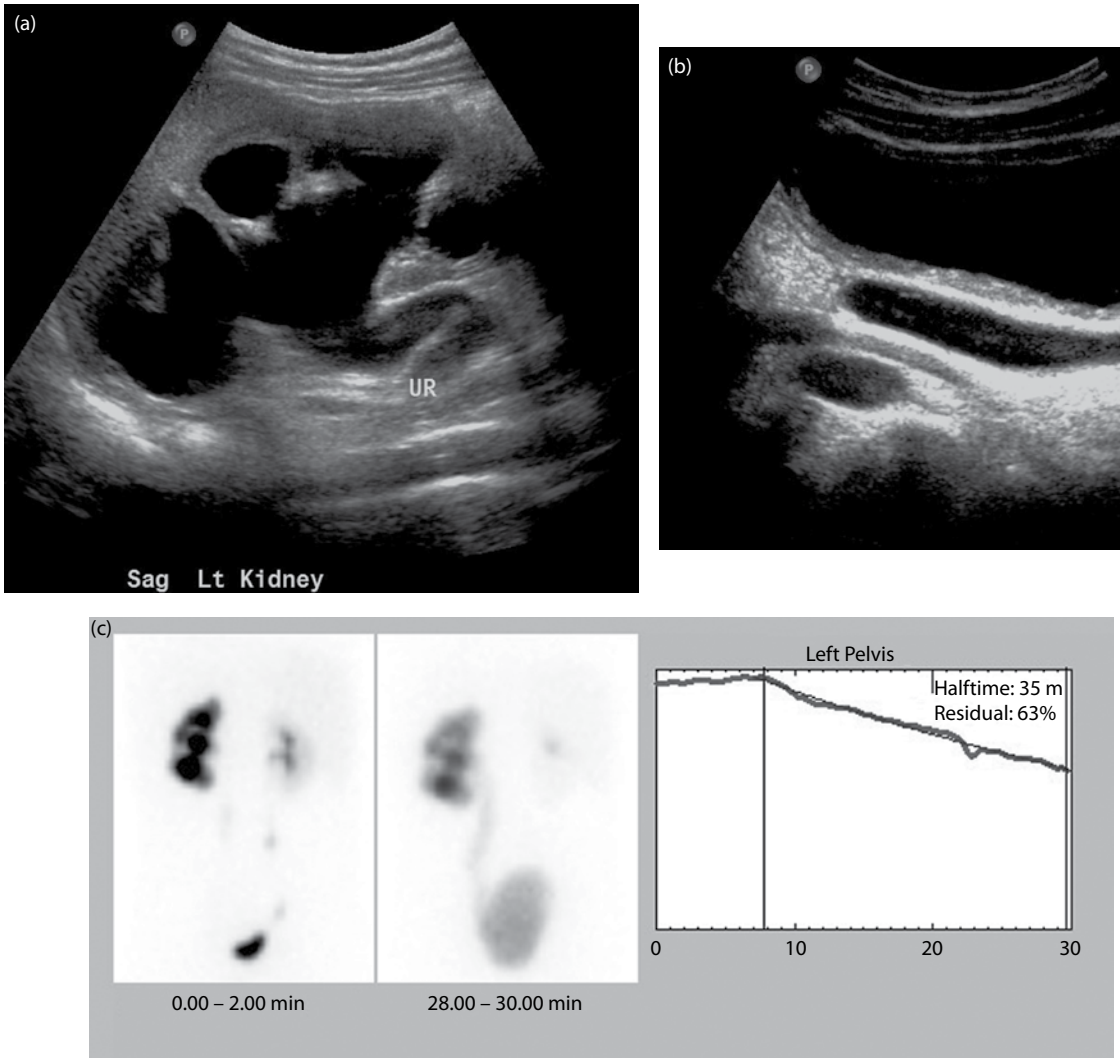

FIGURE 37.11 This patient, who presented with a febrile urinary tract infection, was found to have right primary megaureter. (a and b) The ultrasound images show left hydroureteronephrosis. (c) Obstruction was confirmed with obstructive values on a lasix renogram.

obstructive megaureter from a single-system ectopic ureter. This distinction is important, as a primary megaureter may be managed initially by observation, while an ectopic ureter usually requires surgical correction (Figure 37.11a–c).

Postoperative Assessment

For many patients who undergo repair of a UPJ or UVJ obstruction, the dilatation of the renal collecting system and ureter typically does not resolve during the first few months after surgery. In this setting, a nuclear medicine renogram or intravenous pyelogram may be invaluable in demonstrating that the obstruction has been corrected despite continued dilatation of the collecting system. Alternatively, if there is concern for postoperative collecting system obstruction, IVP is an excellent study for assessing the anastomosis site.

Another setting in which IVP may be valuable is in looking for an anterior crossing vessel that may produce intermittent renal colic due to intermittent kinking at the UPJ. Such a vessel may present as a proximal ureteral filling defect that disappears after surgically transposing the pelvis and ureter anterior to the crossing lower-pole artery (Figure 37.12).

Renogram

Introduction

Dynamic renal scintigraphy, or renogram, can be used to evaluate both renal cortical function and collecting system drainage.[52] Evaluation of the collecting system can be enhanced by adding a diuretic, such as furosemide, to perform a diuretic renogram. The preferred radiopharmaceutical is ^{99m}Tc-MAG-3, which is preferentially excreted by renal tubular secretion with a high extraction efficiency. The North American consensus guidelines[6] recommend an administered dose of ^{99m}Tc-MAG-3 of 3.7 MBq/kg (0.1 mCi/kg), with a minimum dose of 37 mBq (1.0 mCi) and a maximum dose of 148 MBq (4 mCi). A 1-minute flow study is typically performed at the start of the renogram in adults, but it necessitates a

FIGURE 37.12 This intravenous pyelogram of an 8-year-old boy who presented with flank pain shows the "hooked" appearance of the proximal ureter that is characteristic of high ureteral obstruction from a crossing vessel.

higher radiopharmaceutical dose and is rarely indicated in pediatric patients. A renogram also could be performed with ^{99m}Tc–diethylene triamine pentaacetic acid (DTPA), but DTPA produces studies with lower image quality due to its lower extraction fraction compared with MAG-3.[53] As it is excreted essentially by only glomerular filtration, DTPA does have a role in the quantitative determination of glomerular filtration rate (GFR).[54]

Patients should be well hydrated to maintain adequate renal blood flow to reliably assess renal cortical function. Many protocols recommend an intravenous saline infusion during the study to replete intravascular volume and produce a saline diuresis to ensure sufficient urine volume to evaluate collecting system function.[55] This can be particularly important when performing a diuretic-enhanced renogram. Urinary catheterization is recommended, particularly in younger children, who may not void on command, and in patients with bladder dysfunction. Retained urine, especially in a full bladder, may impede ureteral drainage, or rarely may reflux into a ureter. Either of these processes may produce a false-positive study.

Renogram images are acquired using a gamma camera.[55] Images are typically as a dynamic study for 20 minutes, during which time much of the ^{99m}Tc-MAG-3 has been cleared from the soft tissues of the body and excreted in the urine. Renal cortical function can be evaluated by quantitatively assessing cortical uptake of the tracer and transit of the tracer into the collecting system. Frequently, image analysis will demonstrate normal renal excretion and collecting system clearance, and the study can be terminated. Tracer excretion will be slowed with renal insufficiency, and visual inspection of images is required to determine if renal retention of the tracer reflects cortical dysfunction or collecting system obstruction. Sometimes, delayed planar images are helpful to demonstrate slow but continued drainage of the tracer from a dilated or partially obstructed collecting system, but a furosemide diuresis is usually preferred.

Diuresis can be induced by administration of furosemide at a dose of 1 mg/kg. The usual maximal dose is 40 mg, unless there is impaired renal function or if the patient has been on chronic diuretic therapy. There are at least three different approaches for performing a diuretic renogram, with different times for intravenous furosemide administration. Administration of furosemide at least 20 minutes (F + 20) after administration of the tracer was endorsed by a 1992 joint statement of the American Society of Fetal Urology and the Pediatric Council of the Society of Nuclear Medicine.[56] Diuretic can also be administered some period of time (F – 15) before administration of the tracer.[57] Finally, some clinicians, particularly in North America and Australia, favor administering the tracer and diuretic at the same time (F – 0).[58] Each method requires a different approach to image acquisition, analysis, and interpretation. F – 15 and F – 0 have the potential advantage of being shorter in duration, but F + 20 usually has the benefit of allowing collecting system drainage to be assessed in the absence of substantial tracer accumulation in the renal cortex. The F + 20 approach may allow furosemide administration to be avoided in patients shown to have normal spontaneous collecting system drainage. The F + 20 approach may also be useful in identifying a dilated, nonobstructive collecting system after surgical correction of an obstruction. If the dynamic renogram demonstrates significant cortical dysfunction, a diuresis phase may not be indicated to evaluate the collecting system, and moreover, there may be an impaired response to a diuretic.

Hydronephrosis, Hydroureteronephrosis, and Obstruction

For the assessment of a hydronephrotic kidney or hydroureteronephrotic collecting system, the MAG- 3 renal scan provides quantitative information regarding renal function and drainage of the dilated system. Based on the results of the MAG-3 scan, one can determine whether relative renal function appears to have been compromised and whether drainage is in the normal, intermediate, or obstructive range (for clearance time of half the tracer [T1/2], <10–15 minutes is normal, 15–20 [or 10–20] minutes intermediate, and >20 minutes obstructive). This information is particularly crucial for the postnatal assessment of prenatal hydronephrosis in healthy, asymptomatic babies. Typically, one waits until 1 month of age prior to performing the MAG-3 scan in order to ensure adequate renal maturity. Then the severity of an apparent UPJ or UVJ obstruction can be accurately assessed. These functional results, in conjunction with postnatal ultrasound findings, should enable one to develop a rational management plan—rarely for immediate surgery, and usually for follow-up imaging with serial ultrasound or MAG-3 studies, depending on the initial findings (Figure 37.13a–e).

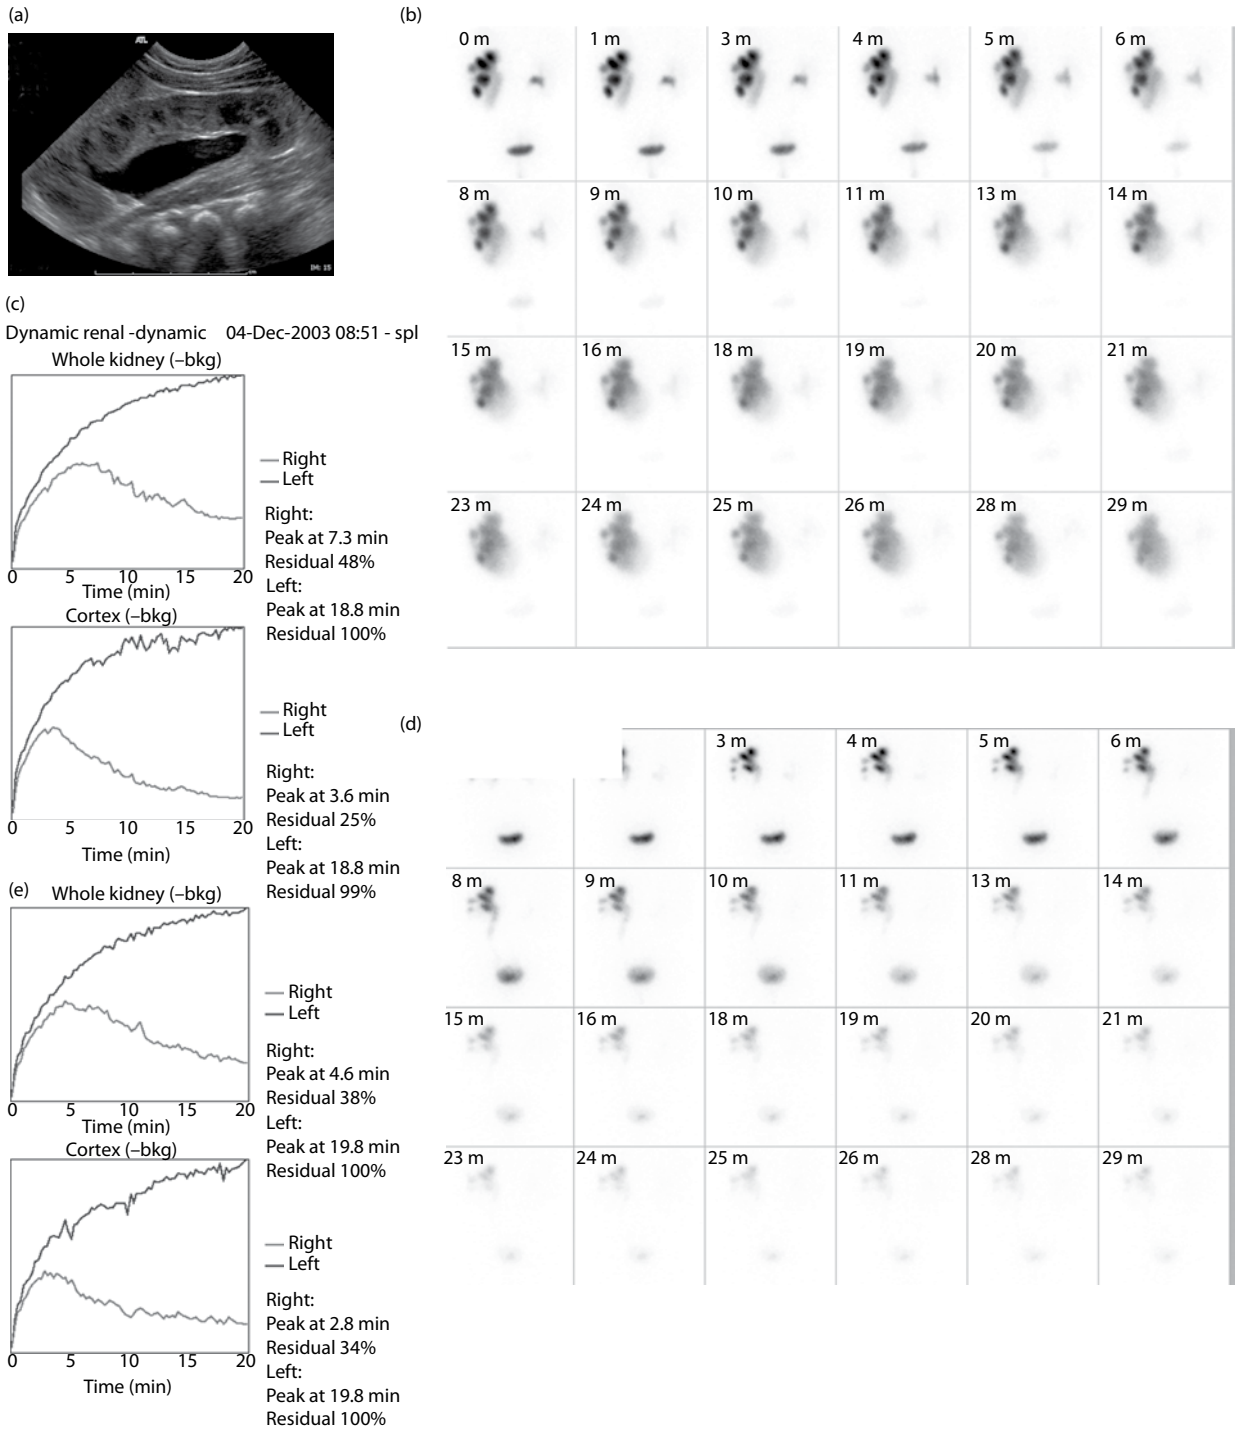

FIGURE 37.13 Two-month-old infant with prenatal hydronephrosis. (a) A postnatal ultrasound demonstrates unilateral moderate hydronephrosis. (b and c) An initial MAG-3 study with lasix demonstrates delayed drainage of the left kidney due to a UPJ obstruction. The time–activity curve demonstrates delayed excretion of contrast in the obstructive range. (d and e) A postoperative MAG-3 examination demonstrates improvement.

Computed Tomography or Computed Axial Tomography

Introduction

Computed tomography (CT), also known as computerized axial tomography (CAT), is a widely used modality for adult urinary tract imaging because of its applicability to stone disease, trauma, and the evaluation of renal masses, but it is used more sparingly in children due to the concern of radiation exposure.

Early CT scans acquired one "slice" or axial cross section of information at a time. With spiral or helical scanners, x-rays are emitted and detected as the patient

moves continuously through the scanner, creating a volume of information. Multislice or multidetector computed tomography (MDCT) scanners have multiple detectors rotating simultaneously around the patient with the effect of increasing spatial resolution and decreasing the time to perform a study over standard spiral scanners.

With a volume of information created, images can be reconstructed in many planes and reformatted to enhance the conspicuity of ureters. The ease and speed of obtaining large quantities of information by CT scan needs to be weighed against the radiation risk and financial cost of the examination. Depending on the method, the absorbed radiation dose of a single CT scan of the abdomen is significantly greater than that of an abdominal radiograph. The rapidly growing tissues of children are very susceptible to the deleterious effects of radiation.

Contrast and non-contrast-enhanced CT scans are used in the evaluation of the ureter. Non-contrast-enhanced CT is used for the evaluation of nephroureterolithiasis and resulting obstruction. Contrast-enhanced CT, especially timed during the excretory phase, is useful for showing the opacified ureters. Multiphase CT scans evaluate the genitourinary system without contrast, and then with contrast, timed to the cortical and excretory phases of contrast enhancement. Multiphase CT scan should be used sparingly in children due to the high radiation dose.

Methods used to enhance ureteral opacification after contrast administration include abdominal compression with bellows,[59] intravenous hydration during the examination,[60] prone and supine imaging,[61] multiplanar reformatting, and virtual endoscopy.[62] The angiographic phase of contrast enhancement is useful in clarifying vascular anatomy in the cases of trauma or UPJ obstruction.[63–65]

Nephroureterolithiasis

The spiral CT scan, without contrast, can rapidly assess the upper tract for a calculus. On the basis of Hounsfield units, it has the advantage, relative to ultrasound, of distinguishing a stone from an air bubble or intraluminal polyp. Its disadvantage is the ionizing radiation entailed; however, multiple low-dose methods have now reduced CT significantly.[66] However, ultrasound remains the initial imaging modality for suspicion of nephrolithiasis[67] (Figure 37.14).

Ureteral Trauma

In the assessment of urologic trauma, the CT scan with contrast is invaluable. Images performed during the excretory phase of contrast enhancement are the best for evaluation of the ureter.[68–70] CT is capable of demonstrating extravasation due to pelviureteric disruption of the ureteropelvic junction secondary to hyperextension injuries or ureteral disruption due to penetrating trauma. It also affords one the capability of assessing injuries to associated organs, such as the spleen or liver (Figure 37.15).

Other Ureteral Anomalies

CT has a wide range of uses, including the assessment of an abnormal course of the ureter, such as a retrocaval ureter,[71] ectopic ureteral insertion,[72] or ureteral obstruction.

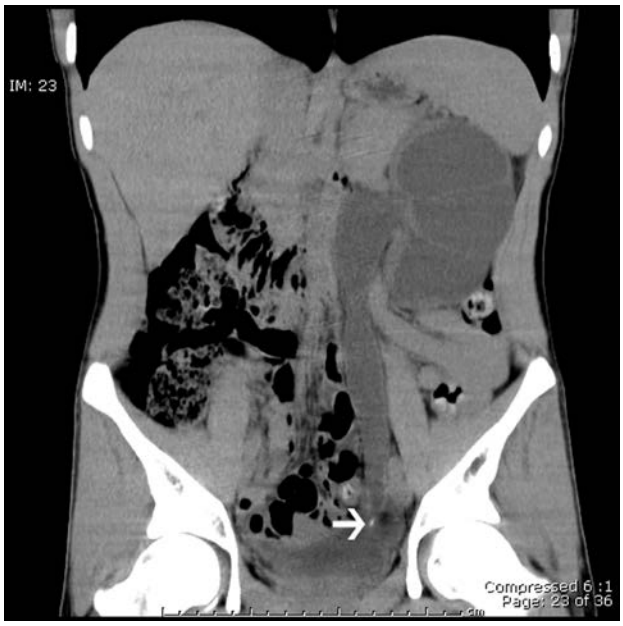

FIGURE 37.14 CT with coronal reformatting showing a left UVJ calculus (arrow) in a patient with primary megaureter.

FIGURE 37.15 Am axial CT image performed during the excretory phase of contrast enhancement demonstrates right perinephric contrast extravasation due to a ureteral tear at the UPJ.

The CT scan with contrast is also valuable in assessing the solid retroperitoneal mass, such as Wilms' tumor or neuroblastoma, and its effect on ureteral anatomy.

Specialized Opacification Techniques

Introduction

The specialized opacification techniques enable one to visualize the ureter precisely in complex anatomical or operative clinical settings.

Retrograde Ureterography and Pyelography

Retrograde ureterography and pyelography are performed cystoscopically in the anesthetized child through

a ureteral catheter using one-half strength Cystografin. It is used to opacify the distal ureter prior to pyeloplasty, to ensure normal distal ureteral anatomy, and to confirm the level of ureteral obstruction. It can be invaluable in distinguishing a typical UPJ obstruction from rare lesions, such as fibroepithelial polyps of the UPJ and midureteral strictures. Retrograde pelography is also useful in the assessment of ureteral trauma and evaluation of the stone patient prior to ureteral stone basketing or lithotripsy. In difficult diagnostic situations, such as unusual duplication anomalies or ectopic ureters, retrograde ureterography and pyelography can be extremely valuable in defining the anatomy (Figure 37.16a and b).

Antegrade Pyelography and Ureterography

Antegrade pyelography and ureterography are uncommon studies, utilized to define unusual anatomy, often in conjunction with the goal of draining a hydronephrotic collecting system. The antegrade study can be extremely valuable in defining postsurgical complications, such as obstruction or urinary extravasation. It is particularly useful in defining the anatomy of duplex collecting systems, dilated ureters draining ectopically, and collecting systems associated with poorly functioning kidneys that do not excrete contrast well.

Whitaker Test

The Whitaker test is a physiologic study combined with the anatomic benefit of antegrade pyelography, used to assess upper tract obstruction. The Whitaker test is performed with percutaneous access to the kidney and catheter drainage of the bladder. Pressures within the renal pelvis and bladder are measured during a constant infusion of contrast into the renal pelvis. Pressure differentials between the kidney and bladder of less than 15 cm of water are considered normal, whereas pressure differentials that exceed 20 cm of water are consistent with obstruction. During the course of the study, imaging of the ureter clearly demonstrates the level of obstruction. This test is particularly valuable in assessing a postoperative result when hydronephrosis persists and renal function is so impaired that nuclear renography is nondiagnostic.

Magnetic Resonance Urography

MRU offers the combination of high-resolution anatomic imaging and functional information of the genitourinary system without radiation. In children, MRU is used to evaluate urinary tract dilatation and differentiate it from obstruction,[73–75] evaluate complex genitourinary anatomy,[76] and assess the ureters.[77]

MRU provides beautiful assessment of renal anatomy and can provide functional imaging comparable to that of renal diuretic scintigraphy.[74,78] Unlike IVP and scintigraphy, visualization of the ureters and kidneys is not dependent on renal function. MRU is especially useful in children with obstruction or complex anatomy. Some advocate this method to replace ultrasound and renal diuretic scintigraphy in the evaluation of hydronephrosis.[74]

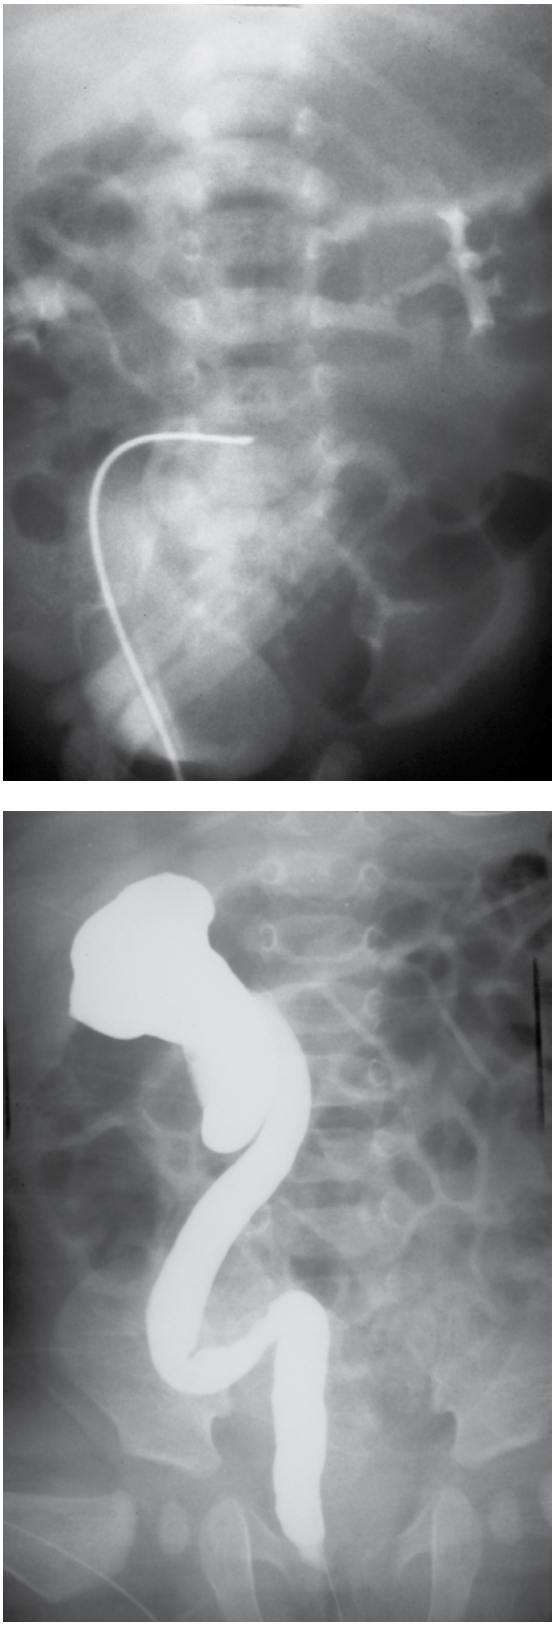

FIGURE 37.16 Intravenous pyelogram and retrograde ureterogram in a patient with a right upper-pole ectopic ureter. (a) IVP in a newborn infant demonstrates lateral deviation of the right lower-pole collecting system. The left kidney appears normal. (b) A retrograde ureterogram demonstrates the ectopic upper-pole ureter and pelvis.

Many protocols are widely available.[73,74,79,80] Modern magnetic resonance techniques and improved coils allow for improved spatial and temporal resolution and faster acquisition time. The anatomy of the genitourinary system can be most easily surveyed using fluid-sensitive sequences, which give good tissue contrast between the fluid-containing collecting system and renal parenchyma and other organs. Functional information can be obtained using fast imaging magnetic resonance techniques after contrast administration and allow evaluation of parenchymal perfusion, the GFR,[81] the renal excretory function, and urinary drainage.[82] However, patients who receive contrast administration of gadolinium-based contrast agents and have severely impaired renal function are at risk for nephrogenic systemic fibrosis (NSF), a rare systemic fibrosing ailment that mainly involves the skin. Thus, patients with acute or chronic renal failure and a low GFR (<45 mL/min/1.73 m^2), or acute renal insufficiency of any severity due to the hepatorenal syndrome or in the perioperative liver transplantation period,[83] should not have contrast administration.

In order to obtain good-quality images, children must lay supine with minimal motion within the bore of the MRI, which is a relatively narrow tunnel. Since even the simplest examinations for the evaluation of genitourinary anatomy requires at least half an hour, those who are unable to hold still for this period of time require sedation. For longer studies that provide functional information, children need an IV for intravenous contrast, furosemide, and hydration. Due to the large volume of urine that is produced after hydration and diuretic use, Foley catheter drainage of the bladder is helpful for patient comfort and to reduce the likelihood of the patient waking up during sedation. Like other studies, patient and family preparation is crucial. Guidance from child life specialists and skilled technologists and use of videos and music often reduce the need for sedation (Figure 37.17).

CHAPTER
38

Ureteral Anomalies and Their Surgical Management

Kathleen Kieran and Christopher S. Cooper

INTRODUCTION

Although ureteropelvic junction obstruction, ureteroceles, and obstructive megaureters account for the vast majority of ureteral obstructions, the pediatric urologist must consider less common causes of ureteral obstruction when evaluating a patient with complaints that suggest ureteral pathology. While the aforementioned common causes of ureteral obstruction are addressed elsewhere in this book, this chapter describes the pathophysiology, evaluation, and management of ureteral obstruction secondary to retrocaval ureter, ureteral valves, ureteral strictures, and ureteral polyps. Anomalies of ureteral number are also briefly discussed, although the reader is directed to the pertinent chapter (Chapter 40) for a more detailed discussion on the surgical management of ureteral duplication anomalies and ectopia.

EMBRYOLOGY

Evaluation of the patient with a suspected ureteral anomaly should be conducted in the context of an understanding of normal ureteral development. The mesonephros develops at 24–26 days and progresses caudally along the longitudinal axis of the embryo, giving rise to the mesonephric (Wolffian) ducts and tubules. The Wolffian ducts ultimately give rise to the ureteral bud, which grows cranially in the fourth week of gestation; upon contact with the metanephric mesenchyme, reciprocal coinduction results in the development of the definitive fetal kidney.[1,2] Abnormalities in the growth or development of the Wolffian bud, or in the reciprocal coinductive pathways, may result in abnormal ureteral structure and function. Additionally, the clinician must remember that nearby structures are also forming as the ureter develops, and abnormalities in these structures may affect ureteral development.

PATIENT PRESENTATION AND EVALUATION

The ureteral anomalies to be discussed all have compromise of the ureteral lumen by either intrinsic or extrinsic factors. Thus, patients typically present with symptoms of ureteral obstruction, such as flank, abdominal, or back pain; hematuria; urinary tract infection (UTI); and nausea and/or vomiting. With the increasing employment of cross-sectional imaging, these ureteral anomalies may be found incidentally; however, on further questioning, many of these patients may recall symptoms similar to those described.

The need for and choice of laboratory and radiographic studies is dictated by the clinician's suspicion for a ureteral etiology for the presenting symptoms. At the very least, a urinalysis should be performed to exclude infection; a chemistry panel, as well as a complete blood count, may also prove useful in patients with suspected infection or severe obstruction. Renal ultrasonography is typically employed as the initial imaging study, since it allows assessment of the degree of pelvic, calyceal, and ureteral dilatation, as well as parenchymal echogenicity. If the initial renal sonogram suggests a ureteral anomaly, further evaluation is typically undertaken with either cross-sectional imaging (computed tomography [CT] scan or magnetic resonance imaging [MRI]) or cystoscopic evaluation with retrograde pyelogram in order to better define the laterality and extent of any pathology.

RETROCAVAL URETER

The reported incidence of retrocaval ureter is about 1 in 1000 and occurs two to three times more frequently in males.[3] Patients with retrocaval ureter may also have cardiovascular or genitourinary anomalies.[4,5] The retrocaval ureter almost always involves the right ureter; however, rare cases involving the left side have been reported, usually associated with situs inversus.[6,7] Despite its name, the retrocaval ureter arises secondary to anomalous vascular development. In the fetus, the supracardinal vein lies dorsal to the ureter and usually forms most of the infrarenal segment of the inferior vena cava. The subcardinal, or posterior cardinal, vein lies ventral to the ureter; if the subcardinal vein persists, it becomes the infrarenal segment of the vena cava. When the inferior vena cava is derived from the subcardinal vein, the ureter encircles the vena cava, with a portion of the ureter running behind

the vena cava.[8] While most patients with a retrocaval ureter are asymptomatic, others may present with pain, hematuria, UTIs, or stones in the setting of functional or anatomic ureteral obstruction;[9,10] the retrocaval segment of the ureter is often stenotic. In children diagnosed with retrocaval ureter, UTI is often the presenting symptom.

Based on radiographic criteria, two types of retrocaval ureters have been described.[11] Type I (low-loop) retrocaval ureter is more common and is associated with moderate or severe hydronephrosis, with significant medial deviation of the ureter at the L3 vertebral body. Type I retrocaval ureters typically have an S-shaped or fishhook deformity (Figure 38.1). Type II (high-loop) retrocaval ureter is seen less frequently; it is associated with less pronounced hydronephrosis and less medial deviation. Type II retrocaval ureters have a "sickle"-shaped appearance at the point of medial deviation. While widespread use of ultrasonography has resulted in more cases of retrocaval ureter being diagnosed following identification of hydronephrosis, the clinician must be careful to exclude other causes of retroperitoneal pathology. Both CT and MRI are sensitive and have specific modalities for confirming the diagnosis;[4,12,13] the latter has the benefit of avoiding radiation exposure. Nuclear medicine renal scans may be helpful to estimate relative renal function and identify the degree of obstruction.

Surgical treatment involves division of the ureter, enabling ureteral continuity to be reestablished anterior to the inferior vena cava. When the proximal ureter is redundant or stenotic, excision of a portion of the ureter may be necessary. Both open and laparoscopic or robotic approaches have been successfully employed for repair (Figure 38.2).[13–17]

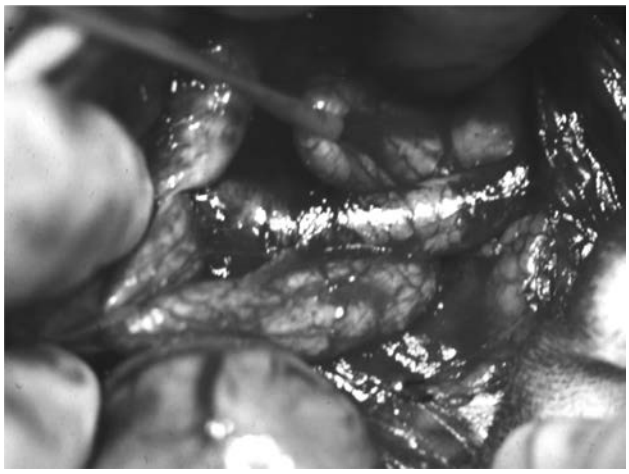

FIGURE 38.2 Retrocaval ureter.

URETERAL STRICTURE

Ureteral stenosis or strictures are most commonly seen in the distal ureter and can be associated with megaureters; however, midureteral lesions may also occur (Figure 38.3).

FIGURE 38.1 Intravenous pyelogram of a patient with a retrocaval ureter. Note the extensive dilatation of the proximal ureter and medial deviation at the third lumbar vertebra.

FIGURE 38.3 Retrograde ureteropyelogram demonstrating short ureteral stenosis.

Congenital strictures tend to occur in locations where the ureter is closely associated with another structure (including the kidney or bladder), but the exact precipitating events leading to stricture development are unknown. Abnormalities of the contralateral renal unit have also been reported in conjunction with congenital midureteral strictures.[18] Although the strictured ureter is uniformly lined by transitional epithelium, other histologic findings are variable and may range from hypertrophied smooth muscle to a near absence of muscular fibers.[19,20] Like other ureteral lesions, the symptoms of congenital ureteral strictures are variable and depend on the degree of obstruction and renal function, and the pathologic changes proximal to the stricture vary, reflecting the severity and duration of the obstruction. Pyelonephritis, complicating obstruction, may lead to decreased renal function.[21]

Ureteral strictures may be discovered incidentally during an evaluation for antenatal hydronephrosis. Although these congenital strictures can be asymptomatic, they may be less amenable to conservative management than other causes of antenatal hydronephrosis.[19] Because obstruction at any location within the collecting system may present with similar symptoms and radiographic findings, the clinician must be careful to identify the precise location of the affected area prior to proceeding with surgical repair. Confirmation of the presence and length of the ureteral stricture is best accomplished by retrograde ureteropyelogram.[22] Endoscopic evaluation also permits consideration of endoscopic treatment. Both dilatation and incision have been successfully employed for ureteral strictures, but the initial success rates and long-term durability of these procedures are lower than for open repair. Open techniques typically involve excision of the affected segment with reestablishment of ureteral continuity.[21] Laparoscopic and robotic modalities have also been used successfully.[23]

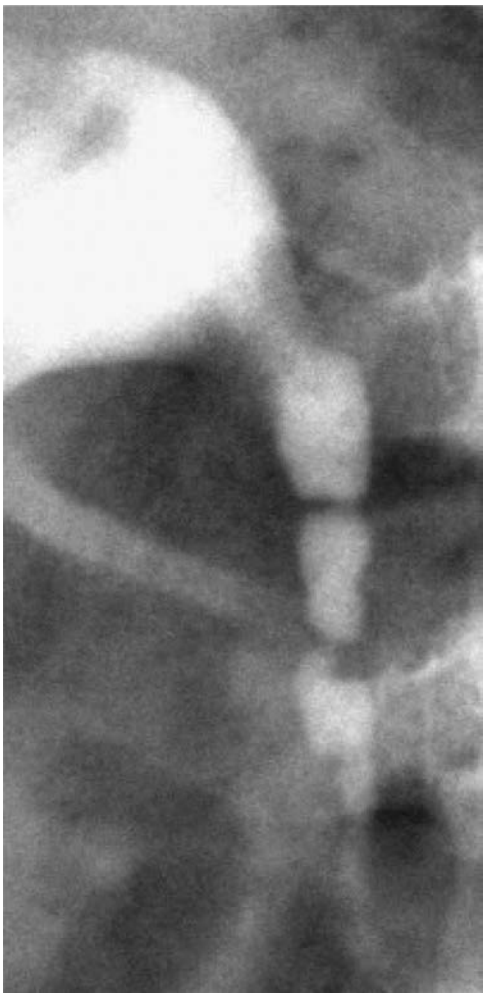

FIGURE 38.4 Intravenous pyelogram demonstrating nonobstructive Ostling's folds in the proximal ureter of a 5-month-old infant.

URETERAL VALVES

Ureteral valves are an uncommon finding, with fewer than 100 cases reported in the literature. Valves are frequently associated with other ureteral anomalies, including duplication, ectopia, and vesicoureteral reflux.[24] Ureteral valves and coexisting ureteral strictures have also been reported.[25] Ureteral valves are more common in boys and on the left side (although more recent publications dispute these findings).[26] Histologically, valves are transverse folds of tissue consisting of smooth muscle extending into and blocking the ureteral lumen, covered by normal transitional epithelium.[20] These valves are believed to represent abnormal persistence of transverse folds that arise as part of normal ureteral development (Ostling's folds; see Figure 38.4).[21] Two types of ureteral valves have been described:[27] one with ureteral stenosis at or distal to the site of the valve, and one that involves a distal ureter of normal caliber. Both types of valves have the orifice and long axis of the distal ureter eccentrically located with respect to the long axis and lumen of the proximal dilated ureter (Figure 38.5). This configuration selectively inhibits antegrade but not retrograde flow.

Patients with ureteral valves typically present with flank pain and hydronephrosis. Treatment of the valves depends on the location and typically involves resection and reconstruction with ureteropyelostomy, ureteroureterostomy, or ureteroneocystostomy.

URETERAL POLYPS

Fibroepithelial polyps of the ureter are the most common benign neoplasm of the ureter;[28] the exact etiology is unknown, and it is believed that some polyps are congenital, while others arise secondary to factors such as inflammation. Histologically, the polyps have a fibrous core covered by normal transitional cell epithelium.[29] Bilateral polyps have been reported, as have polyps in conjunction with upper tract neoplasia.[30] Polyps are more common in adults than children, and in males than females.[31] Symptomatic polyps typically present with flank pain or hematuria, and contrast-enhanced ureteral imaging (intravenous pyelogram or CT) will show a filling defect that is either vermiform or corkscrew in appearance (Figure 38.6).[31,32] Demonstration of contrast enhancement or Doppler waveform within the mass will differentiate polyps from fungal balls, sloughed papillae, and clots.

FIGURE 38.5 Schematic configuration of a ureteral valve; at the level of the valve, the ureteral lumen is eccentric. The proximal ureter is dilated and the distal ureter is decompressed.

FIGURE 38.6 Retrograde ureteropyelogram demonstrating a long, smooth filling defect in the distal ureter, consistent with fibroepithelial polyp.

Resection of the polyp can be accomplished either endoscopically or through surgical excision. Endoscopic management may be performed either antegrade or retrograde, but care should be employed to ensure that the entire base is resected, as recurrent growth may be noted if any polyp tissue remains. Open or laparoscopic polyp excision with ureteroureterostomy may also be employed.[28,31,33]

ANOMALIES OF URETERAL NUMBER

Ureteral duplication is discussed in detail elsewhere in this text.

Ureteral triplication (Figure 38.7) is exceedingly rare, and most publications are case reports or small case series. Triplication arises either from an additional ureteral bud from the mesonephric duct or from division of the existing ureteral bud into three parts. Four types of ureteral triplication have been described.[34] Type I (35%) is complete triplication, Type II (21%) is incomplete triplication, Type III (31%) is a trifid ureter, and Type IV (9%) occurs when one of a set of double ureters is bifurcated. Triplication occurs more frequently in girls than boys and on the left versus the right side. It is associated with coexisting unilateral or contralateral ureteral anomalies, such as contralateral duplication (37%), ureteral ectopia (28%), renal

FIGURE 38.7 Voiding cystourethrogram showing complete (Type I) right ureteral triplication. (Reprinted from *J Ped Urol*, 7, Kokabi N et al., Ureteral triplication: A rare anomaly with a variety of presentations, 484–7, Copyright 2011, with permission from Elsevier.)

dysplasia (8%), ureterocele, vesicoureteral reflux, and contralateral triplication.[35–37] It has also been reported in conjunction with syndromes such as VACTERL.[38] Although many cases of ureteral triplication are likely asymptomatic, patients may present with symptoms of UTI, flank pain, incontinence, or obstruction, similar to patients with duplication anomalies.[38–40] Imaging studies, such as sonography, voiding cystourethrography, nuclear medicine scans, and tomography, should be selected based on patient symptoms; diagnosis of ureteral triplication requires a high index of clinical suspicion. Management of ureteral triplication should be tailored to the individual patient and directed by symptoms. In incidental cases, no therapy may be needed, while patients with ureteral ectopia, ureteroceles, or vesicoureteral reflux may benefit from lower urinary tract reconstruction, and patients with poorly functioning renal moieties may benefit from partial nephrectomy.

Ureteral quadruplication has been reported in only a few cases.[41] Again, a high index of suspicion is necessary for the diagnosis, and imaging studies and definitive therapy should be guided by the patient's presenting complaints.

SURGICAL TECHNIQUE

Ureteral obstruction often requires operative intervention. Both laparoscopic and open approaches have been employed with equivalent success rates; hospital stays may be shorter and pain medicine requirements minimized with the laparoscopic approach. Regardless of the surgical modality selected by the surgeon, careful attention should be paid to basic surgical principles.

The blood supply of the ureter is derived from nearby structures, with anastomosing vessels allowing mobilization and division of portions of the ureter. Proximally, the ureteral blood supply is derived from branches of the renal and gonadal arteries, while the pelvic portion of the ureter derives its blood supply from the vesical and middle rectal arteries and, in some cases, from the internal and common iliac arteries. Anastomosing blood vessels, as well as nerve fibers, run in the adventitia, before penetrating the muscle layers and forming a submucosal plexus.[42] Thus, rough handling of the ureter may damage any of these layers with resulting compromise of the ureteral blood supply. Gentle handing, aided by ureteral traction sutures, will in many cases avoid iatrogenic ureteral injury and subsequent stricture.

The majority of ureteral anomalies discussed in this chapter are best managed by ureteral division with or without excision of the affected segment, followed by primary reanastomosis. Surgical wound healing is optimized by a tension-free closure, which may require mobilization of the proximal and/or distal ureter, the bladder, and/or the kidney. Spatulation of the ureter prior to reanastomosis will help prevent iatrogenic stricture secondary to wound contracture; spatulation of the stenosed segment with incorporation of this area into the repair may also be considered if there is concern for adequate ureteral length. Absorbable sutures should be employed for the anastomosis, with the knot tied outside the lumen, in order to minimize exposure to urine and ensuing local tissue reaction. Because urine extravasation may result in a local inflammatory reaction with subsequent fibrosis,[43] either ureteral stents or external drains are typically employed to minimize the sequelae of extravasation. Ureteral stents promote urinary flow through the ureter and diminish extravasation of urine. Nonsuction drains placed near the anastomosis permit evacuation of any extravasated urine from the site of repair.

CHAPTER
39

Megaureter

David B. Joseph

INTRODUCTION

In 1923, J. R. Caulk described a patient with distal ureteral dilatation without evidence of hydronephrosis and coined the term *megaloureter*.[1] The word *megaureter* conveys the image of a grossly dilated ureter. The term is nonspecific and does not provide insight into the pathophysiology. In 1958, D. Innes Williams described the term *megaureter* as "a chronic dilatation of the ureter for which no organic obstructive cause can be found: it implies an ignorance of the fundamental pathology and it is hoped that it will be replaced in time by a more enlightened nomenclature." He also excluded the term in conditions such as those secondary to ureterocele, congenital stricture, urethral obstruction, ectopic ureteral insertion, and urinary retention. Swenson, in 1955, postulated a neurologic etiology and, in order to provide peristalsis, treated such patients with urinary diversion, ureteral substitution, and ileal augmentation.[2] Knowledge of the megaureter has changed greatly over the past 15 years. In the past 15 years, and with the advancement in fetal sonography, we better understand the natural history of the megaureter and have gained better insight into treatment, but we still have a rather poor understanding of its pathophysiology (Figure 39.1).

HISTORIC PERSPECTIVE

Classification

Megaureter is synonymous with a dilated ureter, megaloureter, wide ureter, big ureter, and hydroureter—all descriptive terms that lack true meaning.[3] Cussen, in 1971, reported on autopsy findings of the urinary system in infants and children. He found that a child's ureter consistently measured less than 5 mm.[4] This was supported by the work of Hellstrom and coworkers, who reviewed excretory urograms in 100 boys and 94 girls. They directly measured ureteral size from imaging studies and uniformly found the ureter to be less than 6 mm.[5] By definition, a megaureter equates to a ureter of >8 mm in diameter. In 1977, Smith et al.[6] reported on a classification system developed by a working party of pediatric urologists.[7] The group presented their findings and recommendations at an international pediatric urologic seminar in Philadelphia in 1976. An agreement was made to standardize the nomenclature and classification of the megaureter. The megaureter was classified as primary, referring to a lesion intrinsic to the ureter, and secondary, denoting a reaction of the ureter to a process elsewhere. They went on to create the ABC subclassification: A, representing a refluxing ureter; B, obstructed; and C, not refluxing and unobstructed. King modified this classification in 1980, adding a fourth subclassification consisting of the refluxing, obstructed megaureter.[8] King's classification is used most often when describing the megaureter (Figure 39.2).

ANATOMY

In order to understand pathophysiology, it is important to have a framework of normal anatomy. The ureter is divided into three distinct regions: (1) the ureteropelvic junction, (2) the middle spindle, and (3) the ureterovesical junction. The ureterovesical junction is subsequently divided into the juxtavesicoureter and terminal ureter. The terminal ureter then separates into intramural and submucosal segments.[9]

The ureter is enclosed in a loose, ill-defined sheath within the retroperitoneum. This sheath forms a protective barrier for the adventitia, particularly when confronted with a neoplastic or inflammatory retroperitoneal process. Proximally, the ureteral sheath and the ureteral adventitia become continuous with the renal pelvis. Distally, the sheath and ureteral adventitia join to form Waldeyer's sheath, which extends into the bladder wall as a portion of the deep trigone.[9]

The ureter consists of three layers: adventitia, muscularis, and mucosa. The adventitia is composed of longitudinally running collagen[10] loosely attached to the underlying muscularis, allowing for unrestricted peristaltic activity. The muscularis is made up of smooth muscle cells interspersed with collagen. The inner muscle bundles are arranged longitudinally; the middle, circumferentially; and the outer, longitudinally.[11] This configuration changes into longitudinally oriented muscle fibers in each layer with sparse collagen as the ureter enters the bladder and intramural portion.[12,13] The mucosa consists of multiple layers of transitional epithelium lying adjacent to the lamina propria.

The ureter is supplied by a rich anastomotic arterial network. The proximal ureter is vascularized predominantly

FIGURE 39.1 Obstructed, refluxing megaureter with an unusually long obstructing distal ureterovesical segment. (Adapted from Joseph DB, Ureterovesical junction anomalies—megaureters. In. Gearhart JP, Rink RC, Mouriquand PDE eds., *Pediatric Urology*, WB Saunders: Philadelphia, 2000, p. 347.)

by an artery originating from the renal artery. The middle spindle receives a branch from the aorta and gonadal artery. The distal ureter is supported by arteries from the internal iliac, superior, and inferior vesical arteries.[14] A periureteral arterial plexus courses the full extent of the ureter through the adventitia.

The proximal ureter receives neuronal input via the renal and aortic plexus. Unmyelinated nerves travel throughout the adventitial layer.[10] The middle spindle is innervated by the superior hypogastric plexus, and the ureterovesical segment by the pelvic plexus.[15] Both adrenergic and cholinergic nerves have been identified within the ureter.[16] It is interesting that ureteral peristalsis is modulated by, but not dependent on, neuronal input.

PATHOPHYSIOLOGY

Obstructed Megaureter

The primary obstructed megaureter has generated the most interest and investigation. It has been reported in approximately 25% of children with obstructive uropathy.[17–20] It is bilateral in 25% and four times more common in boys.[18,21] The left ureter is more frequently affected, and in 10%–15% of cases, the contralateral kidney may be dysplastic or obstructed.[3,21] Endoscopically, the obstructed ureteral orifice can have a normal appearance and insert appropriately on the trigone. Caulk and Swenson et al.[1,22] proposed that the obstructed megaureter was similar to the megacolon seen in Hirschsprung's disease. This, however, has been refuted based on histologic evidence showing ganglia present in the distal primarily obstructed megaureter in a distribution similar to that of a normal ureter.[23]

Several different histologic abnormalities have been associated with the primary obstructed megaureter, indicating a spectrum of pathologic events. A localized deficiency of muscle fibers within the ureterovesical ureter with hypertrophy of circular muscle bundles immediately proximal to the deficiency has been described as an adynamic distal segment resulting in obstruction (Figure 39.3).[24–26] The degree of obstruction may be correlated with the percentage of circular fibers. Gregoir and Debled found three histologic variants of obstructed

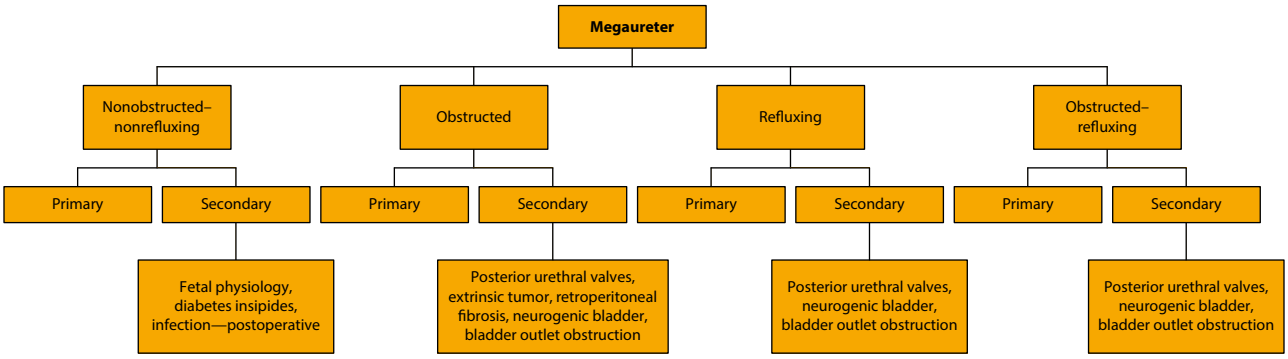

FIGURE 39.2 Classification of the megaureter. (Adapted from King LR. *J Urol* 1980;123(2):222–3.)

FIGURE 39.3 Obstruction due to an adynamic distal segment. (Adapted from Joseph DB, Ureterovesical junction anomalies—megaureters. In. Gearhart JP, Rink RC, Mouriquand PDE eds., *Pediatric Urology*, WB Saunders: Philadelphia, 2000, p. 355.)

megaureters: dense collagen infiltration of the terminal ureter, distal circular muscular hypertrophy, and varying degrees of distal muscular dysplasia.[27]

An increase in collagen deposition between the lamina propria and muscle bundles of the distal ureter has been seen with electron microscopy.[28–30] These pathologic changes result in muscular derangement and increased interstitial connective tissue within the ureterovesical junction. The middle spindle and ureteropelvic junction segments are spared.[31] Vlad et al. have found histologic qualitative and quantitative anomalies of connective, muscular, and nervous tissue, all of which are consistent with incomplete ureteral development and may compromise peristaltic activity.[32]

Dixon and associates assessed the histologic structure of the ectopic obstructed ureter and found that the terminal ureter was encircled by an additional thick collar of smooth muscle.[33] Normally oriented muscle layers were also present but had a diminished diameter. They speculate this embryologic malformation does not spontaneously resolve and becomes the subgroup of obstructed megaureter that requires early intervention.

Others have suggested abnormal acetylcholinesterase activity in the juxtavesical segment, a tonic response to noradrenaline, and increased intracellular calcium as etiologies of the obstructed megaureter.[34,35]

Some forms of the megaureter indeed improve with time.[17,18,36–40] Spontaneous improvement may be due to segmental maturation of the obstructed distal ureter. Nicotina and associates postulate segmental hypoplasia of the inner longitudinal muscle layer and the possible pathogenic involvement of transforming growth factor β (TGF-β), which has been shown to effect maturation of smooth muscle cells.[36] TGF-β delays muscle cell differentiation and is detectable in the 11- to 21-week-old fetus but diminishes thereafter. TGF-β has been found in the distal ureters of children who are less than 2 years of age with obstructive uropathy, but not in children older than 2 years of age who had repair of a nonobstructed megaureter.[36] The spontaneous improvement in the obstructed megaureter may correlate with TGF-β depletion within the first 2 years of life.[36]

Refluxing Megaureter

The refluxing megaureter is endoscopically characterized by a gaping lateral ureteral orifice. Bladder filling and cyclic voiding can transmit pressure into the ureter, resulting in mechanical enlargement (Figure 39.4). Lee and associates have found a twofold increase in the ratio of collagen fibers to smooth muscle fibers in the refluxing megaureter compared with the obstructed megaureter and control ureter.[41,42] They defined collagen fiber types and have shown an increase in collagen types I and III for both obstructed and refluxing megaureters. However, the refluxing megaureter contained a significantly greater percentage of type III collagen than other megaureters. Type III collagen is less distensible, raising speculation that this intrinsic characteristic stiffens the ureter. This may play an important role in the failure rate after operative correction of refluxing megaureters compared with the success noted in other forms of megaureters.[41]

FIGURE 39.4 Vesicoureteral reflux in a male neonate with elevated voiding pressure.

The influence of interstitial cells of Cajal on the pathophysiology of the megaureter has been explored (described by over 100 years ago as primitive intestinal neurons with similar cells noted by Klemm in the urinary system in 1999.126,127 These cells are localized with in muscle layers and thought to contribute in the control of peristaltic activity.[127]). Interstitial cells of Cajal have been reported as sparse or absent in the longitudinal muscle layer.[43] There is preliminary evidence to show that in the refluxing megaureter, compared with the obstructed ureter, the percent of smooth muscle is lower, along with a lower number of apoptotic cells and a lower percent of interstitial cells of Cajal. These factors can affect ureteral peristalsis.[44]

The refluxing megaureter associated with prune belly syndrome represents a unique abnormality.[45] The gross appearance of these ureters is elongated, tortuous, and dilated. Endoscopically, the ureteral orifices are lateral, golf hole in appearance, and frequently associated with diverticulum. The distal ureter is characterized by asymmetric ectasia and more often involved than the proximal ureter. Secondary obstruction may occur from kinking and folding of the redundant ureter. Primary obstruction has been reported at the ureterovesical junction in a select group.[45] Histologically, there is an increase in fibrous tissue at the expense of normally developed ureteric muscle. Children with prune belly syndrome and vesicoureteral reflux have been reported to have an increased ratio of collagen to smooth muscle fibers in the muscularis.[46] This may help explain the poor dynamic characteristics of the ureter, resulting in ineffective peristalsis and urinary stagnation.[45] Degeneration of nonmyelinated Schwann fibers and a decreased number of nerve plexus may also contribute to decreased ureteral peristalsis.[47] Ureteric abnormalities tend to predominate in the distal portion of the ureter, an important concept to consider during operative intervention.

Nonrefluxing, Nonobstructed Megaureter

The nonrefluxing, nonobstructed megaureter is most often encountered in the neonate with the antenatal diagnosis of hydronephrosis. While the etiology remains in question, fetal renal physiology may play a role. Rapid changes in renal vascular resistance, glomerular filtration rate (GFR), and urinary concentration result in a four- to sixfold increase in urine production prior to birth. This increase in urine output may surpass the dynamic ability of the ureter to transmit the increased volume to the bladder, resulting in transient ureteral dilatation.

McLellan et al. report resolution of the nonrefluxing megaureter in the majority of children, with the time to resolution based on the initial grade of hydronephrosis. In children with grades 1–3, the hydronephrosis resolved at a median age of 13, 24, and 35 months, respectively, and in children with grades 4 and 5, it resolved at a median age of 48 months.[48]

Refluxing, Obstructed Megaureter

The refluxing, obstructed megaureter occurs due to ectopic insertion of the ureteral orifice in the region of the bladder neck. During bladder filling, the bladder neck is closed, acting as a distal obstruction. With voiding, the bladder neck opens and allows for reflux. A cyclic voiding cystourethrogram may be required for diagnosis in suspected cases.

DIAGNOSIS

The routine use of fetal sonography has dramatically increased the diagnosis of the megaureter. Brown et al. delineated the impact fetal sonography has had on identification of the megaureter.[49] Prior to fetal sonography, megaureter was diagnosed after the development of symptoms such as urinary tract infection, hematuria, and pain.[3] In the presonography era, clinically significant megaureters accounted for 8% of children found to have hydroureteronephrosis (ureteropelvic junction obstruction was noted in 22%, posterior urethral valves in 19%, and ectopic ureterocele in 14%).[49] With current routine use of fetal sonography, the incidence of the megaureter occurs in 23% of asymptomatic neonates and is only surpassed by hydronephrosis, which is seen in 41%.[49] This increased incidence can only be explained by more routine use and improved quality of fetal sonography. Even in the era of fetal sonography, Anderson and associates found that 17% of their patients with a primary megaureter presented with a history of pain, of which 10% had acute onset of severe pain.[50]

The percentage of children with asymptomatic megaureter who will eventually develop symptoms is unknown. Chertin et al. found on long-term follow-up that 31% of children diagnosed with a megaureter went on to surgical correction. Side and gender were not predictive, but grade of hydronephrosis (Society for Fetal Urology [SFU] grades 3 and 4), ureteral diameter of >1.33 cm, and renal function of <30% were all significant predictors of operative intervention.[51] Shukla and associates reported similar findings, with resolution of the megaureter in the majority of their patients and the rare incidence of problems occurring after 14 years of age.[52] Arena et al. found a similar rate of resolution and need for surgical intervention, noting that neonatally diagnosed megaureters typically improve within 3.6 years.[20]

EVALUATION

Ultrasonography

Ultrasonography plays a key role in the assessment of megaureter and is the primary imaging modality in the assessment of antenatal hydronephrosis and the initial imaging study obtained for symptomatic genitourinary abnormalities. Ultrasound can provide information regarding the size, shape, tortuosity, and bulbar appearance of the ureter, and also degree of dilatation of the renal pelvis and renal calyces. The course of the ureter can be traced from the renal pelvis to its distal insertion. Careful pelvic sonography can further detail the course of the distal ureter. The ureter may enter an obstructed ureterocele or end in an ectopic location within the bladder neck or posterior urethra. An obstructed distal segment may be recognized when a peristaltic wave of urine abruptly stops a few centimeters from the bladder and rebounds into the dilated proximal ureter (Figure 39.5). The echogenicity of the kidney is a helpful

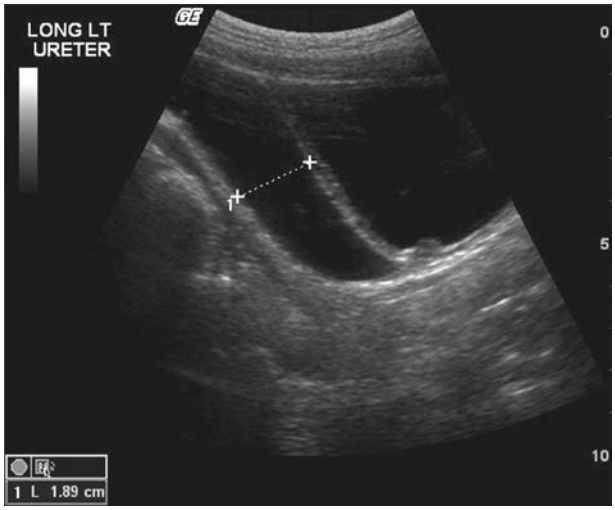

FIGURE 39.5 Sonographic appearance of the distal megaureter with a diminutive terminal segment.

parameter used to distinguish between an obstructive and unobstructive process, with increased echogenicity supporting obstruction.[53] A renal resistance index of >0.70 has been shown to correlate with obstruction. However, the utility of the resistance index in the pediatric population may be limited due to the lack of normalized standards for age.[54,55] Sonography, however, provides us with anatomic findings but lacks the ability to quantify a dynamic process, and the true significance of any abnormal megaureter must be determined by a functional imaging study.

Voiding Cystourethrography

Voiding cystourethrography is essential to rule out vesicoureteral reflux. A conventional fluoroscopic cystogram is preferred over a nuclear cystogram in that assessing the anatomic appearance of the bladder, bladder neck, urethra, and ureters is necessary for precise diagnosis and treatment. The cyclic voiding cystourethrogram is beneficial when an ectopic, sphincteric ureter is suspected. In this scenario, the ureter can be obstructed when the bladder is at rest and reflux only during the voiding phase. Blickman and Lebowitz characterize the obstructed, refluxing megaureter to have a markedly enlarged proximal ureter with a normal-appearing ureterovesical segment.[56]

Excretory Urography

Excretory urography and tomography are waning as diagnostic modalities in the evaluation of pediatric uropathy. Stool, bowel gas, and maturational immaturity of the neonatal kidney limit their utility. In addition, the degree of hydronephrosis noted does not equate to severity of obstruction. Rarely, when anatomic definition is required, excretory urography may play a role.[57]

Renography

Diuretic renal scintigraphy provides the greatest quantitative information of functional and dynamic data. The degree of obstruction can be determined by evaluating multiple parameters, including renal uptake, excretion, time to peak activity, and $T_{1/2}$ following lasix washout. Two of the more common radiotracers used to evaluate obstruction are TC-99m diethylenetriaminepentaacetic acid (DTPA) and TC-99m mercaptoacetyltriglycine (MAG3).[58,59] DTPA is a glomerular agent and provides limited information during the first month of life because of a low neonatal GFR. MAG3 is extracted by the kidney and dependent on effective renal plasma flow, not GFR. This results in less background artifact. These factors make MAG3 a more attractive agent during the neonatal period.[58]

Multiple variables affect data acquisition and interpretation. For that reason, renal scintigraphy must be performed in a standardized fashion using a protocol that optimizes the hydrational state, administration of diuretic, and acquisition of time–activity curves.[60] It is important to have a separate activity curve generated for the kidney and the ureter when assessing for an obstructive pattern. Isolating simply over the kidney can produce deceiving results, showing an acceptable washout of the radiotracer from the kidney without assessing washout from an obstructed ureter (Figure 39.6). Obtaining time–activity curves over the ureter will help confirm distal ureteral obstruction. The timing of diuretic administration can play a role in assessing $T_{1/2}$, with benefits attributed to administration at a standard time either before or after radiopharmaceutical administration.[61] Regardless of the protocol used, it is most important that consistent standards are maintained in order to compare successive studies in the same individual.

Magnetic Resonance Urography

Magnetic resonance urography (MRU) can be very helpful in the evaluation of the megaureter without the use of radiation (see Video 39.1). MRU with gadolinium has less nephrotoxic effects than contrast agents used for intravenous urography and conventional computed tomography (CT) imaging. With improved technology and the advent of open MRI scanners eliminating the need for anesthesia, this imaging modality may become the anatomic study of choice, particularly when renal compromise is present.[62–64,86]

Percutaneous Profusion Studies

Upper urinary tract urodynamic assessment can be helpful in difficult cases. The Whitaker test has traditionally been the procedure of choice.[66] However, the Whitaker test has limitations in the pediatric population. It is invasive and requires sedation for placement of a percutaneous renal catheter and bladder catheter. Whitaker described the test using a constant infusion of 10 cc per minute, with obstruction defined as an elevation in renal pressure greater than 22 cm H_2O over baseline.[66] The rate of infusion accommodated by the normal infant ureter is unknown. Infusing the renal pelvis at a rate of 10 cc/min may overcome the peristaltic flow potential of the normal infant or child's ureter, proving a false indicator for obstruction. A constant profusion of testing medium while recording the renal pelvic pressure may produce less artifact and be a more appropriate test.[67,68]

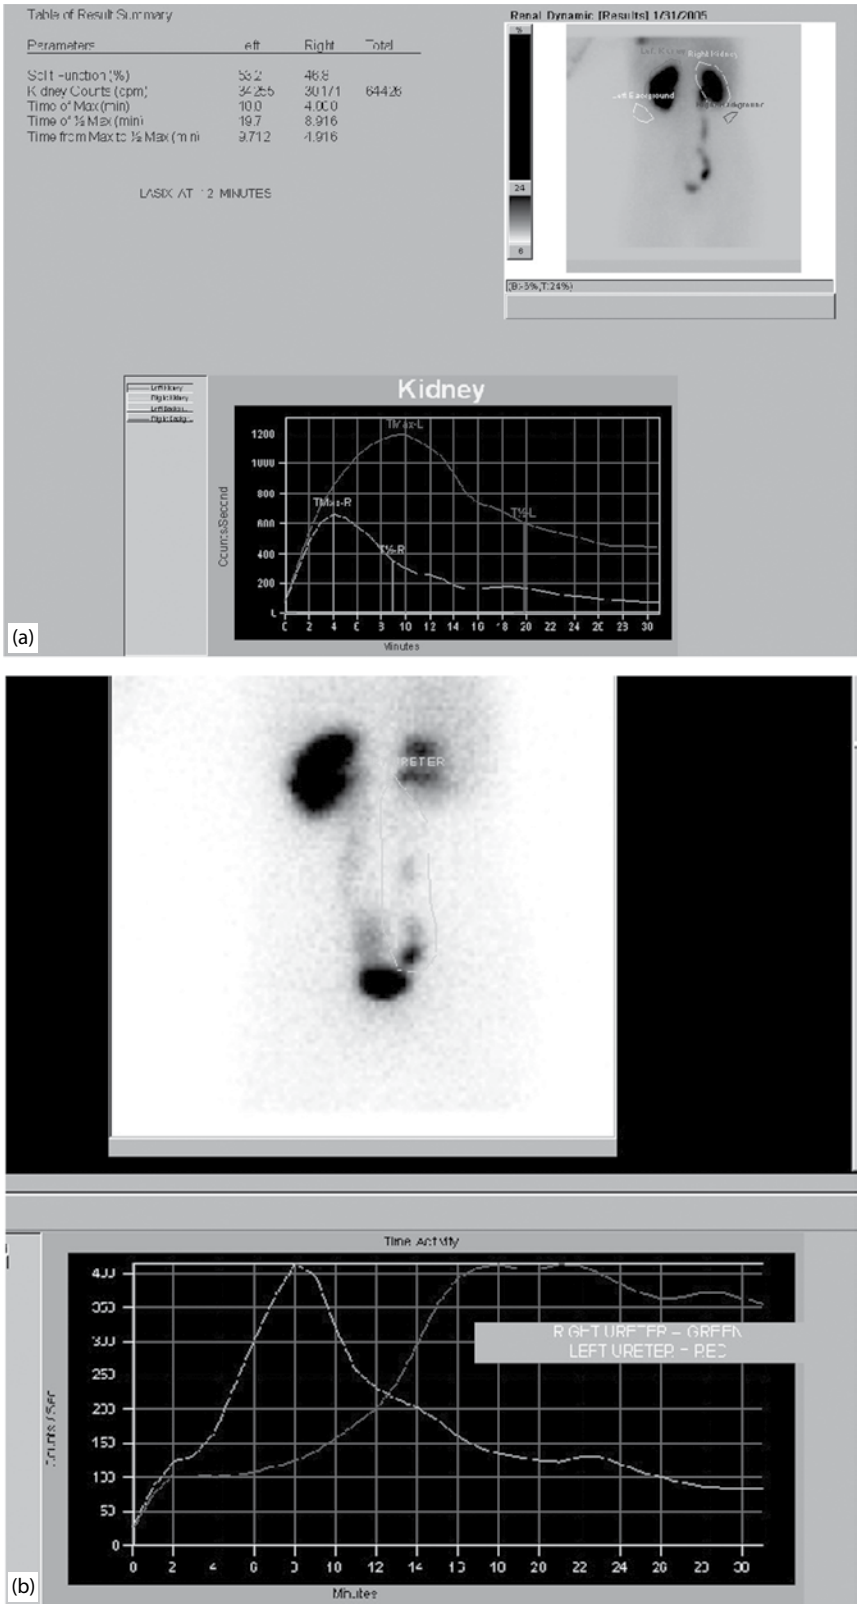

FIGURE 39.6 (a) MAG3 renal scan showing a composite pixel image and computer-generated kidney washout curve. There is relatively equal function with a delay in peak activity of the left system. The T½ washout of both kidneys is <20 minutes. (b) Right ureteral pixel image and curve indicating normal time–activity washout. The left ureteral time–activity curve shows an obstructive pattern with progressive accumulation and no washout.

Fung and associates explored ureteral opening pressure as a novel parameter for evaluating the obstructive nature of pediatric hydroureteronephrosis.[68] Renal pelvic pressure was assessed while simultaneously documenting the passage of contrast material from the distal ureter into the bladder. The infusion rate was individually calculated for each patient and maintained within a physiologically relevant range. A pressure increase of 14 cm H_20 within the renal pelvis was deemed consistent with distal ureteral obstruction. While this approach is invasive, it eliminates the problems of the infusion rate noted in the classic Whitaker study.[68]

DIFFERENTIAL TREATMENT

Therapeutic intervention of the megaureter is dependent on accurate classification. Secondary causes of a megaureter justify treatment of the primary problem, whether it is due to a neurogenic bladder, a posterior urethral membrane, ureterocele, diabetes insipidus, or a retroperitoneal process. Treatment of those problems are described elsewhere.

In general, a conservative approach can be taken in most cases of the megaureter.[18–20,51,52,69] There are no hard-core predictors for resolution. Improvement appears to be independent of gender, side, or bilaterality. A ureteral diameter greater than 1.33 cm and overall grade of hydroureteronephrosis (SFU grades 3 and 4) may be predictive of outcome.[51,70–72,93]

The role of antibiotic prophylaxis in megaureter is controversial.[72–74,93] Roth et al. reported a 4% risk of a urinary tract infection associated with an upper tract obstruction. This was not dependent on gender, level of obstruction, low grade, or circumcision status. The authors do not recommend the routing use of prophylaxis with nonrefluxing hydroureter with SFU grade 3–4 hydronephrosis.[75] Castagnetti and associates have explored the use of antibiotics and have identified children under the age of 6 months at the highest risk of developing symptomatic urinary tract infection, particularly if they undergo instrumentation.[73]

Refluxing Megaureter

Traditionally, grades 4/5 and 5/5 vesicoureteral reflux* have prompted operative intervention.[76] That approach may be appropriate for older children presenting with symptomatic urinary tract infections. However, there is growing evidence that operative intervention is not required in all neonates with refluxing megaureters, especially when identified during the workup of asymptomatic antenatal hydronephrosis. High-grade vesicoureteral reflux in neonates occurs more often in males than females, and improvement can occur during the first year of life.[76] There is little reason to proceed with early intervention, particularly when an infant has remained symptom-free on prophylactic medical management.

The association of megacystis–megaureter was first described by Williams in 1954[77] and is now well understood.[78] By definition, megacystis–megaureter is a large-capacity, thin-walled bladder with massive primary vesicoureteral reflux.[77,78] Megacystis–megaureter occurs in approximately 80% of boys diagnosed antenatally with bilateral reflux and found to have renal impairment.[79] The etiology of male predominance is unknown and does not appear to be due to bladder outlet obstruction. It is speculated that higher voiding pressure occurs in the male neonate. Children with megacystis–megaureter show progressive upper tract hydroureteronephrosis and bladder enlargement due to the recurrent cycling of urine into the upper tract during a detrusor contraction, followed by rapid refilling of the bladder upon relaxation of the detrusor after voiding. Over time, this cyclic event continually increases bladder volume and hydroureteronephrosis. In toilet-trained children, double voiding can temporize this process in children. Ten to fifteen minutes after the initial void, the child is encouraged to void again, allowing for an overall decrease in volume of retained urine. Positive effects of this technique occur first with stabilization of bladder volume, followed by reduction in bladder size and improvement of hydroureteronephrosis. Intermittent bladder catheterization can be an effective technique to eliminate residual urine in neonates and toddlers who are not toilet trained, allowing the child to reach an age where operative reconstruction would be beneficial. Ultimately, children with a megacystis–megaureter are best served by operative correction of the reflux.[78]

Nonrefluxing, Nonobstructed Megaureter

Approximately 6%–10% of neonates diagnosed with fetal sonography will have a nonrefluxing, nonobstructed megaureter.[80] A functional study is required to confirm adequate ureteral drainage. The initial medical management may be prophylactic antibiotics. Children with a nonrefluxing, nonobstructed megaureter maintain normal renal function, and the megaureter often reverts to normal.

Obstructed, Refluxing Megaureter

The obstructed, refluxing megaureter occurs due to a laterally positioned aperistaltic distal segment, or ectopic insertion of the ureter into the bladder neck or posterior urethra. While not emergent, operative correction of this entity is required in order to diminish the risk of upper urinary tract deterioration and to reduce the risk of urinary tract infections associated with obstruction.

Obstructed Megaureter

The indication for treatment of the obstructed megaureter prior to fetal sonography was relatively straightforward. Most children presented with a symptomatic urinary tract infection, abdominal pain, nausea, or vomiting and underwent repair.[3] Fetal sonography has identified a substantial number of neonates with an obstructed megaureter, many of whom will not have clinical symptoms. Current management of the obstructed megaureter is controversial.[17,81–84] Medical management, based on prophylactic antibiotics and watchful waiting, allows for potential spontaneous regression of the obstructed megaureter. Serial sonography will allow us to follow progression or resolution of hydronephrosis. Renal function must be objectively followed with renography in order to identify renal compromise.

* International study classification.

Repair of the infant megaureter is technically feasible but remains a challenge even in experienced hands. Secondary operative procedures have been reported as high as 10% when correcting an obstructed megaureter in an infant less than 8 months of age.[85] If possible, it is best to postpone repair of a megaureter until the child is older than 12 months of age, at which time technical hurdles are not as great.[86]

Occasionally, a neonate with an obstructed megaureter will present with severe renal compromise. In this situation, a distal cutaneous ureterostomy can provide temporary relief,[80] adequately draining the upper urinary tract and decreasing the risk of infection. The decompressed ureter may regain tone and a more normal caliber as the child grows and develops.[80]

OPERATIVE APPROACH

Temporary Diversion

A percutaneous nephrostomy is helpful when rapid drainage is required, and especially if the process involves both ureters with renal compromise. But small nephrostomy tubes are difficult to maintain longer than a few weeks. When prolonged drainage is required, a distal ureterostomy is appropriate. A pyelostomy can be undertaken, but it results in unnecessary proximal diversion when the pathology exists at the bladder level.

A cutaneous ureterostomy is practical for the severely obstructed neonatal megaureter. The procedure carries minimal morbidity, allows for rapid continuous decompression, and can often be performed in the outpatient setting. The ureter is approached through a 1.5–2 cm incision placed within an ipsilateral low inguinal skin crease. The muscles are separated and the space of Retzius entered. Identification of the ureter is facilitated when the bladder is partially full and usually easily visualized due to its size. Caution should be taken before opening the ureter because bowel can be mistaken for a distended ureter, particularly in the infant. When there is doubt, a 21-gauge needle should be used to aspirate the contents and confirm urine. If the ureter is not easily identified, the obliterated umbilical artery provides a suitable landmark for initiating the search. The ureter will often be found just beneath the transected obliterated umbilical artery. Once mobilized, a cutaneous loop ureterostomy provides adequate drainage. The ureter is secured to the anterior rectus fascia with a 4-0 or 5-0 absorbable suture and to the skin with the same. The size of the ureter prevents postoperative stenosis.

Definitive Reconstruction

The approach to the ureter for definitive urinary reconstruction can be either intravesical, extravesical, or combined. The dilated ureter is redundant and tortuous. Straightening and tapering the ureter without devascularization is required. The functional ability of the ureter to transmit urine into the bladder via peristalsis is inversely related to the size of the megaureter. In order to form an antirefluxing submucosal tunnel, the ureter is tapered to achieve a ureteral diameter that will allow for a 4–5:1 ratio of submucosal tunnel length to ureteral diameter. Enough ureter is mobilized in order to taper the intravesical ureter and a short portion of extravesical ureter. There should be a gradual transition from the tapered to dilated ureter to prevent a sharp gradient, which can act as a pseudo-obstruction. Multiple tailoring techniques exist for ureteral tapering and include ureteral imbrication and formal ureteral excision.[87–90,111]

The techniques described below are based on an open approach. However, the utility of minimally invasive alternatives, such as laparoscopic and robotically assisted procedures, has shown great promise and is gaining in popularity.[91–100] In addition, endoscopic procedures have been tried for primary obstructive megaureters utilizing high-pressure balloon dilatation of the distal ureteral or endoureterotomy, followed by several weeks (most commonly 8 weeks) of ureteral intubation with a ureteral stent.[129] Short-term success with improvement in hydroureteronephrosis and obstruction has been reported in 56%–100%, while postoperative vesicoureteral reflux has not been reported to be significant.[101–108] Longer follow-up will be required in order to determine long-term outcomes.

Imbrication

Ureteral imbrication is appropriate for marginally dilated ureters. Two common imbricating techniques include the Starr and Kalicinski plications.[87,88] In the Starr plication, a Lembert technique with a 6-0 absorbable suture is used to "fold in" the redundant ureter over a 10 or 12 Fr catheter[87] (Figure 39.7). Kalicinski established a plication technique that excludes the redundant ureter from the urinary system (Figure 39.8).[71,88] A 10 or 12 Fr catheter is used for a template, and an avascular segment of excess ureter is isolated. A running 5-0 or 6-0 absorbable suture follows the course of the ureter, separating it from the redundant segment. The redundant segment is then folded over the ureter and secured with a second absorbable suture layer (Figure 39.9). Regardless of the imbrication technique, the plicated ureter is brought into the bladder and the anastomosis with a submucosal tunnel is created in either a cross-trigonal or a Politano–Leadbetter fashion.

Ureteral stents may be placed for 3–7 days but are often unnecessary. The advantage of ureteral plication relates to preservation of the blood supply, a decreased incidence of devascularization, minimal risk of urinary leak, and infrequent obstruction. When massive ureteral dilatation is present, imbrication will add unwanted bulk, making the ureter difficult to reimplant, particularly if a bilateral procedure is performed. A variation to these two primary techniques has been reported to reduce the ureteral caliber while preserving the ureteral blood supply, and eliminating the problem of bulk.[109]

Excisional Tapering

Formal excisional tapering of the ureter is required for extremely bulky ureters or a bilateral process. Hendren pioneered ureteral remodeling, and the technique has stood the test of time.[89] The ureter is loosely tapered over a 10 or 12 Fr catheter, depending on the child's age and size. Straight Allis clamps are placed longitudinally along the ureter in a region of least vascularity. Angled Allis

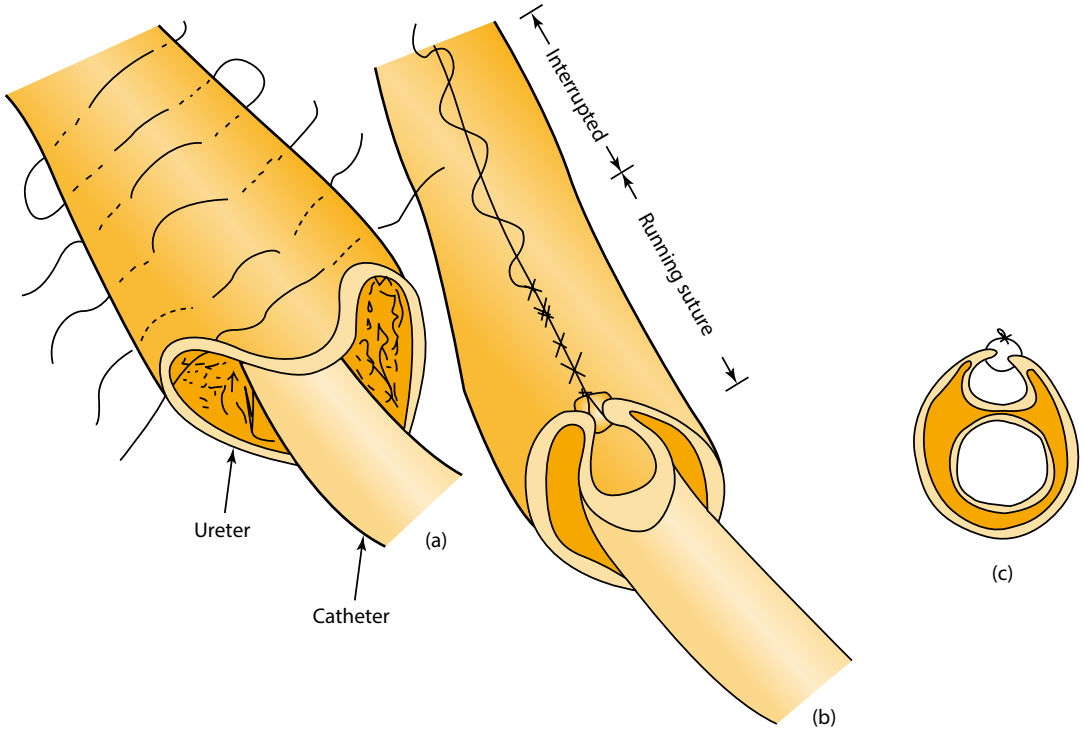

FIGURE 39.7 Starr technique of ureteral imbrication. (a) The ureter is folded inward over a 10 or 12 Fr catheter as a guide. (b) The distal portion is secured with interrupted sutures to allow for transection without compromising the running suture line. (c) Cross section of (b).

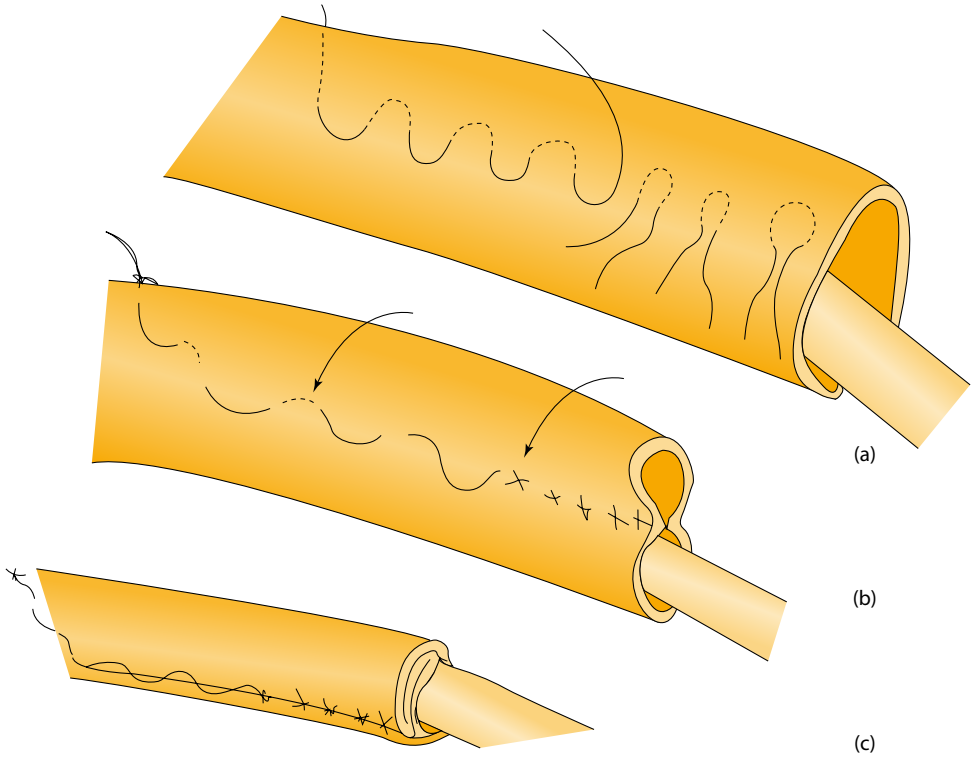

FIGURE 39.8 Kalicinski technique of ureteral imbrication. (a) The excess segment of ureter is excluded from the flow of urine. (b) It is then folded over the ureter using a 10 or 12 Fr catheter as a guide. (c) The distal portion is secured with interrupted sutures to allow for transection.

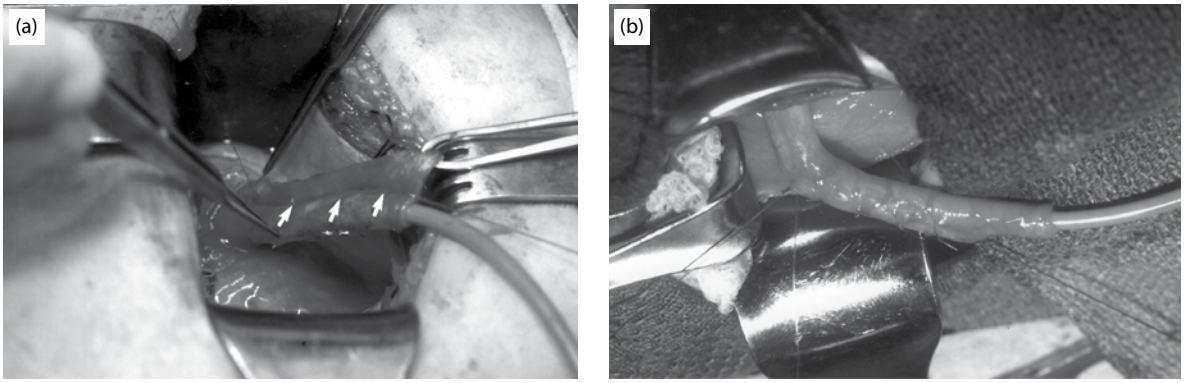

FIGURE 39.9 (a) Kalicinski plication technique isolating the redundant ureter from the distal flow of urine (arrows). (b) The excluded segment has been folded and secured to the distal ureter. (Adapted from Joseph DB, Ureterovesical junction anomalies—megaureters. In. Gearhart JP, Rink RC, Mouriquand PDE eds., *Pediatric Urology*, WB Saunders: Philadelphia, 2000, p. 355.)

clamps are then placed over the ureter securing the internal 10–12 Fr catheter (Figure 39.10). Care is used to prevent the temptation of excluding too much redundant ureter, which results in excessive tapering around the catheter. The ureter is closed in two layers. First, a running, locking 5-0 or 6-0 absorbable suture directly opposes the mucosa and the muscularis of the ureter. The locking technique limits ureteral reefing and decreases extravasation. A second running adventitial layer of absorbable suture decreases leaking. Both running layers stop a few centimeters from the distal end of the ureter. The very distal portion of the ureter is closed in two layers with interrupted sutures. This allows for excision of the distal ureter if required without interruption of the running suture line. A ureteral stent can be placed to decrease urinary extravasation. Stenting also provides a scaffold for the ureter to conform to during the postoperative period, helping to prevent kinking and bypassing the tapered region, which initially may act as an obstruction due to postoperative edema. The ureter may be stented 7–14 days. The necessity for periureteral drainage in the form of a Penrose drain or a Jackson–Pratt drain is variable, dependent on the technique used for ureteral tailoring and the presence of a ureteral stent. Periureteral drainage may be helpful when a ureteral stent has not been placed and a substantial portion of tapered distal ureter remains extravesical.

In most situations, only the portion of the distal ureter that is going to be placed within the bladder and 1 or 2 cm beyond needs to be tapered. There should be a gentle transition from the ureteral hiatus at the bladder to the nontapered ureter. Proximal ureteral tapering is rarely required and is limited to children with persisting proximal hydroureteronephrosis, with an obstructed pattern in the face of a patent distal ureter.[90]

In complex reconstructive cases, consideration should be given to a transureteroureterostomy and a unilateral tapered reimplant, particularly when there is a small bladder.

POSTOPERATIVE MANAGEMENT

Removal of the ureteral stent is dependent on the procedure performed. The stent can be removed 3–7 days after imbrication, and 7–14 days following an excisional repair. Some use a JJ ureteral stent, but this requires a second anesthetic for removal, usually around 4–6 weeks after surgery. Ureterograms at the time of stent removal are not necessarily beneficial. Postoperative edema can limit drainage, giving

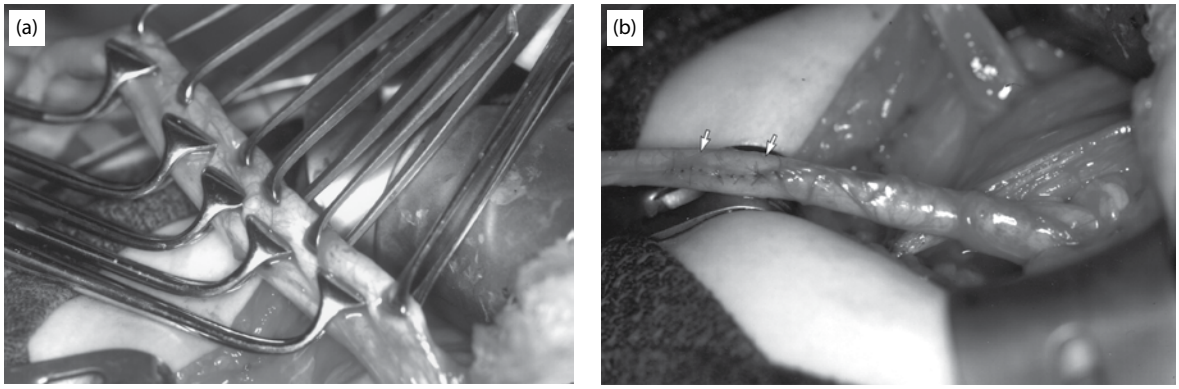

FIGURE 39.10 (a) Angled Hendren clamps placed loosely over a 10 or 12 Fr catheter securing the retained portion of the distal ureter. Straight Allis clamps isolate the segment to be excised. (b) A two-layer technique is used to close the ureter, interrupting the distal-most portion and allowing for excision as needed. The arrow indicates the interrupted portion. (Adapted from Joseph DB, Ureterovesical junction anomalies—megaureters. In. Gearhart JP, Rink RC, Mouriquand PDE eds., *Pediatric Urology*, WB Saunders: Philadelphia, 2000, p. 356.)

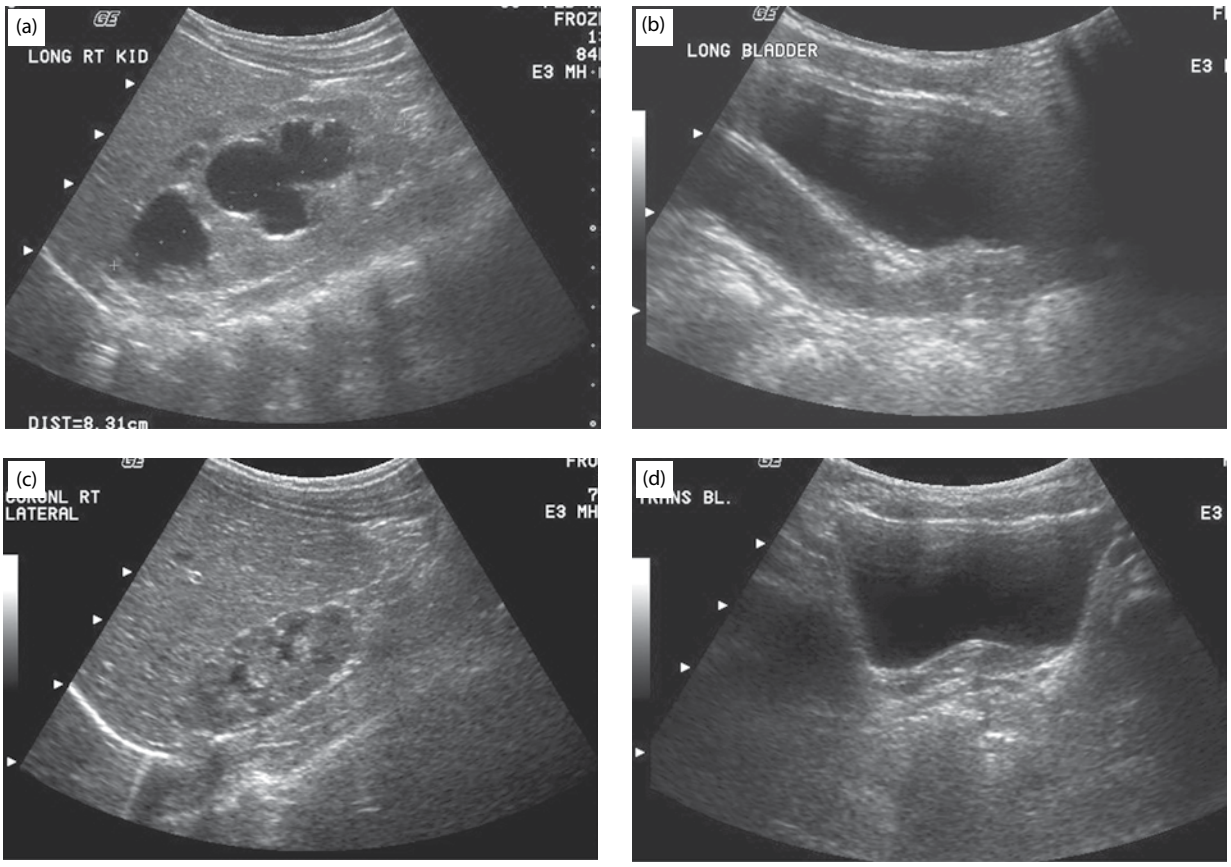

FIGURE 39.11 6 weeks following repair of a right refluxing megaureter revealing (a) right hydronephrosis and (b) right hydroureter. Ultrasound sound at 3 months postop shows resolution of right hydronephrosis (c) and megaureter (d).

the appearance of a high-grade obstruction when, in fact, removal of the stent is all that is required. Administration of a broad-spectrum antibiotic prior to removing a stent decreases the possibility of urosepsis even when the child has been maintained on prophylactic antibiotics.

Postoperative ureteral edema can persist for 6 weeks. Imaging studies, either sonography or renal scintigraphy, should be avoided during that time. The initial images on sonography may show increased hydronephrosis and proximal hydroureter when compared with preoperative sonographic imaging, particularly when repairing a refluxing megaureter (Figure 39.11). This is due to the compliant proximal ureter and relative resistance of flow through the tapered segment. It is important to review the ureteral size on the preoperative cystogram to help determine the significance of postoperative sonographic dilatation. Renal scintigraphy should be used to assess for postoperative obstruction in troublesome cases.

A postoperative voiding cystourethrogram at 6 months is performed to confirm the absence of vesicoureteral reflux. Prophylactic antibiotics can be discontinued with resolution of the reflux.

COMPLICATIONS

Successful operative outcomes of megaureter reconstruction have been reported to be 93%–95% for imbrication[85,88,110–114] and 74%–90% for excisional tapering.[85,110,112,115–118] Overall, the complication rate and morbidity are greater for a tapered procedure than for a nontapered ureteroneocystostomy. The two most common complications are obstruction and persisting reflux.

Postoperative complications are not simply due to technical error, inherent ureteral characteristics, and bladder dysfunction. A higher rate of postoperative vesicoureteral reflux may also be secondary to increased collagen deposition and altered smooth muscle.[33,41]

Postoperative edema can lead to obstruction requiring temporary percutaneous nephrostomy diversion. Physician patience is prudent to allow for the operative edema to subside, which might take 2–3 months. Persistent obstruction is likely due to ureteral ischemia and will ultimately require revision.

Persisting vesicoureteral reflux has been reported to occur in approximately 5% of tapered reimplants.[85,88,110–120] Transient mild reflux noted at 6 months can resolve spontaneously with time. Reflux persisting more than 3 years after surgery is unlikely to improve.[85] When significant and symptomatic, secondary corrective intervention is required; salvage endoscopic procedures using ureteral bulking agents have been successful.[121–123] When a reoperative procedure is performed, attention must be paid to preserving the ureteral blood supply and maximizing the ratio of the ureteral tunnel length to the diameter to at least 5:1. In situ ureteral tailoring

is an appealing alternative to a formal excisional repair. It achieves a gradual decrease in intraluminal diameter without compromising vascularity and avoids the difficult ureteral dissection. This should be considered in cases when the ureteral tunnel length had been maximized at the first encounter.[119]

Contralateral reflux may occur more often following repair of the refluxing megaureter than the obstructed megaureter. It has been suggested that the functional anatomy of the trigone is impaired in reflux but not obstruction.[124]

SUMMARY

The asymptomatic megaureter is commonly encountered due to the routine use of fetal sonography. The natural history of the megaureter supports observation and nonoperative management of most infants. When operative management is required, precise classification of the pathophysiology, along with intervention by a pediatric specialist, should result in a successful outcome.

CHAPTER 40

Ureteral Duplication Anomalies: Ectopic Ureters and Ureteroceles

Michael A. Keating

INTRODUCTION

Ureteral duplication is one of the most common anomalies affecting the genitourinary tract. A spectrum of involvement and clinical presentations exists, at times offering pediatric urologists with some of their more challenging diagnostic and therapeutic dilemmas. Common variations, including incomplete ureteral duplication and complete duplications with normally developed ureters and renal moieties, constitute the vast majority. As such, they represent no more than radiologic curiosities. Anomalies with clinical significance, including ectopic ureters and ureteroceles, are much less common. Historically, the majority of these probably remained clinically silent.[1,2] A smaller portion became evident as a consequence of hydronephrosis, vesicoureteral reflux (VUR), or incontinence, either in combination or alone. More recently, antenatal diagnosis has uncovered a large number of urologic anomalies, including different variants of ureteral duplications, that are asymptomatic. Antenatal detection enables the preservation of renal function and the avoidance of illness for some children. For others, perinatal identification creates controversy by introducing a large group of abnormalities that might have gone harmlessly undetected in the past.

Despite these decision-making dilemmas, it seems prudent to institute preemptive therapy for urinary tract anomalies that pose a risk to the affected child, until those characteristics that typify their spontaneous resolution or a lifetime free of urologic problems are better defined. Spontaneous resolution of most ectopic ureters and ureteroceles seems unlikely. As a consequence, pediatric urologic surgeons must remain familiar with the natural history of duplication anomalies, well versed in the evolving recommendations for their management, and familiar with the variety of surgical techniques available for their reconstruction. Ectopic ureters and ureteroceles represent distinct entities. However, they also appear to represent variations along the same general mechanisms in development. These result in differences in appearance but a number of common clinic features that, in some cases, offer similar paradigms in management.

EMBRYOLOGIC CONSIDERATIONS

Normal Development

A review of normal development provides the basis for understanding the pathophysiology of anomalies of the ureter and, in some cases, aids in their diagnosis and clinical management.

Ureteral development coincides with that of the kidney between the fourth and eighth weeks of gestation. The *ureteral bud (metanephric duct)* projects from the *Wolffian (mesonephric) duct* just proximal to its junction with the cloaca (Figure 40.1). As the ureteral bud elongates in a cephalad direction, it penetrates the adjacent metanephric tissue and divides into the calyces and collecting ducts. Proper fusion of the bud and the nephrogenic blastema is critical to tubular maturation within the renal anlage and ultimate function of the kidney. Mesenchymal–epithelial interactions, perhaps under the influence of local paracrine factors acting via receptors on the ducts, help pattern normal formation.[3]

The segment of the Wolffian duct between the cloaca and the takeoff of the ureteral bud (the future ureteral orifice) is called the *common excretory duct*. The migration of tissue that occurs during the excretory duct's replacement or incorporation into the urogenital sinus helps to explain the variable relationships that sometimes occur between the ureters and the trigone of the bladder, and genital ducts. Conceptually, these events represent some of the most difficult to understand in urinary tract embryology.

In the classic description, as the common excretory duct is absorbed into the bladder, the ureteral orifice migrates in a cranial and lateral direction. While this occurs, the excretory duct migrates to the midline and fuses with its contralateral partner to form the primitive trigone. This would explain a presumed mesodermal origin of the trigone and, depending on its relationship with the mesonephric and ureteral buds, ureteral location. However, recent studies have suggested that the trigone may instead be endodermal in origin.[4,5] Regression of the common excretory duct occurs through apoptosis. Formation of the trigone then occurs as the excretory duct is replaced by endoderm, with expansion of trigone dictating ureteral bud location.

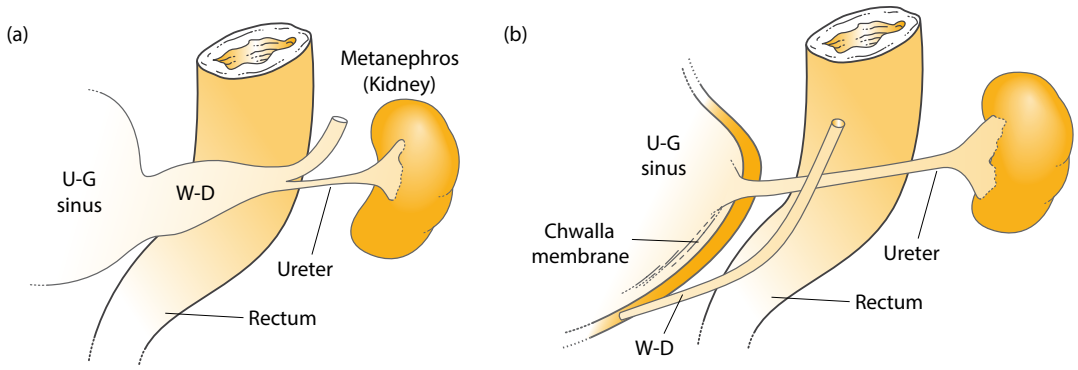

FIGURE 40.1 (a and b) Relationships of ureteral bud, Wolffian (mesonephric) duct (W-D), and urogential sinus (U-G). The segment of the Wolffian duct between the urogenital sinus and ureteral bud represents the common excretory duct.

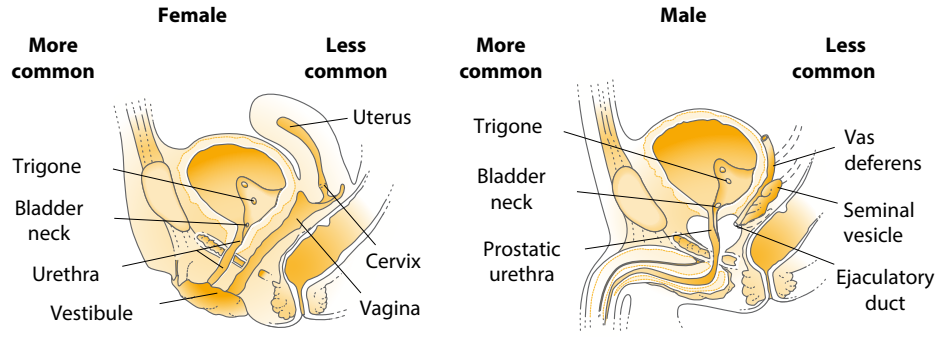

FIGURE 40.2 Anatomic locations of ectopic ureters.

Regardless of the mechanism, the orifice of the Wolffian (mesonephric) duct ends in a caudal and medial position at the utricle. The Wolffian duct ultimately differentiates into the prostate, seminal vesicles, vas deferens, and epididymis in males. In females, the Wolffian ducts guide the Mullerian ducts into position in the midline, where the latter fuse to form the uterus, proximal vagina, and fallopian tubes. After their involution, Wolffian remnants persist in as many as 25% of women as Gartner's duct lying along the anterolateral vaginal wall and uterus, and the epoophoron and oophoron within the broad ligament supporting the fallopian tubes.

Explanations for the variety of anomalies that affect the ureter have their basis in this developmental progression, although the causes of the initial insults remain unclear.[6] An alteration in complex temporal–spatial timing seems indisputable.

Abnormal Development

Lateral ectopia occurs when the ureteral bud originates from a more caudal position than usual on the mesonephric duct, for reasons that remain to be defined. As a result, the ureteral orifice has more time to be absorbed within the bladder and to begin its cranial and lateral migration. As the degree of laterality becomes more exaggerated, the length of the submucosal ureter is progressively shortened. In addition, because the common excretory duct is shortened by the premature takeoff of the ureteral bud, its mesenchymal contribution to the trigone is blunted. This results in muscular deficiency of the trigonal–ureteral complex. Primary reflux becomes a common consequence of lateral ectopia and is thoroughly discussed elsewhere (see Chapter X on vesicoureteral reflux).

Caudal ectopia of the ureter results from an abnormally high takeoff of the ureteral bud. This allows less time for the orifice to be absorbed into the bladder. Now more closely positioned to ductal tissue typically destined to become Wolffian, the ureter arrives in a medial trigonal or urethral position or is extravesically positioned along the path of Wolffian structures or remnants. The location of Wolffian remnants helps explain an important difference in presentation of ectopic ureters between males and females (Figure 40.2). *Ectopic ureters in males are connected to structures that continue to drain into the bladder proximal to the urinary sphincter.* Urinary control should be normal. In contrast, ectopic ureters in females potentially vent into remnants adjacent to the fallopian tube (epoophoron), body of the uterus (paroophoron), and vagina (Gartner's duct), where they presumably rupture or are absorbed. Since the urinary sphincter is bypassed, incontinence results.

Ureteral duplications occur when a single ureteral bud branches prematurely during its ascent or when two distinct ureteral buds arise from the Wolffian (mesonephric) duct (Figure 40.3). The clinical significance of these anomalies depends on the location of the buds and their interplay with the developing kidney.

An incomplete ureteral duplication results if a single ureteral bud branches after its takeoff from the

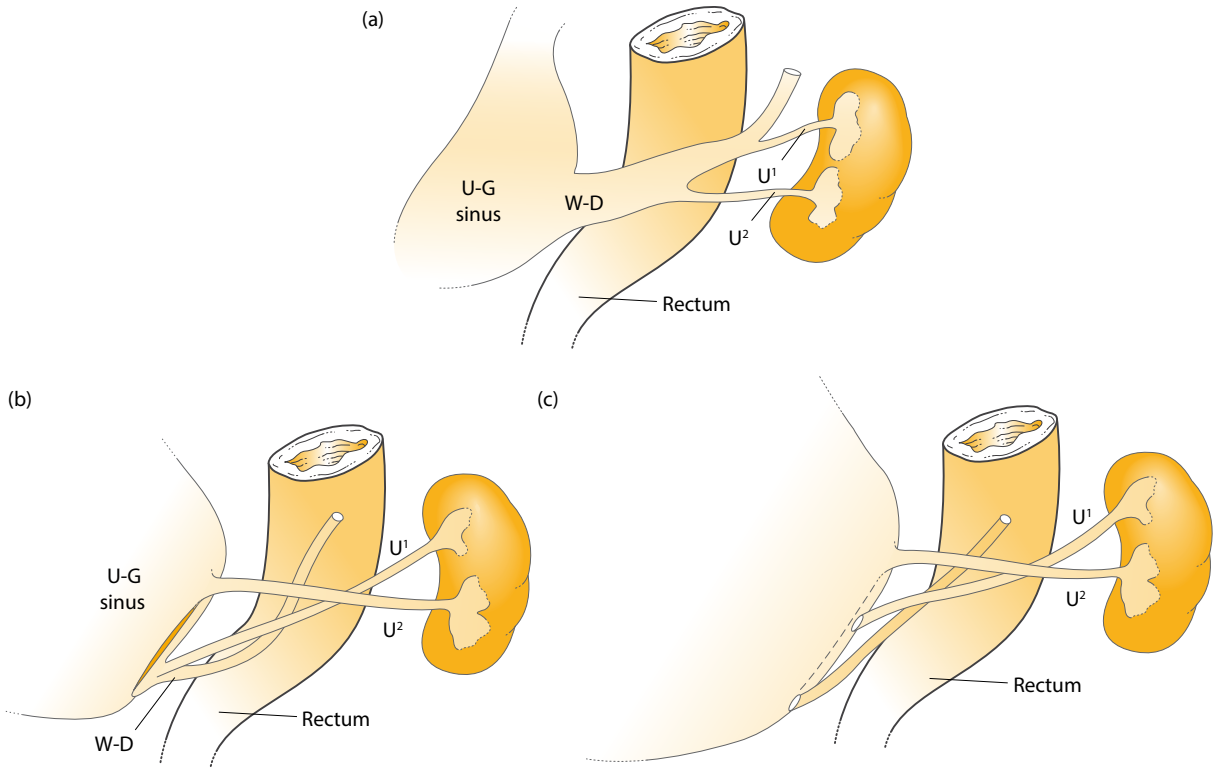

FIGURE 40.3 Complete ureteral duplication. *Caudal ectopia* (U^1) results from an abnormally high takeoff of the ureteral bud, which remains positioned near Wolffian duct tissue. *Lateral ectopia* (U^2) results from a more caudal position, allowing more time for intravesical migration.

mesonephric duct. The configurations that can occur range from anomalies as mild as a bifid renal pelvis (late branching) to nearly complete duplications having a common intravesical stem (early branching). The location of the ureteral orifice with incomplete duplications depends on the takeoff of the ureteral bud in the sequence cited above. Bifurcation can occur at any level from the bladder to the renal pelvis but can begin in the lower third of the ureter.[7] Most buds are normally positioned along the mesonephric duct, and as a consequence, incomplete duplications are usually radiologic curiosities having little clinical significance.

Complete ureteral duplication occurs when two ureteral buds project from the mesonephric duct, each having a separate interaction with the metanephric blastema. During their early takeoff, the buds interact with the primordial kidney in logical fashion. The most superior or cephalad bud induces the upper portion of the blastema (upper pole), while the lower bud joins the lower-pole moiety. However, *the ultimate positions of the ureteral orifices are governed by the same enigmatic rules of tissue migration and incorporation into the bladder described for singlets* above.

When both buds are close together and project from an acceptable position along the mesonephric duct, both ureters will have normally positioned orifices. When the buds are more widely separated, one or both will be ectopic. *If the superior or upper-pole bud projects from an abnormally high position along the mesonephric duct, caudal ectopia is the outcome. If the bud to the lower pole originates from a more caudal position along the duct, lateral ectopia results*. To achieve their ultimate positions, the ureters and their orifices complete a 180° clockwise rotation along their longitudinal axes. These relationships, defined by the *Weigert–Meyer law*, are unusually consistent.[8,9] Exceptions have been described but are rare.[10,11]

The molecular and hormonal basis of the epithelial–mesenchymal interplay of the ureteral bud and developing renal blastema are discussed elsewhere (see Chapter X on embryology). A polygenic mode of inheritance is suggested for ureteral abnormalities. Similarities in renal development to the relationships defined by Mackie and Stephens (below) have been correlated with these more complex studies.

Ureteroceles

Several theories have been proposed for the development of ureteroceles, although their etiology remains unclear. Some of the more popular theories are

1. *Persistence of Chwalle's membrane*, which is a two-layered membrane that transiently separates the caudal end of the Wolffian duct from the urogenital sinus (37 days gestation),[12] is possible. Incomplete dissolution of the membrane could account for the cystic dilatation of the terminal ureter and stenosis of the orifice found with ureteroceles. A delay in the apoptosis felt to occur between the ureteral bud and developing trigone may be implicated.[5]
2. *Abnormal muscular development* of the terminal ureter has been implicated by a number of studies.[13]

Ballooning of the distal ureter could be explained by a deficiency or an absence of its muscular investing layers, a finding shown in more than 90% of specimens in one study.[14] By comparison, the distal segments of ectopic ureters consistently have better developed musculature than ureteroceles.[15] The ureterocele itself is covered with vesical mucosa, whereas its internal lining is made up of ureteral mucosa. Varying degrees of attenuated smooth muscle and connective tissue are sandwiched between. *An element of meatal or perisphincteric obstruction*[16] *may contribute to the dilatation*. However, some ureteroceles present without a functioning kidney, suggesting to some clinicians that urinary output is an unnecessary impetus to distal ureteral ectasia.[17] It is also plausible that the kidneys associated with these so-called "blind ureteroceles" produce urine during an early critical stage in development but subsequently involute.[18]

3. *Abnormal widening of the mesonephric duct* may occur in the segment between its insertion at the urogenital sinus and the ureteral bud. This area normally dilates in concert with an undefined stimulus for vesical and urethral expansion. Ureteral migration is presumably completed before this expansion occurs. *Proximal extension of the widening process into the distal ureter* could result in ureterocele development.[6] This explanation seems plausible for intravesical ureteroceles, the ureter and orifice of which have migrated appropriately. *Late incorporation of the ureteral bud from an abnormally proximal position* within this dilated segment is another possibility. This explanation is more compatible with extravesical ureteroceles accompanied by ectopic orifices. Notably, ectopic ureters associated with even more proximal buds that insert into Wolffian remnants are rarely ectatic at their distal ends. They are presumably unaffected by the stimulus that alters the urogenital sinus.[13]
4. *Defective ureteral maturation* affecting the detachment of the ureteral bud from the mesonephric duct as it moves into the bladder has been suggested in mouse models.[5] As discussed below, the concept of abnormal bud position may also account for the renal dysplasia that accompanies many extravesical ureteroceles.

URETERAL–RENAL INTERACTIONS

The ultimate maturation of the renal blastema is dictated by its interaction with the ureteral bud. When this interplay is experimentally altered, the transformation expected of blastema to normal nephron does not occur.[19,20] Mackie and Stephens[21] proposed the midregion of the elongate metanephric blastema as being most conducive to becoming normal renal parenchyma. *Ureteral buds that originate from abnormally cephalic or caudal positions along the Wolffian duct are destined to induce polar blastema, which results in cystic dysplasia* (Figure 40.4). This theory offers a ready explanation for the dysplasia and scars found within kidneys with associated VUR where urinary tract infections (UTIs) have never occurred. It could also explain why ectopic ureters with urinary insertions

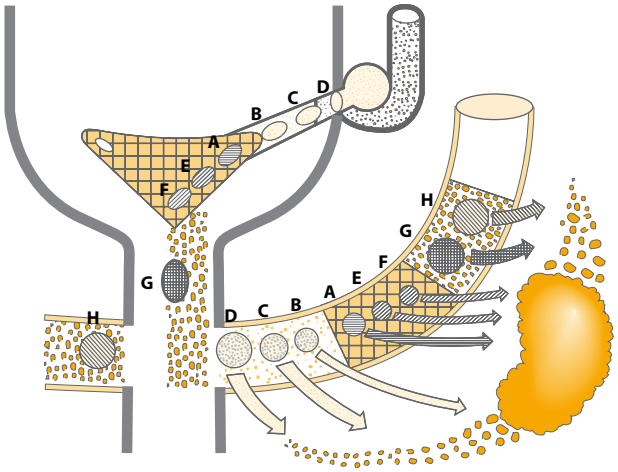

FIGURE 40.4 In theory, the position of the ureteral bud on the Wolffian (mesonephric) duct corresponds to the final position of the ureteral orifice and differentiation of the metanephric blastema. Lateral and caudal ectopia can both result in renal dysplasia.

(GU-ectopy) are more likely to be associated with functioning renal parenchyma than ectopic ureters having Wolffian or gynecologic (GYN-ectopy) insertions, where dysplasia is often present.[22] Ureteral bud takeoff could also explain the difference between the salvageable renal function usually seen with intravesical ureteroceles and the poor function that occurs with extravesical ureteroceles.

Clinical correlates offer only guarded support of this theory, despite its attractiveness. Most studies generally cite poor renal function in the presence of severe reflux or marked ureteral ectopia,[23] although the difference between GU- and GYN-ectopy has come into question.[24] In addition, antenatal detection has added some new twists. In one review of specimens from 50 consecutive patients undergoing partial nephrectomies, dysplasia was seen in 70% from ureteroceles and 30% from ectopic ureters.[25] Each had been diagnosed antenatally, yet none were felt to have histological changes that may have benefited from renal preservation surgery. In contrast, in a similar series of 40 consecutive antenatally diagnosed duplication anomalies, only 6 required heminephrectomy because of poor function, and none of these showed evidence of dyplasia.[26]

Most historical reports cite renal function with only 20%–30% of ureteroceles. This pales next to the yield of contemporary series, whose numbers are inflated by the addition of antenatally diagnosed anomalies and the sensitivity of better diagnostics. The clinical implications are obvious (see the "Recommendations for Management: Ectopic Ureters" section). Are these renal moieties previously destined to lose renal function as a consequence of progressive obstruction? Do they benefit from being surgically diverted or endoscopically decompressed? Or is renal parenchyma being preserved that has an intrinsic developmental insult? Nodular renal blastema has been reported in upper-pole nephrectomy specimens removed with ectopic ureteroceles.[27] Dysplasia is also a common finding.[28] The study by Arena et al.[29] failed to show any evidence of reversible histologic changes in partial nephrectomy

specimens of patients whose ureteroceles had been prenatally diagnosed. It is unclear as to whether this is cause for concern. To date, no chronic complications of retained renal segments have been reported (hypertension or tumor formation, for example).

NOMENCLATURE AND CLASSIFICATIONS

Ectopic Ureters

The term *ectopic ureter* refers to a ureter that has migrated with the Wolffian duct structures and is more caudally positioned than a normal ureter. With a duplex system, this is invariably the upper-pole ureter. By definition, such ureters drain beyond the bladder neck into the urethra, Wolffian, or Mullerian structures. The ureter to the lower pole of a duplication, which is sometimes laterally displaced and ectopic in the purest sense, is regarded as orthotopic. Single-system ureters, which are laterally misplaced and reflux as a consequence, are discussed elsewhere (see Chapter 42 on vesicoureteral reflux).

Ureteroceles

Historically, ureteroceles associated with single systems were regarded as *orthotopic* or *simple* and considered adult type, despite the fact that some such variants are clearly ectopic and occur in children (Figures 40.5 through 40.9). Ureteroceles subtending the upper-pole ureter of a duplex system have been described as *ectopic* and pediatric, although exceptions to both descriptions also commonly occur.[30] Gonzales[31] felt it simplest to describe the anomaly based on the location of its orifice. Other than their association *with a single or duplex*

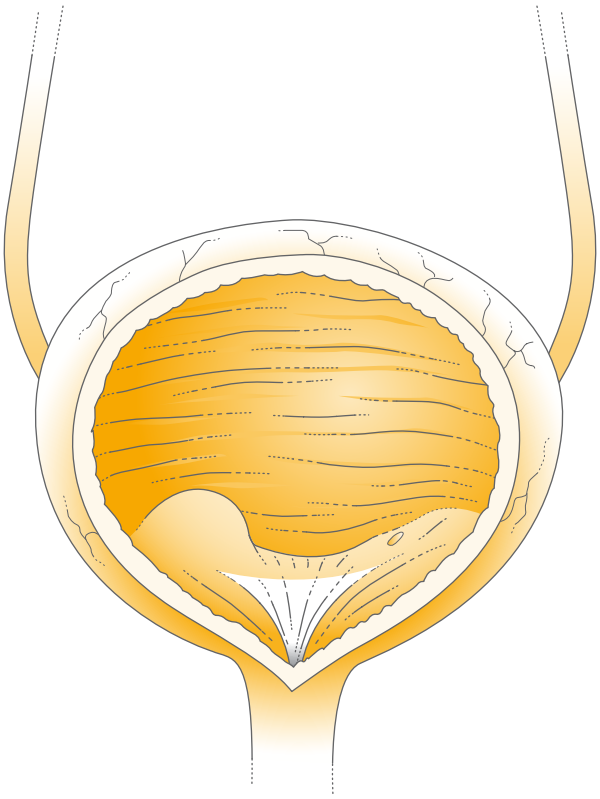

FIGURE 40.5 Intravesical ureterocele subtending a single ureter. This could also be classified as orthotopic or simple.

FIGURE 40.6 Excretory urogram showing bilateral single-system intravesical ureteroceles. Right is larger than left. Renal function is typically preserved.

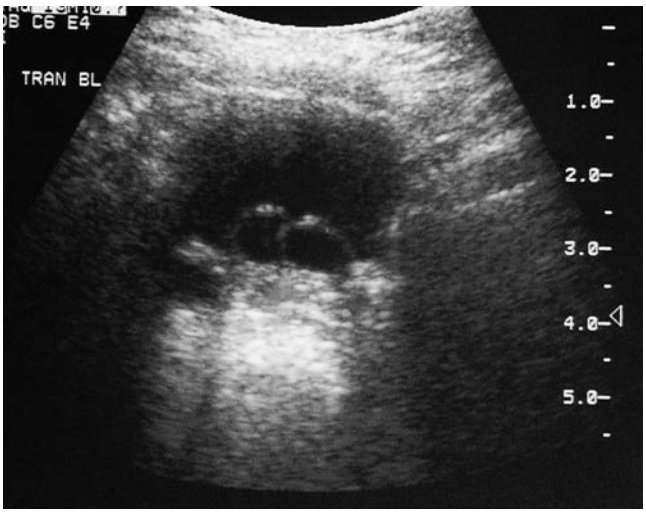

FIGURE 40.7 Ultrasonic appearance of similar patient with bilateral intravesical ureteroceles.

FIGURE 40.8 Intraoperative photograph of bilateral intravesical single-system ureteroceles.

system, two types of ureteroceles exist, *intravesical or extravesical*. This approach avoids the confusion associated with the terms *ectopic* and *orthotopic*. In addition, such nomenclature reflects the embryologic importance of the ureteral bud or orifice to renal development and distortion of the bladder neck. However, this form of categorization potentially mislabels ureteroceles with an intravesical orifice but an extension into the bladder neck or urethra. Anatomically, these too could be considered extravesical.

A variety of other classification schemes have been proposed for ureteroceles, although no system has been adopted universally. Stephens's[16] categorization can be used to provide additional information about the location

FIGURE 40.9 Large ureterocele extending toward the bladder neck (top). Catheter is in the lower-pole ureter, which is displaced and freely refluxes.

and configuration of the orifice of the ureterocele. These factors presumably account for the degree of distortion of the bladder neck and urethra, as well as the extensiveness of the renal dysplasia accompanying the anomaly (Table 40.1, Figures 40.10 and 40.11).

TABLE 40.1 Classification of duplex ureteroceles

Intravesical
Stenotic—40%: Involve a congenitally small ureteral orifice adding an element of obstruction for the upper pole.
Nonobstructed—5%: The ureteral orifice is large and balloons open without any ureteral obstruction.
Extravesical
Sphincteric—40%: The orifice opens outside the bladder and the ureterocele extends into the bladder neck and urethra. The orifice is normal or large and usually opens proximal to the external sphincter. In females, the meatus may open distal to the sphincter. At rest, the bladder neck and sphincter contract on the ureter and orifice, causing obstruction.
Sphincterostenotic—5%: Similar to sphincteric, although the ureteral orifice is stenotic.
Cecoureteroceles—5%: A large orifice opens in the bladder, but a blind pouch or cecum extends into the submucosa of the urethra. When the cecum distends with urine, urethral obstruction can result.
Blind ectopic—5%: Similar to sphincteric, with no ureteral orifice.

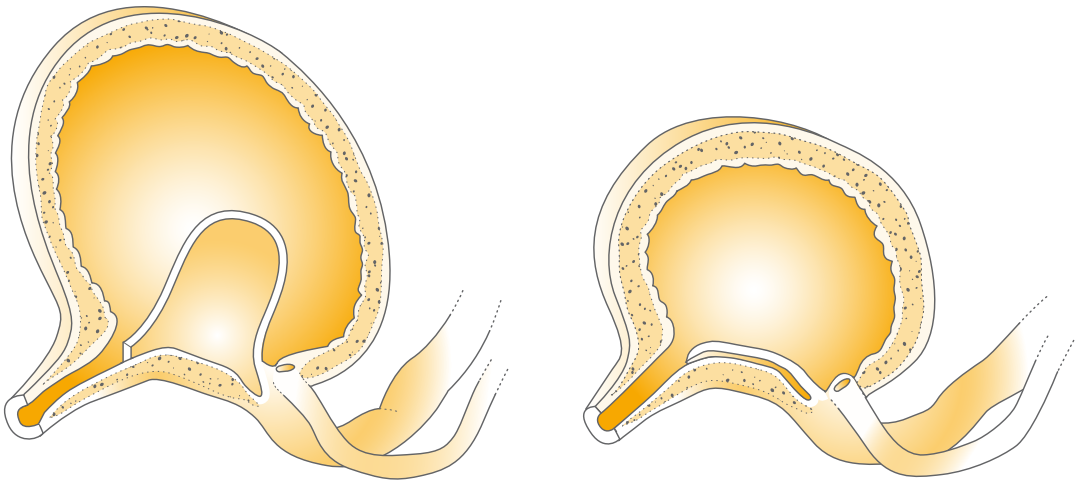

FIGURE 40.10 Sphincteric variant of extravesical ureterocele subtending upper-pole ureter of a duplex system. The orifice opens proximal to the external sphincter. Normal contraction of the bladder neck may contribute to ureteral obstruction.

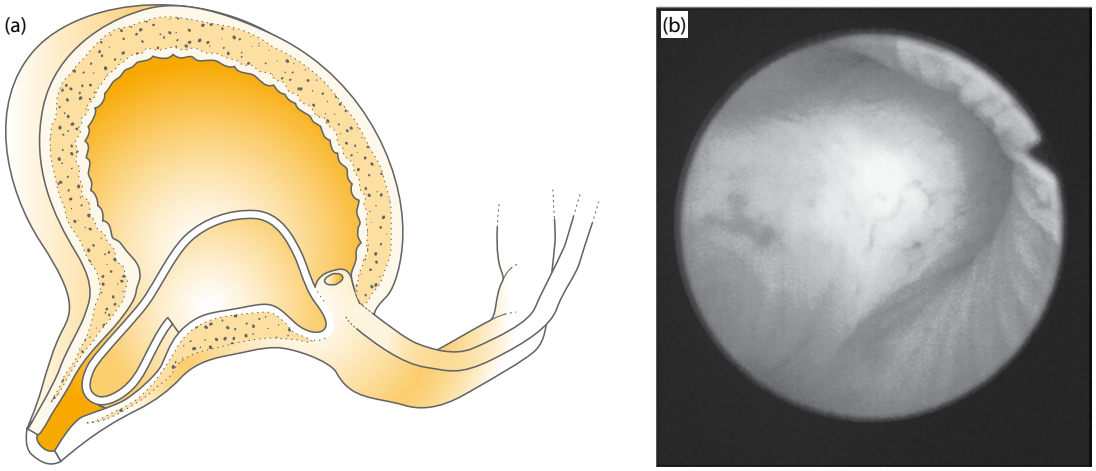

FIGURE 40.11 (a) Cecoureterocele variant of an extravesical ureterocele. Blind-ending extension beneath submucosa of the urethra can prolapse and/or cause bladder outlet obstruction. (b) Cystoscopic appearance of urethral extension of cecoureterocele.

Characteristics

Ureteral Duplications

Duplication is the *most common congenital anomaly in the urinary tract*: a *0.7% incidence* was found in one series of more than 50,000 autopsies.[32] Intravenous urograms demonstrate duplications in 4% of studies, and hydronephrosis and scarring are seen in 27% of these.[33] Females are affected two to four times more commonly than males. The right and left collecting systems are affected equally. Bilateral duplications occur in 17%–33% of cases. The anomaly is an inheritable defect transmitted in an autosomal fashion having variable penetrance.[34] The parents or siblings of a child with a duplex ureter have as much as a one in eight chance of having a similarly affected child.[35]

Ectopic Ureters

The incidence of ureteral ectopia was approximately 1 in 2000 in one series of autopsies in children. Many remain asymptomatic, and a true incidence is difficult to determine.[36]

Ectopic ureters occur in *females two to three times more commonly* than in males,[1,2,37] although as high as 12-fold increases have been cited.[38] *More than 80% of females with ectopic ureters have duplex systems. The majority (75%) in males are singlets.*[39,40] Between *70% and 80%* of ectopic ureters are associated with *complete duplications*. Nearly 20% of patients with ureteral ectopy have bilateral involvement.[37] In one report of nearly 500 ectopic ureters, the posterior urethra and prostatic urethra (57%) were the most common sites of drainage in males. The seminal vesicle (33%) was also commonly involved. More remote terminations at the ejaculatory duct and vas were rare (10%). The urethra and vestibule were the most common drainage sites for 69% of females. Vaginal ectopy occurred in another 25%.[37]

Ureteroceles

The incidence of ureteroceles was as high as 1 in 500 in one autopsy study.

They occur in *females four to six times more commonly* than in males.[41–43] Ureteroceles in girls are associated with

duplex systems 95% of the time. By contrast, up to 66% of boys have single-system anomalies.[44] Nearly all appear in Caucasians.

Eighty percent of ureteroceles are associated with the upper pole of a duplex system. The remainder are single-system ureteroceles. Bilateral involvement occurs in 15% of cases.[45,46] A genetic predisposition has been shown,[47] but familial cases are rare.[48] The anomaly is more commonly seen in Caucasians than in other races.[43]

CLINICAL PRESENTATION

Antenatal ultrasonography has dramatically increased the detection of urinary anomalies and, in some cases, has altered our understanding of their natural history. The yield from routine screening is significant. Abnormalities of the urinary system are detected in approximately 1 in 500 studies, second only to those of the nervous system. The breakdown of diagnoses in a typical series is shown in Table 40.2. Notably, ectopic ureters, duplications, and ureteroceles can all be detected prenatally. Further evaluation after birth is warranted, even in instances where the anomaly was present earlier in gestation and has presumably resolved.[49] In many cases, the exact etiology of hydronephrosis, the most common finding, cannot be determined until after delivery. Prenatal cases of bladder outlet obstruction have been reported.[50] Antenatal intervention has been described for rare cases of bladder outlet obstruction caused by ureteroceles.[51,52] Such cases are exceptional, and intervention is unlikely to provide much benefit. Because of the tendency for urinary infections to occur with hydronephrosis, it seems reasonable to keep newborns on prophylactic antibiotics (amoxicillin, for example) until their anatomy is better defined (see the "Evaluation and Diagnosis" section below).

After delivery, an *extravesical ureterocele represents the most common cause of bladder outlet obstruction in newborn girls and the second most common cause in boys, after posterior urethral valves* (PUVs). A true pediatric urologic emergency can result, depending on the degree of obstruction. The diagnosis of an obstructing ureterocele should be considered in any infant, especially a girl, with bladder distension, anuria, or ascites.[53] When full-blown prolapse occurs, clinicians will encounter a congested, ecchymotic interlabial mass (Figures 40.12 through 40.15). The mass may have varying hues, depending on the degree of vascular compromise. Since prolapse usually occurs down the posterior wall of the urethra, the meatus will be evident anteriorly and can be catheterized. Cecoureteroceles, the distal projections of which extend down the urethra, have a less protuberant appearance if they reach the perineum. They are rarely ecchymotic since vascular compromise is not an issue (Figure 40.16). The smooth wall of the ureterocele helps differentiate it from the more ominous grapelike sarcoma botryoides. The white mucus-filled periurethral (Skene's) duct cyst is considered in the differential, as is Gartner's duct cyst. The latter can protrude from the vagina and become

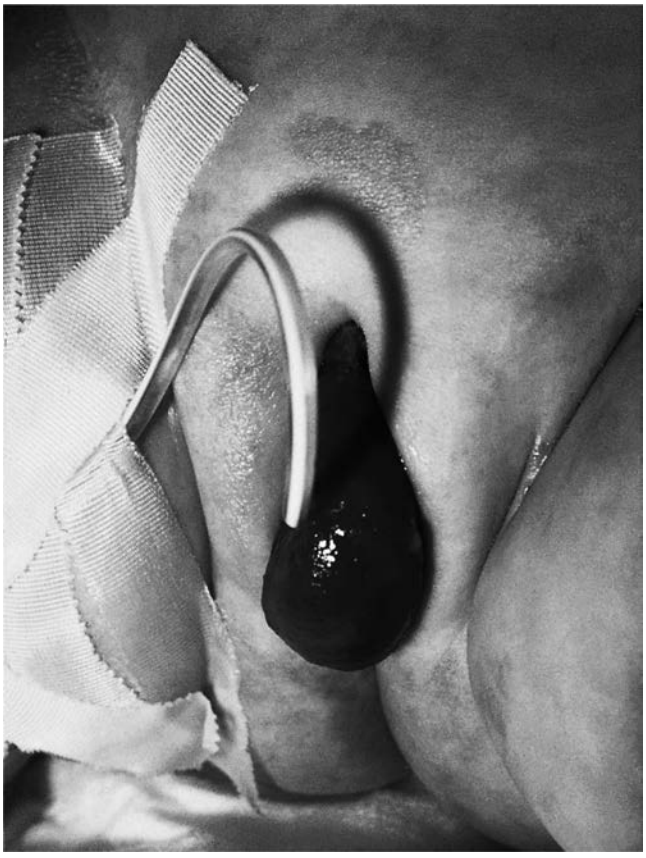

FIGURE 40.12 Congested and ecchymotic prolapsed ureterocele presenting as an interlabial mass.

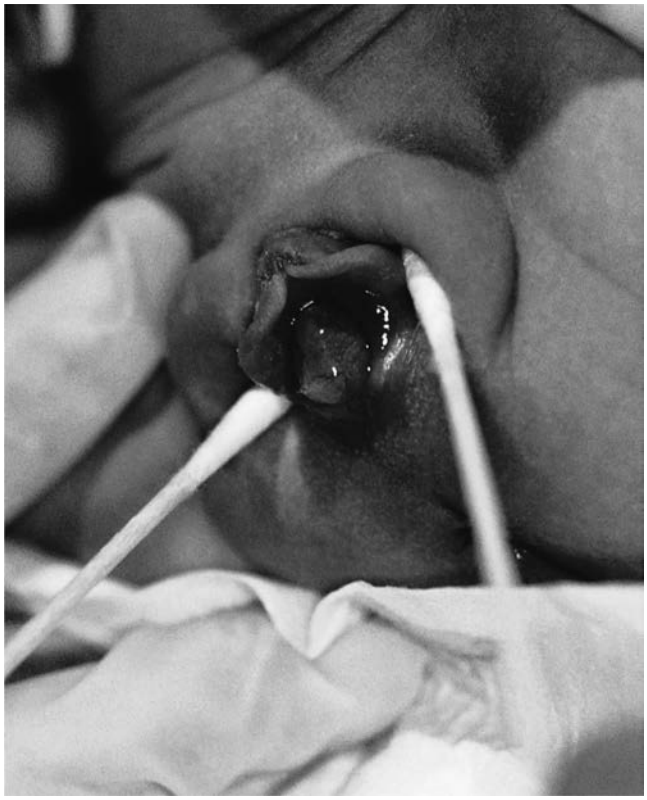

FIGURE 40.13 After incision at bedside, the ureterocele is decompressed and retracts into the bladder after a few days. Given the severity of this type of defect, lower urinary tract reconstruction is ultimately warranted in affected infants.

FIGURE 40.14 Prolapsing ureterocele associated with nonfunctioning upper-pole moiety appears as a filling defect occluding the urethra on EU.

infected. It is often associated with an ectopic ureter that is blind ending at its proximal extent or connected to a rudimentary kidney.[54,55] When not evident on examination, the diagnosis of an obstructing ureterocele (or other urethral obstruction) is suggested by the history of a weak or intermittent stream.

More commonly, ureteroceles cause unilateral hydronephrosis from ureteral blockage. In severe cases, an abdominal mass becomes palpable. Patients not detected antenatally typically present with UTIs (Figures 40.17 and 40.18). Duplication anomalies were detected in 63 (8%) of 774 children evaluated for an initial UTI during the first 6 years of life.[56] In another series of 58 ureteroceles, 90% were identified before age 3, half of whom presented with UTIs.[15] Nonspecific symptoms of failure to thrive and colic also occur.

Flank pain, fever, and abdominal mass are common presentations of ectopic ureters left undetected until a later age.[57] Urine cultures can be negative when the infected ectopic system is not draining into the bladder. Intermittent vaginal discharge is sometimes seen. A high index of suspicion is warranted. Ureteroceles can cause irritative voiding symptoms secondary to obstruction or infection, but voiding abnormalities accompany ectopic ureters far more commonly. In addition, the distal segment of ectopic ureters inserting at the verumontanum can elevate the bladder neck, causing outlet obstruction in boys of any age.[58] It is important to remember that *ectopic ureters always insert proximal to the urinary sphincter in males*. As a result, incontinence does not usually occur in boys with the anomaly. Bilateral single ectopic ureters, associated with bladder neck maldevelopment and lack of sphincter control, are one exception (see below). Another is the frequency and urgency that sometimes results from the trickle of urine into the posterior urethra.[37] However, the more usual proximal insertions into structures of Wolffian origin (seminal vesical, vas, and epididymis) present their own problems for affected boys. Ureteral ectopia should be suspected in any infant or child who presents with a culture-proven case of epididymo-orchitis.

Clinicians should be wary of any girl who reportedly has never been fully toilet trained. These patients must be approached with an open mind, and the possibility of an ectopic ureter always entertained, especially when damp underwear is found on examination. In many cases, a cadre of physicians have treated the patient for presumed bladder dysfunction or psychosocial problems, including sexual abuse.[59] When the ureter exits along the urethra, the voiding pattern often includes seemingly normal bladder control and spontaneous emptying (from the other ureters having normal bladder insertion), followed by an uncontrollable loss of urine as the obstructed system vents secondarily (Figure 40.19). With vaginal ectopy,

FIGURE 40.15 Large ureterocele associated with nonfunctioning right kidney occluding the bladder and contralateral kidney. Given its size and position, prolapse through the female urethra of such a variant, especially with urethral extension, is easy to envision.

continuous wetting in a girl having an otherwise normal micturition pattern and control (in contrast to bladder dysfunction) is a classic presentation (Figures 40.20 and 40.21).[60] The degree of incontinence depends on the urinary output from the affected kidney. In occasional cases where small amounts of urine are produced, sporadic incontinence occurs only while standing. The latter is commonly mistaken for vaginal voiding or stress incontinence. Table 40.3 summarizes the clinical manifestations of these two ureteral anomalies.

Both anomalies sometimes remain undetected until adulthood.[61,62] Ectopic ureters in girls that pass through the urinary sphincter but are positioned proximal to the meatus can maintain continence during development. Multiparity can unmask the anomaly, which is often mistaken for stress incontinence. With cases of ectopic ureters that terminate in the male genital tract, prostatitis, seminal vesiculitis, and epididymitis can all occur. Most do not become apparent until the onset of sexual activity. Historically, single-system ureteroceles usually presented during adulthood. An intravesical location coupled with preserved renal function allowed most to go unnoticed until later age (Figure 40.22). This accounted for their prior designation as "adult type," a label since dropped with the advent of antenatal diagnosis. Common presentations still include urinary calculi, milk of calcium, and recurrent UTIs.[63]

EVALUATION AND DIAGNOSIS

Ectopic ureters and ureteroceles present diagnostic dilemmas when it is difficult to determine from which renal moiety they arise. They can also mimic one another at the bladder level, which has implications for treatment.

A sonogram (also called ultrasonography, ultrasound, or US) and voiding cystourethrography (VCUG) are indicated in the initial evaluation of any child suspected of having a ureteral anomaly. Once detected, a functional test (radionuclide renal scan) becomes necessary to the decision-making process when considering the different

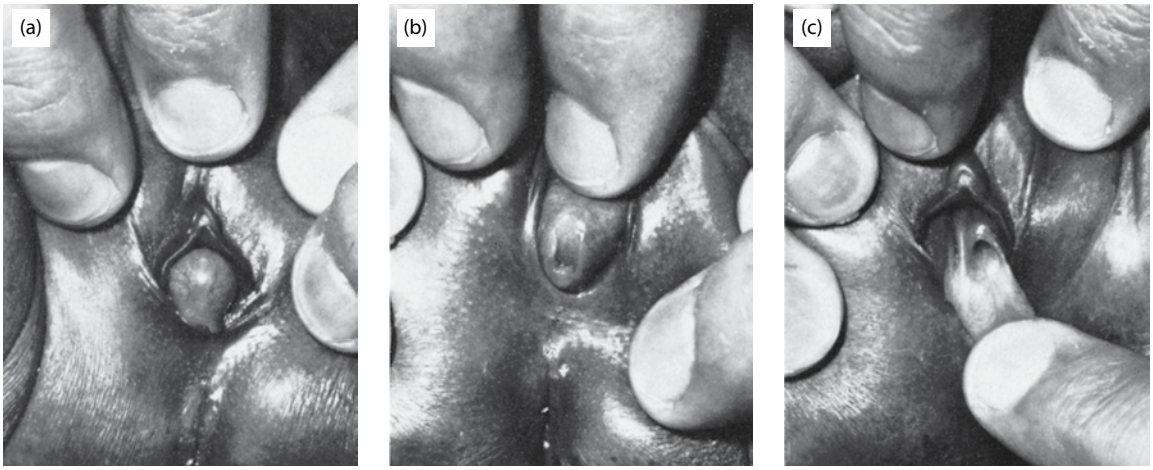

FIGURE 40.16 (a) Typical presentation of a cecoureterocele. (b) The cecoureterocele is pushed upward, revealing the hymenal ring below. (c) The urethra can be seen above the ureterocele. This ureterocele has a more natural pink coloration, distinguishing it from a periurethral skene's duct cyst, which is yellow and mucus filled.

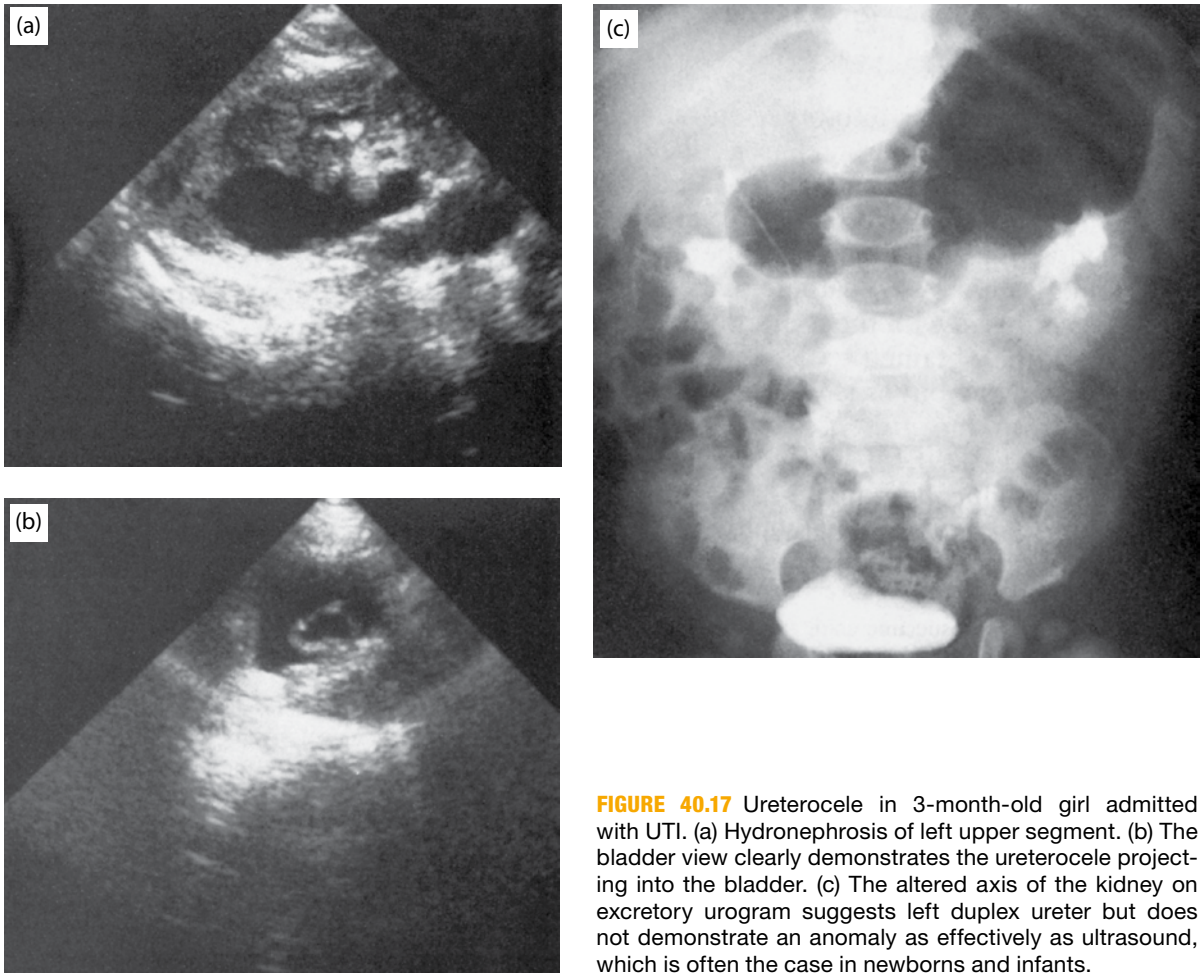

FIGURE 40.17 Ureterocele in 3-month-old girl admitted with UTI. (a) Hydronephrosis of left upper segment. (b) The bladder view clearly demonstrates the ureterocele projecting into the bladder. (c) The altered axis of the kidney on excretory urogram suggests left duplex ureter but does not demonstrate an anomaly as effectively as ultrasound, which is often the case in newborns and infants.

options in management. Additional studies—e.g., excretory urography (EU), computerized tomography (CT), or magnetic resonance urography (MRU)—are also sometimes necessary. Cystoscopy, sometimes in concert with retrograde ureteropyelography (RUP), completes the evaluation.

Ultrasonography

During initial screening, the differentiation of single from duplex systems is usually made possible by ultrasound evaluation. *The renal manifestations of ureteroceles and ectopic ureters can be identical*. Variable degrees of hydronephrosis of the affected kidney or upper-pole moiety depend on the severity of ureteral obstruction (Figure 40.23). Hyperechoic parenchyma is suggestive of dysplasia. With duplication, the adjacent lower pole can also be hydronephrotic. Reflux (because of lateral ectopia) or obstruction caused by the dilated upper-pole ureter must be considered. Hydronephrosis of the lower-pole moiety and contralateral kidney can also result from bladder outlet obstruction or direct compression by ureterocele.

Ultrasonography should always include a survey of the bladder, where the two anomalies can often be differentiated. Ultrasound is probably the best study for making the diagnosis of ureteroceles, which usually appear as thin-walled cystic protrusions from the posterolateral side of the bladder (Figure 40.24). The ureter can then be followed deep within the bony pelvis and, in some cases, up to the kidney.[64,65] The degree of bladder fullness, however, can reduce the sensitivity of the study. Overdistension causes some ureteroceles to collapse, whereas an empty bladder can allow a large ureterocele to completely fill the bladder. This gives the impression of a partially full but normal bladder. Ectopic ureters will sometimes displace the bladder and mimic a ureterocele, resulting in a so-called *pseudoureterocele* (Figures 40.25 and 40.26).[66] The muscle wall of the bladder gives a thicker line of demarcation between its lumen and that of an ectopic ureter than the thin wall of a ureterocele. More typically, the dilated ectopic ureter will taper and terminate into an abnormally inferior position beneath the bladder base. Occasionally, the ureter associated with either anomaly is so tortuous and dilated that it mimics a cystic abdominal mass with multiple septae.

In occasional cases, these ureteral abnormalities result in dilatation of the renal moieties they subserve. More typically, the kidneys associated with single-system anomalies are sometimes small and abnormally positioned, making them difficult to localize (ureterocele disproportion) (Figure 40.27).[67] In similar fashion, the upper-pole variants accompanying duplex variants can be tiny dysplastic

FIGURE 40.18 Gross pus from vagina of infant with ectopic ureter.

remnants crowning otherwise normal kidneys. In both instances, a dilated ureter or ureterocele is still often visualized at the level of the bladder. Additional diagnostics become necessary to define the anatomy more fully.

Voiding Cystourethrography

The voiding cystourethrogram provides the most definitive assessment of the bladder, urethra, and in some cases, distal ureters. Infant feeding tubes are used to perform this test. These allow for spontaneous voiding and avoid any confusion or distortion offered by the balloons of Foley catheters. Ureteroceles appear as smooth, broad-based filling defects positioned near the trigone. Some ureteroceles evert into the ureter with the bladder full and appear as a diverticulum.[68] This is especially true of single-system ureteroceles, where mimics of periureteral diverticula were seen in nearly one-half of VCUG in one series.[69] Other ureteroceles efface during the latter stages of bladder filling and cannot be appreciated. Obtaining images early during the filling phase aids in detection before contrast can obscure the ureterocele. An eccentric position may help define the involved side, although many ureteroceles appear centrally located. When laterality cannot be determined and cystoscopy is inconclusive, a cyst puncture with retrograde injection may become necessary.

The presence of VUR plays an important role in the management of ureteroceles. Reflux can occur into the ipsilateral lower pole, since the backing required of an effective flap valve is presumably lost with the posteriorly positioned ureterocele (Figure 40.28). Lateral ectopia, trigonal distortion, and eversion of the ureterocele can also contribute and become important factors in the planning of subsequent management. At times, the ipsilateral reflux is severe enough that the ureterocele and its duplex kidney are not detected until the time of surgery.[70] Reflux is also seen in the contralateral system if the anomaly is large enough to distort the trigone and opposing submucosal ureteral tunnel. In one series of 148 ureteroceles, ipsilateral VUR was seen in 80 (54%), whereas contralateral reflux was appreciated in 28%.[71] Smaller series have documented similar incidences.[72,73] Reflux into the ureterocele itself is uncommon but can also occur (Figure 40.29).

VUR is also a common finding with ectopic ureters (Figure 40.30). The ipsilateral lower-pole ureter refluxes in at least 50% of cases. Upper-pole VUR can also be appreciated, depending on the position of the ectopic orifice. Ectopic ureters whose distal extent is positioned within the bladder neck can both reflux and obstruct. Obstruction is intermittent, and emptying occurs during voiding, in concert with relaxation of the surrounding musculature. Reflux occurs once the ureter is somewhat emptied. This phenomenon may only be appreciated by *performing cyclic (repeated) voiding studies*.[74] Orifices proximal to the bladder neck freely reflux with or without voiding.

Excretory Urography

Despite its declining role in the routine evaluation of children with urinary tract problems, EU sometimes remains a useful tool in the workup of certain ureteral anomalies (Figures 40.31 and 40.32). This is occasionally the case with ureteroceles, when the anatomy is indefinable with ultrasound and renal scintigraphy alone, and is more often true with ectopic ureters. For girls with infrasphincteric ectopia, who arrive with the classic history of constant urinary dribbling despite being successfully toilet trained, EU is often the only imaging study necessary to make the diagnosis (Figures 40.33 and 40.34).[75] Radiographic signs of the nonfunctioning, occult duplications found with ectopic ureters are shown in Table 40.4.

Ureteroceles with minimally functioning upper-pole moieties can cause identical upper tract findings. The ureterocele appears as a filling defect within the bladder that gradually fills with contrast from the other functioning kidney. When ureteroceles are associated with a functioning kidney, they appear as a contrast-filled "cobra head" at the ureterovesical junction.

Renal Scintigraphy

Radionuclide scans help to quantify the amount of functioning renal parenchyma. This is crucial information when renal salvage is being considered. The degree of

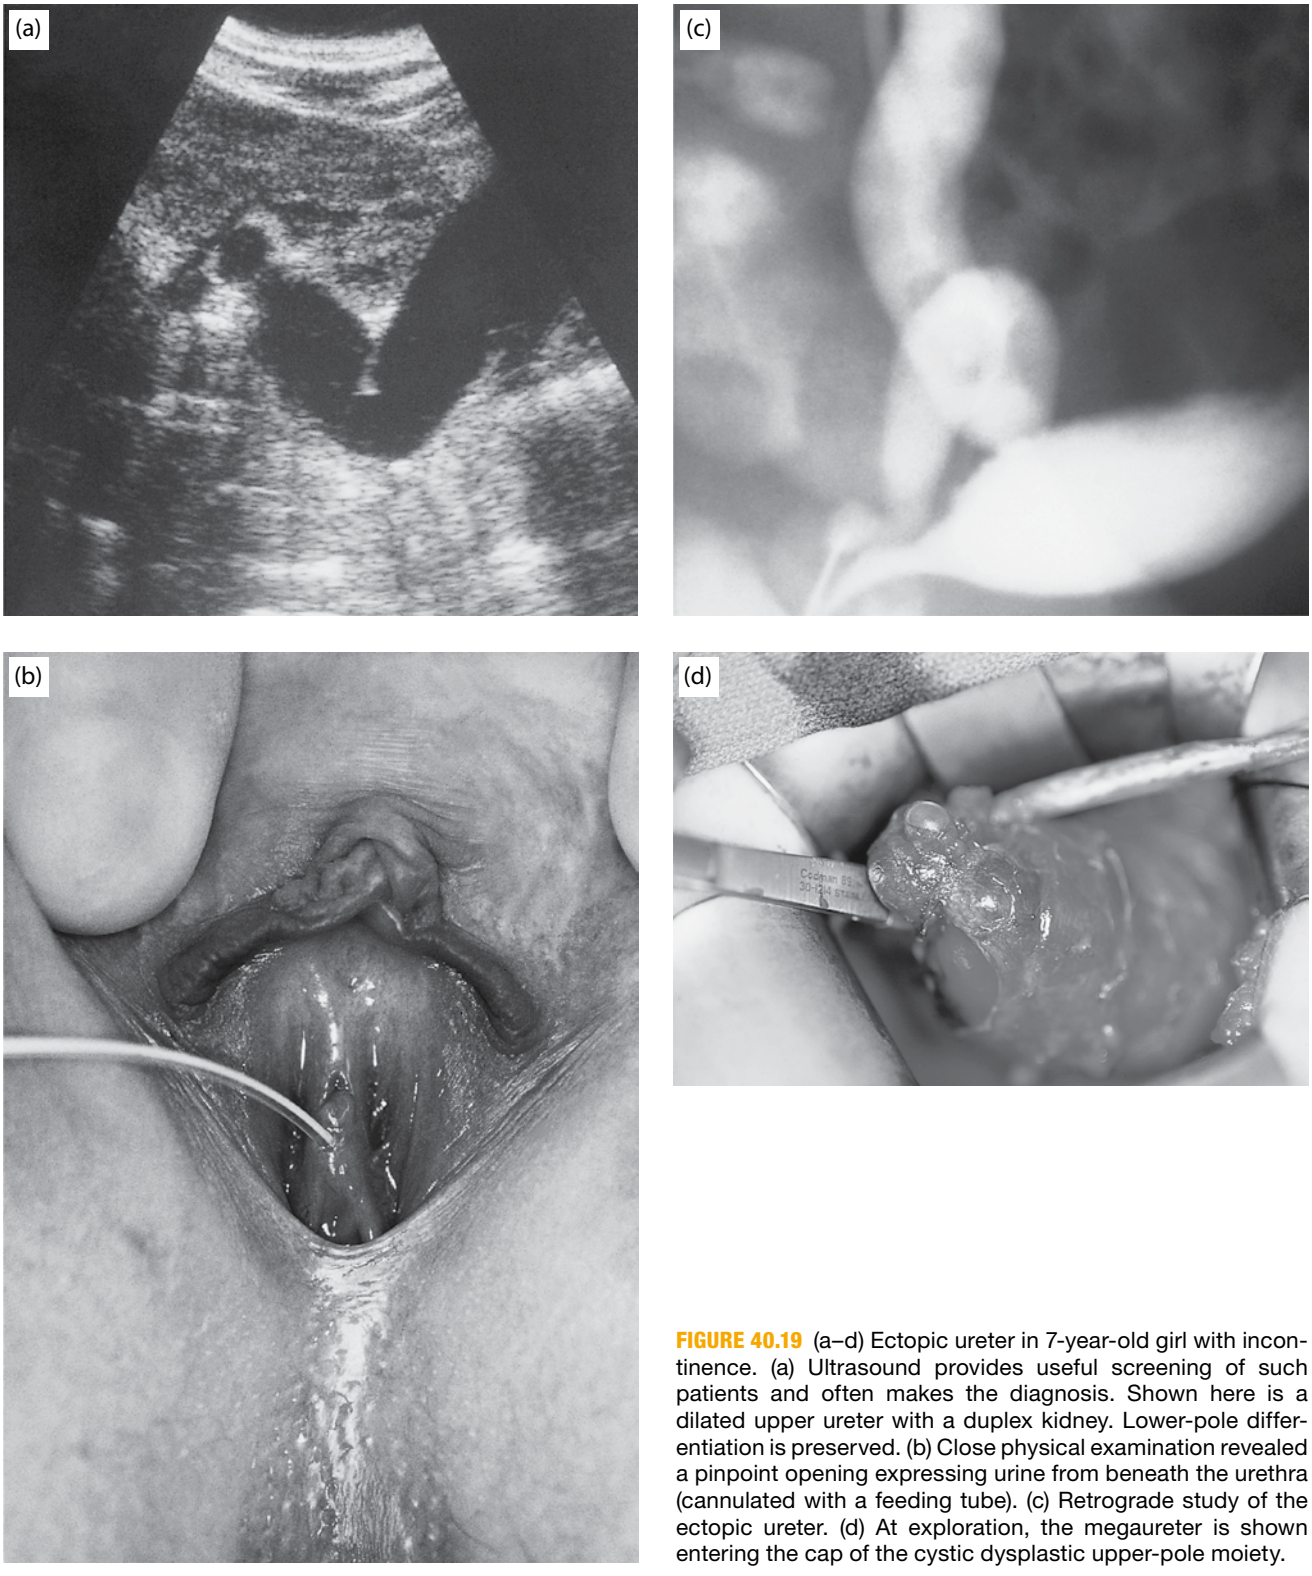

FIGURE 40.19 (a–d) Ectopic ureter in 7-year-old girl with incontinence. (a) Ultrasound provides useful screening of such patients and often makes the diagnosis. Shown here is a dilated upper ureter with a duplex kidney. Lower-pole differentiation is preserved. (d) At exploration, the megaureter is shown entering the cap of the cystic dysplastic upper-pole moiety.

obstruction is also assessed, although most ectopic ureters and ureteroceles, by default, exhibit delayed drainage because of ureteral dilatation. Technetium 99m (^{99m}Tc) diethylenetriamine pentaacetic acid (DTPA) and mercaptoacetyltriglycine (MAG3) scans provide reasonable assessments of function and obstruction. Since ^{99m}Tc dimercaptosuccinic acid (DMSA) scans result in renal tubular labeling and are unaffected by obstruction, they are more sensitive to low levels of renal function and are sometimes helpful in detecting occult duplex anomalies and small kidneys associated with ureteral anomalies that are not identified by other techniques.[76,77] It provides the gold standard in assessment of renal function. DMSA scintigraphy can also detect subclinical cortical defects and

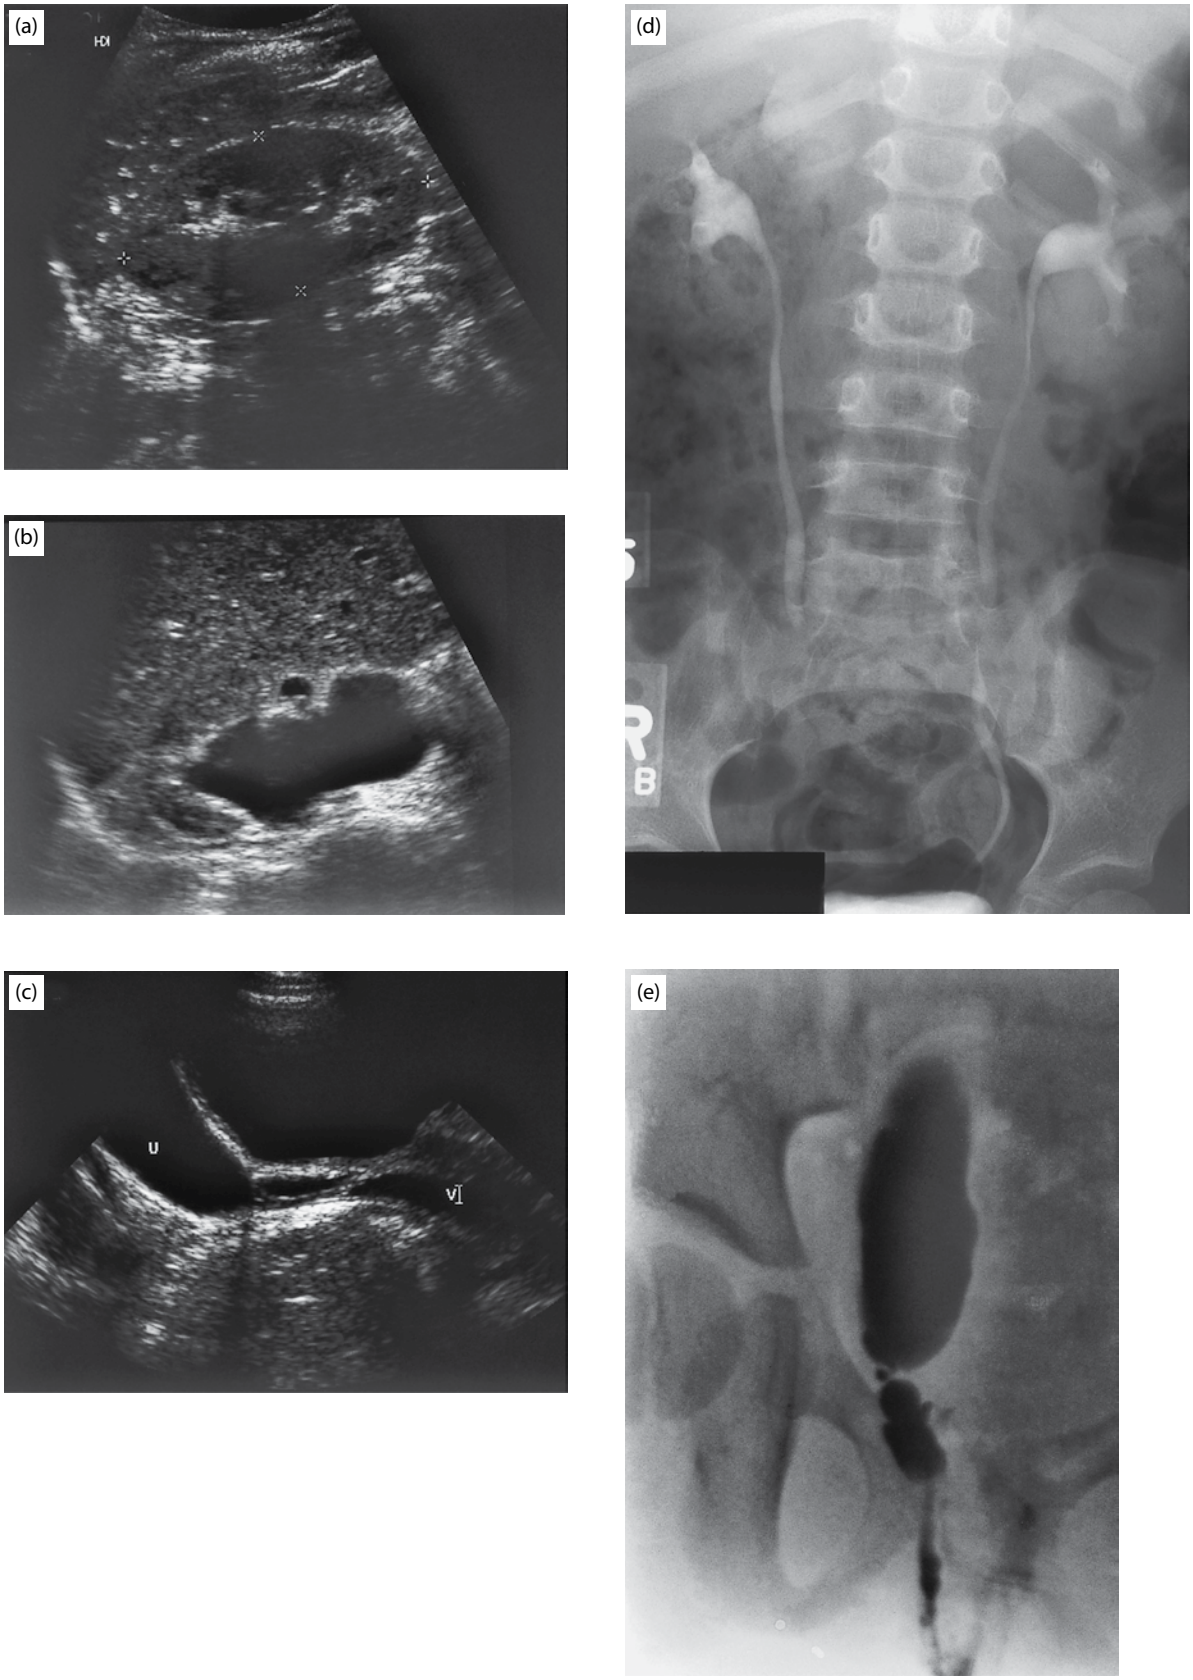

FIGURE 40.20 Urinary incontinence in a teenage girl felt to have bladder dysfunction. (a) Some views of the right kidney by ultrasound look fairly benign. (b) More proximal views are revealing and show a superiorly positioned cystic mass. (c) Pelvic views demonstrate the ureter entering the vagina. Bladder outlet obstruction

functional impairment in lower-pole moieties that show no ultrasonic evidence of parenchymal damage.[78]

Some clinicians believe that the transitional physiology of the newborn may affect the perinatal kidney's handling of radionuclides and contrast. This could contribute to the lower yield of functioning kidneys in historical series when EU was obtained in newborns and provided the usual measure of function. It could also result in overestimates of the recovery of function after procedures done to alleviate obstructed newborn kidneys, when early scans are compared with studies performed when the physiology is more conducive to scanning. As a consequence, scans performed early after delivery may not provide an accurate assessment of renal function and should probably be deferred for 4–6 weeks after delivery to allow for some maturation of renal function.

Magnetic Resonance Imaging

MRU is becoming increasingly useful in cases where conventional imaging studies fail to delineate occult dysplastic renal moieties, ectopic ureters, and ureteroceles.[79,80] Respiratory-gated excretory and static fluid MRUs appear to complement each other well in evaluating such systems.[81] In one study of 55 patients, virtual magnetic resonance was compared with cystoscopy and

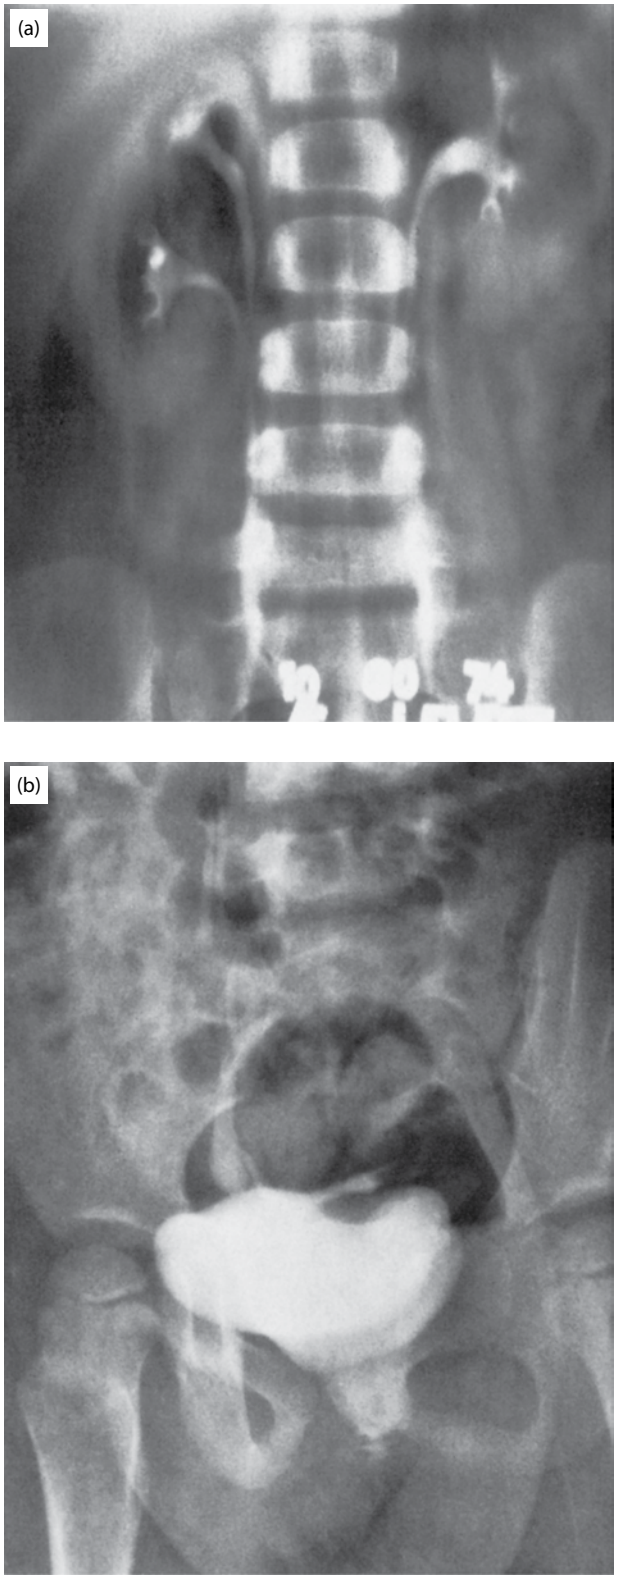

FIGURE 40.21 Ectopic ureter in a 4-year-old girl with incontinence, demonstrated by excretory urograms. (a) Duplication on the right. (b) Pooling of medium into the vagina from the ectopic ureter.

FIGURE 40.22 Single-system intravesical ureterocele presenting as UTI in a 16-year-old. If the impressive dilatation above a small ureterocele represents a progressive change, questions are raised about the natural history of the anomaly and the validity of expectant treament of antenatally diagnosed ureteroceles.

other diagnostic modalities, including ultrasonography. It was found to be the most sensitive modality in assessing concurrent genitourinary abnormalities. The modality allowed uniquely better definition of ureterocele anatomy and the insertions of ureters felt to be possibly ectopic.[82,83] Others have confirmed these findings.[84] Contrast-enhanced T1-weighted sequencing provides a contemporary alternative to intravenous urography. The T2-weighted sequences provided unenhanced static-water views and assessment of the adjacent soft tissue. Taken together with three-dimensional reconstruction, MRU offers an extremely sensitive and attractive alternative to any other option in diagnostic assessment. Availability, expense, and the need for sedation are detriments to its widespread usage, and at present, the study is utilized for cases where complex anatomy cannot be defined with other modalities.

Other Diagnostic Modalities

CT scans are sometimes helpful in defining the anatomy of kidneys with collecting systems of bizarre appearance. Duplications in which both ureters and renal pelves are dilated are one example. CT can also be considered for patients suspected of having ureteral ectopia or ureterocele disproportion but whose poorly functioning renal moiety cannot be defined by other modalities (Figure 40.35).[85–87]

Percutaneous drainage can also be used to vent obstructed kidneys or renal segments that appear salvageable by ultrasound but function poorly. However, recoverability of function is rare when renal scintigraphy demonstrates little function.

A variety of *dye tests* have been used to clinically diagnosis ectopic ureters. For example, indigo carmine or methylene blue can be instilled in the bladder with a catheter, which is then removed. Continued evidence of dampness and leakage of clear urine implicates ureteral ectopia. Another test involves placing a dental roll in the vagina. After indigo carmine is given intravenously, the roll will appear blue, provided that there is some function to the affected kidney and the child has not stained the roll by spontaneously voiding. The relative invasiveness of such tests, coupled with the increased sensitivities of today's diagnostics, has reduced their utility in most cases.

Cystoscopy

Examples of the cystoscopic appearance of ureteroceles are shown in Figure 40.47. With smaller *intravesical ureteroceles*, the cystic dilatation expands with each peristalsis and then shrinks as urine drains through its orifice. Not all variants are as easy to appreciate, however, and appearances can change with bladder filling. Starting with the bladder empty and examining with the slow filling of irrigant is helpful. *Extravesical variants* have ill-defined borders that can undermine the bladder neck and urethra. If the bladder is overfilled, they efface and can even appear to be a diverticulum. The orifice of the ureterocele may be difficult to appreciate but is often positioned distal to the bladder neck and, with cecoureterocele and sphincteric variants, will balloon open with the efflux of irrigant. With larger ureteroceles, the adjacent ureteral orifices are also difficult to appreciate because of displacement.

Cystoscopy is less helpful for ectopic ureters. The ectopic orifice cannot be appreciated in more than half of cases. Bladder neck and urethral ectopy offer a high yield. Prostatic ectopy sometimes presents as a widened ejaculatory duct that allows easy retrograde study.[39] Examining the vaginal vault along its anterior or lateral aspect for GYN-ectopy is less fruitful. In rare cases, a small cystic structure is identified that can be unroofed and cannulated for retrograde study.[31] Intravenous indigo carmine is sometimes excreted by even minimally functioning

kidneys and can aid in identification. Within the bladder, the hemitrigone on the affected side is often underdeveloped and may be elevated from behind by the dilated ureter. In some cases, the dilated ureter can be palpated on rectal examination. Failure to identify the ectopic orifice rarely changes management. In cases where a lower tract approach is planned, the ectopic ureter can be identified outside the bladder or transvesically after incising the trigone on the affected side (see the next section, "Management Considerations").

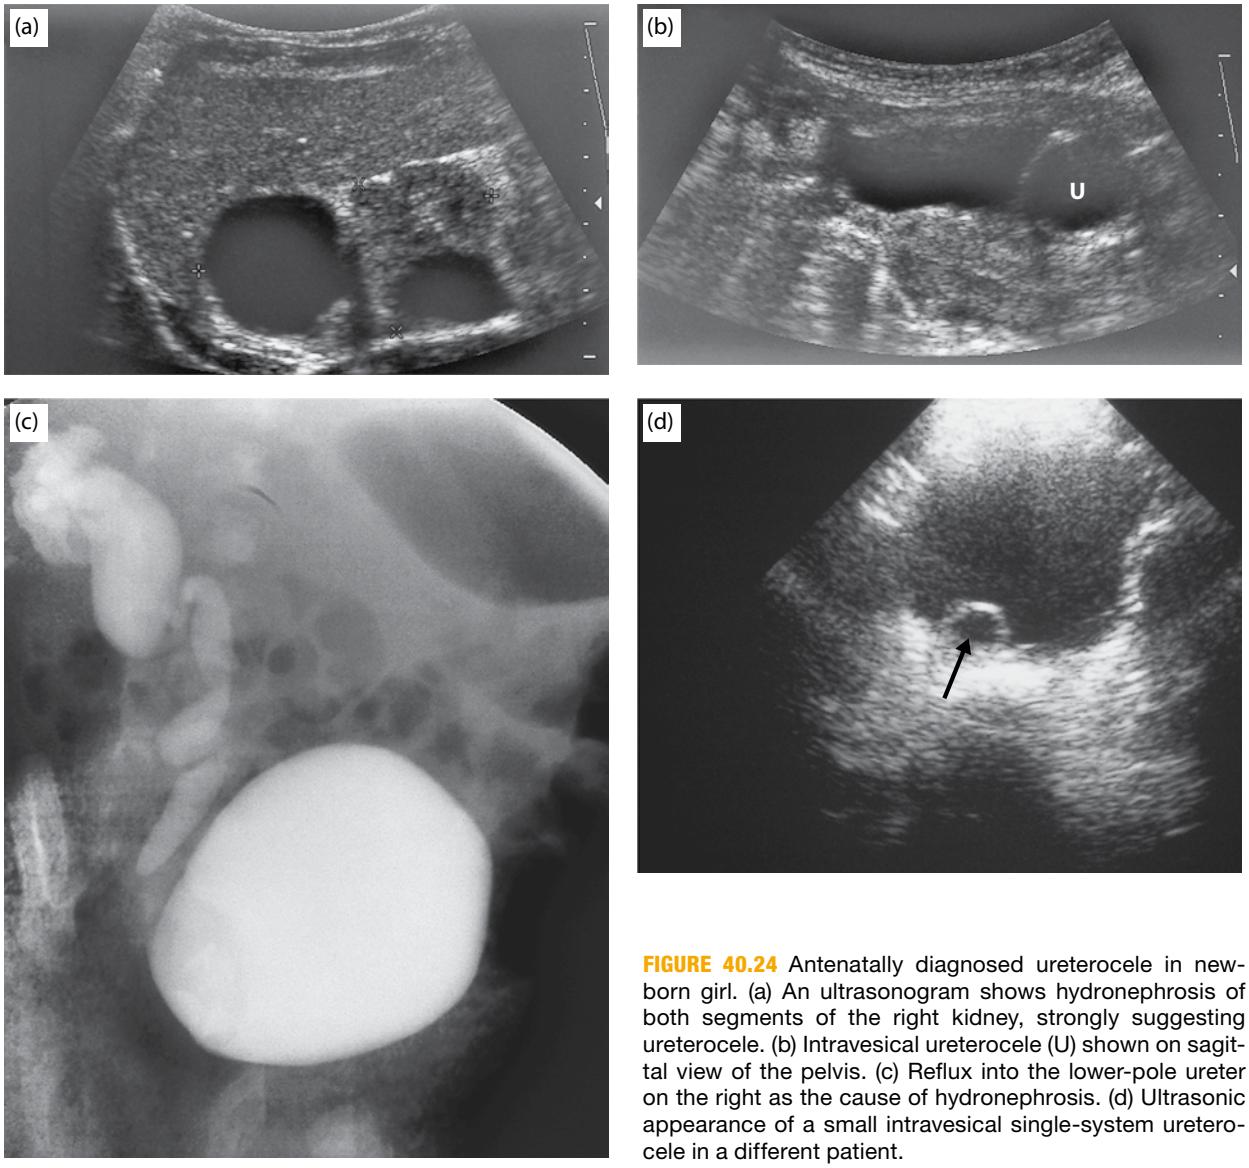

FIGURE 40.24 Antenatally diagnosed ureterocele in newborn girl. (a) An ultrasonogram shows hydronephrosis of both segments of the right kidney, strongly suggesting ureterocele. (b) Intravesical ureterocele (U) shown on sagittal view of the pelvis. (c) Reflux into the lower-pole ureter on the right as the cause of hydronephrosis. (d) Ultrasonic appearance of a small intravesical single-system ureterocele in a different patient.

MANAGEMENT CONSIDERATIONS

Once the workup is complete and the diagnosis made, the management of ectopic ureters and ureteroceles is defined by the answers to the following questions:

1. Is the affected ureter a singlet or a portion of a duplex system?
2. Is the affected ureter obstructed, refluxing, or both?
3. Are the contralateral and/or ipsilateral ureters and/or the bladder affected by the primary anomaly?
4. What is the status of the kidney or portion of kidney associated with the ureter in question?
5. What is the age and clinical status of the patient?

A description of the experience with various techniques and their technical nuances follows. Simply put, the algorithms in the management of these two anomalies historically branched with two main decisions: whether to save or discard the involved kidney and whether there is a need to reconstruct the bladder. These remain the mainstays of management for *ectopic ureters*.

The recommendations for *ureteroceles* have become controversial, however, with the inclusion in the treatment armamentarium of selective puncture. A minimally invasive and a seemingly simple solution, the benefits of cystoscopically decompressing ureteroceles must be weighed against the risks of creating reflux in the involved ureter.

Until recently, the *two main areas of contention with ureteroceles* dealt with the salvage of functioning upper-pole moieties and the need, if any, for removal of ureteroceles subtending upper-pole segments after partial nephrectomy or proximal ureteral diversion (ureteroureterostomy or ureteropyelostomy) brought about their collapse (Figure 40.36). The introduction of selective

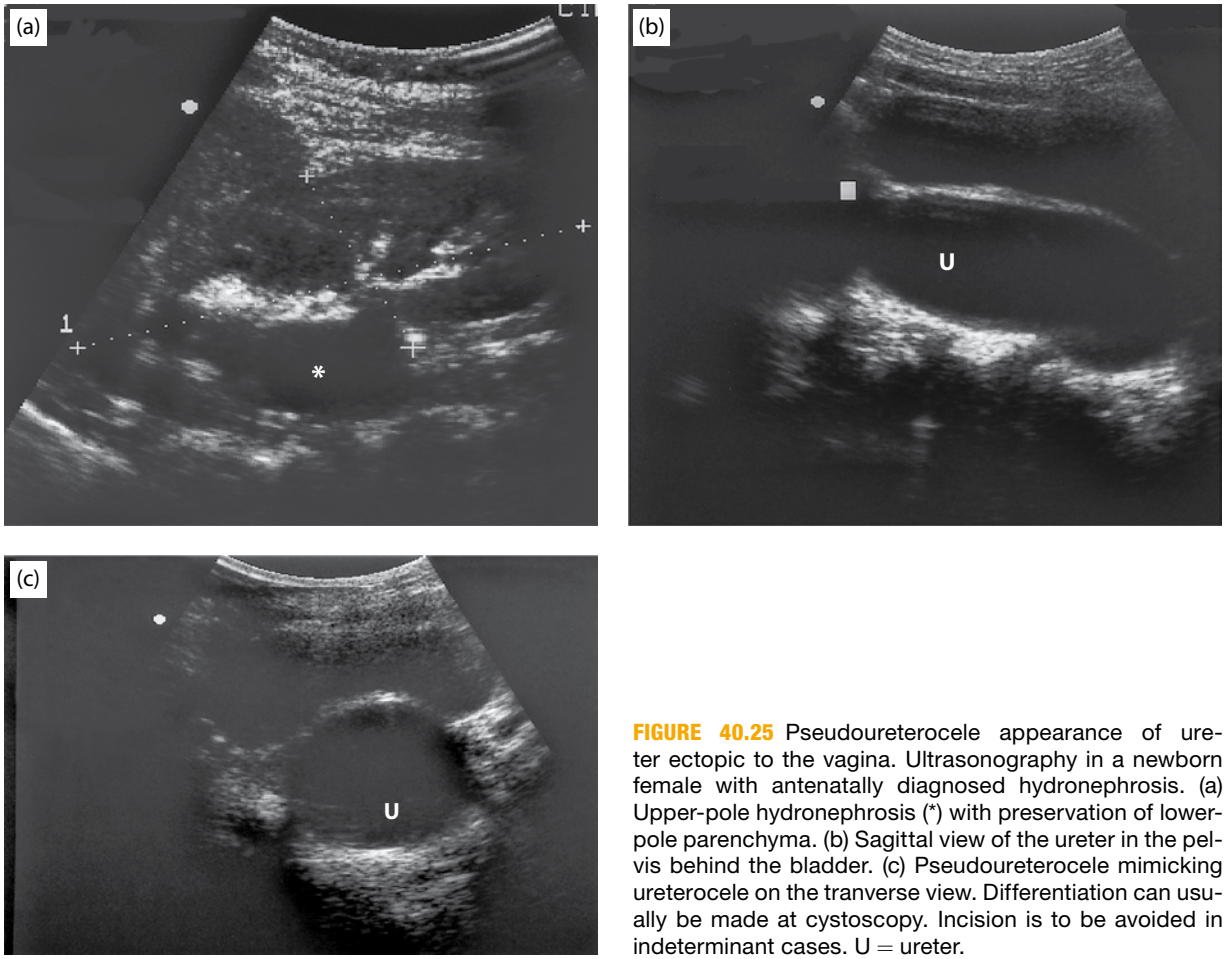

FIGURE 40.25 Pseudoureterocele appearance of ureter ectopic to the vagina. Ultrasonography in a newborn female with antenatally diagnosed hydronephrosis. (a) Upper-pole hydronephrosis (*) with preservation of lower-pole parenchyma. (b) Sagittal view of the ureter in the pelvis behind the bladder. (c) Pseudoureterocele mimicking ureterocele on the tranverse view. Differentiation can usually be made at cystoscopy. Incision is to be avoided in indeterminant cases. U = ureter.

(b) More typical appearance of ectopic ureter (U) en route to the vagina, where detrusor separating bladder lumen from the ureter is well developed.

puncture offers the obvious third controversy of which ureteroceles to decompress. The answers to these questions continue to be modified by contemporary clinical studies. A recent survey of pediatric urologists confirmed a considerable variation in management when offered typical clinical scenarios. Most practitioners reported seeing fewer than 10 cases per year, placing additional emphasis on the need for multi-institutional randomized controlled studies.[88]

A "cookbook approach" should be avoided when composing algorithms for the management of any urinary abnormality. The goals of therapy are generic to each

FIGURE 40.27 Gross example of ureterocele disproportion. Remnant dysplastic caps of tissue, as shown, are typically associated with massively dilated ureteroceles and ectopic ureters whose renal moiety cannot be appreciated diagnostically.

FIGURE 40.28 Massive reflux into the lower-pole ureter. An element of obstruction from the significantly enlarged ureterocele can also contribute to the dilatation.

patient: preservation of renal function and urinary continence with the elimination of obstruction, reflux, and infection. However, each patient requires individualized treatment, since there is often no uniform solution to every urologic anomaly. Nevertheless, trends become apparent in reviewing the literature that allow certain recommendations to be applied to most cases, which give the highest likelihood of a favorable outcome.

Recommendations for Management: Ectopic Ureters

Single System: Minimal or Nonfunctioning Kidney

Most kidneys (90%) that accompany single-system ectopic ureters do not function appreciably. Nephrectomy is the treatment of choice. In some cases, the question of renal salvage is raised by the appearance of marginal function on nuclear scintigraphy. *How much function is enough to warrant ureteral reconstruction rather than ablation of its associated kidney?* Nephrectomy is indicated when the creatinine clearance provided by the affected kidney, if it were isolated, would not eliminate the need for dialysis. Using percent function as a cutoff, like the commonly cited standard of 10%–15%, may have little meaning, especially if the contralateral kidney exhibits impaired function. In addition, kidneys that function marginally in infancy sometimes assume a progressively smaller portion of overall renal function with interval growth of the affected child, even in the absence of obstruction or infection. An intrinsic developmental insult and/or the rules governing renal hypertrophy, where healthy kidneys do not relinquish the additional renal function they are asked to assume, can be implicated when this occurs.

One area of controversy for some ectopic ureters involves the *management of the lower ureteral segment. In cases of Wolffian or GYN-ectopy, where an element of obstruction is the rule, the lower ureter need not be removed.* Once decompressed, ascending infections of these dry, isolated segments are uncommon and the need for secondary ureterectomies after subtotal ureterectomy is rare. The obstructed ureters found with GU-ectopy typically enter the bladder neck or urethra. These can also

FIGURE 40.29 Reflux into the ureterocele and upper-pole system of the left kidney.

remain, although a small number will predispose to recurrent urinary infections that ultimately necessitate their removal. It may be that such systems begin to reflux after the outflow of urine ceases from above (see the "Voiding Cystourethrography" section above).

Refluxing lower ureters have typically been removed in concert with nephrectomy. An extravesical approach through a second lower transverse muscle-splitting (Gibson) incision adds little additional morbidity. However, the necessity for a simultaneous approach for these variants has been questioned. In a study by Plaire et al.,[89] secondary surgery for removal of the distal ureter was required in only 4 of 38 such patients. Subsequent series have drawn similar conclusions. Long ureteric stumps or those in patients with dysfunctional voiding and incomplete bladder emptying appear to pose the most risk.[90] In cases where a ureteral stump is left, be it refluxing or obstructed, it should be taken as distal as possible and ligated with absorbable sutures, and urine should be aspirated from its distal end before closure. Urinary fistulas have occurred when presumably obstructed ureteral stumps have been left open and unappreciated reflux commences.

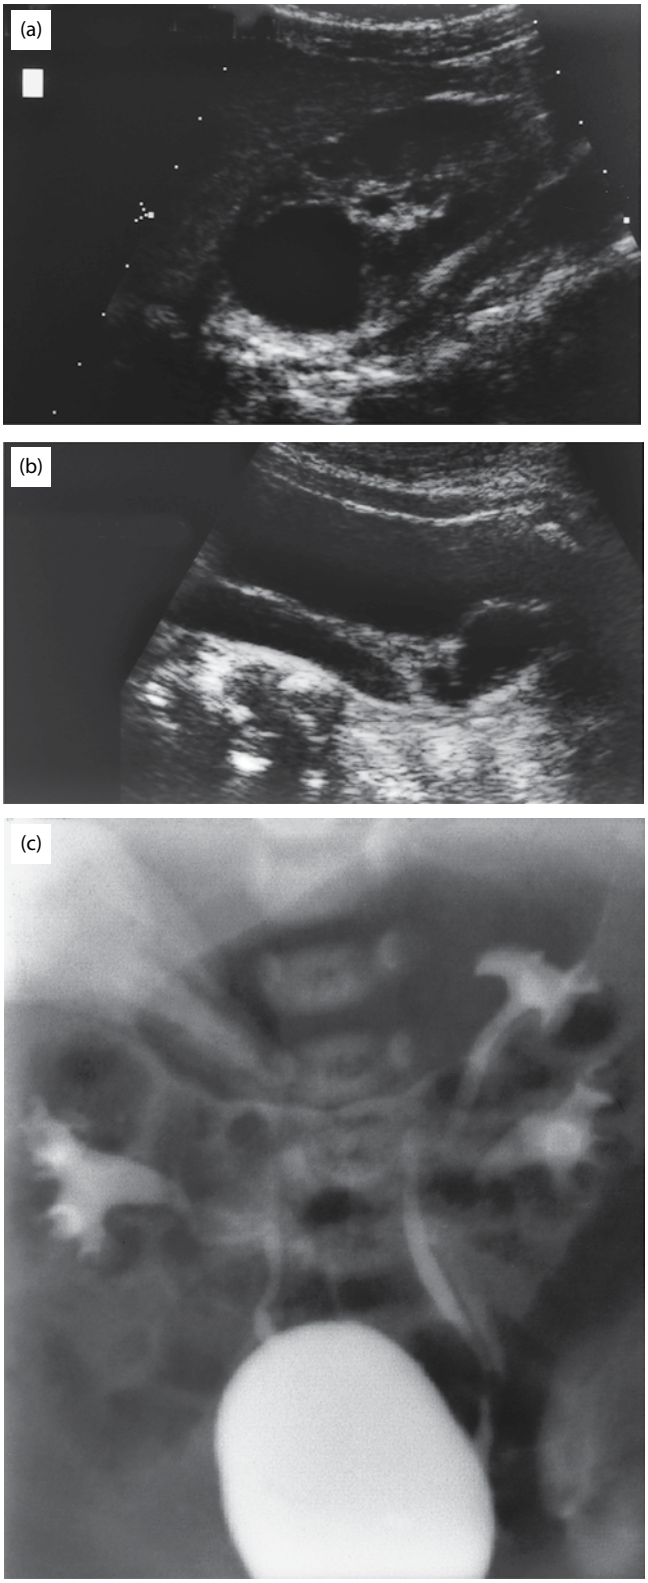

FIGURE 40.30 VUR associated with ectopic ureter to the urethra. (a) Duplex right kidney with hydronephrotic upper pole. (b) An ectopic ureter behind the bladder could be confused with a ureterocele. (c) A voiding cystourethrogram shows reflux into duplicated ureters on the left and the lower pole on the right.

(b) Poorly functioning upper right segment and functionless upper left segment. (c) Functionless upper right segment and displacement of the lower segment. (d) Reflux into the displaced lower-pole segment of the left kidney. (e) Functionless upper left segment simulating tumor in the upper pole.

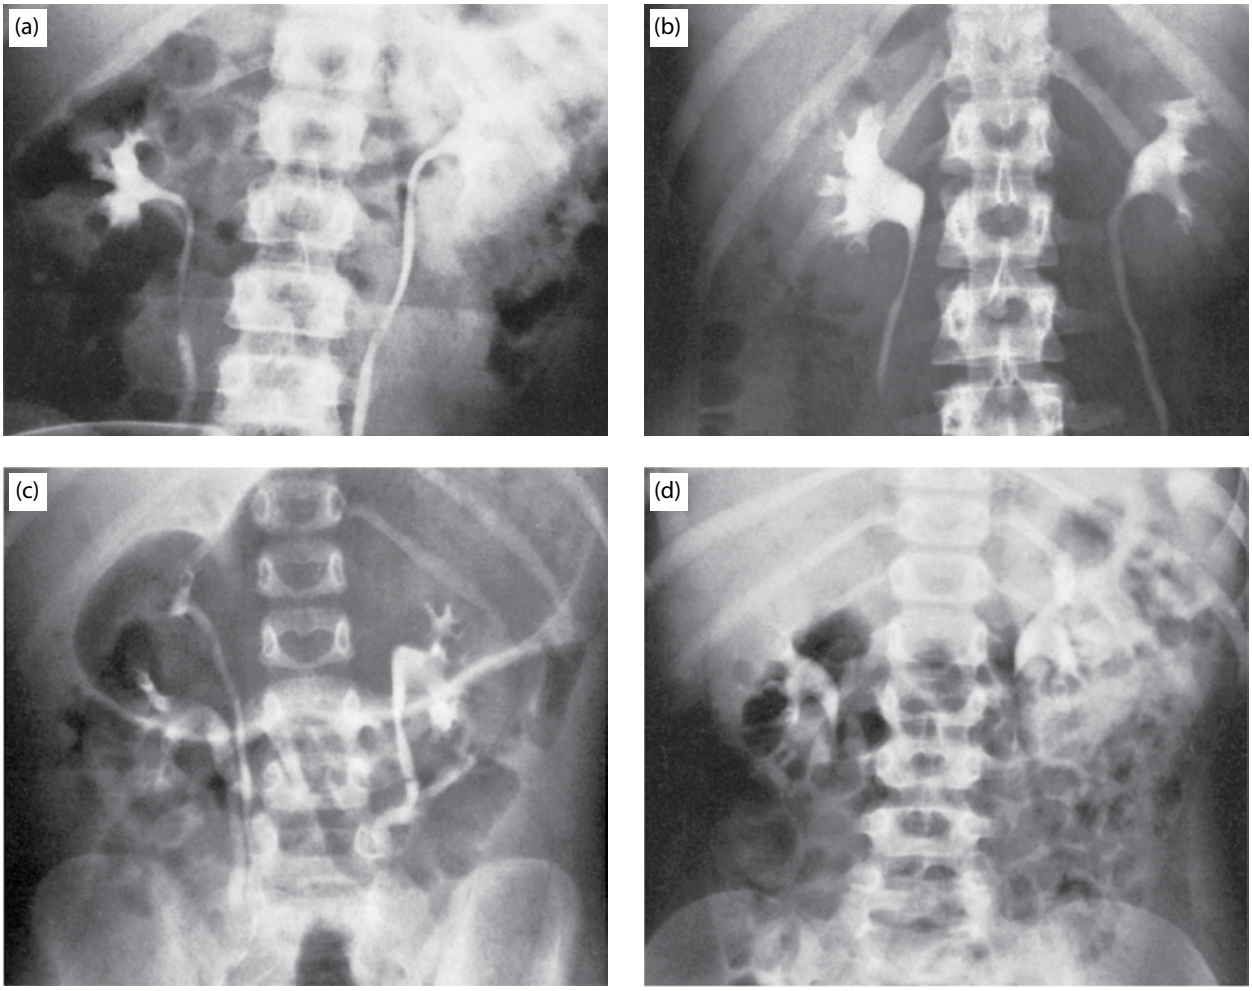

FIGURE 40.32 Appearance of lower-pole pelvis when the upper pole is functionless and nondilated. (a) Functionless upper right segment. The calyceal system of the lower segment is smaller but relatively normal. (b) Functionless upper pole on left with decreased number of calyces of the lower segment. (c) Functionless upper left segment with apparent increase in renal substance of the upper pole. The presence of a duplication of the contralateral kidney is often a key to diagnosis. (d) Functionless upper right segment with apparent increase in renal thickness on the medial side of the upper pole.

Duplex System: Minimal or Nonfunctioning Upper Pole

Partial nephrectomy is recommended for the affected upper pole.[91] The case made for salvage is similar to that in singlets and depends on relative function. Developmentally, the upper "half" of a *normal* duplex kidney typically contributes only one-third of that kidney's glomeruli, or, at most, 16% of overall renal function. The lack of an optimal inductive influence during fetal development, combined with an element of obstruction, significantly reduces the contribution of most upper-pole moieties drained by ectopic ureters. As in single systems, a subtotal ureterectomy is usually sufficient, taking the ectopic ureter as far distal as possible through a flank incision. When there is reflux into the upper pole and concerns about the ureteral stump persist, it can be removed through a second incision. However, as with single systems, most residual ureteral stumps do not present later problems.[92]

Single System: Salvageable Function

Reimplantation of the affected ureter is the treatment of choice. It helps to initially identify the ureter outside the bladder, especially when the insertion of the ectopic meatus cannot be localized cystoscopically. Once the ureter is mobilized, a transvesical or extravesical approach to ureteroneocystostomy can be successfully applied. The distal-most segment that enters the bladder neck or urethra can be disregarded with these and other ectopic ureters. The tedious dissection required of their removal risks damaging the urinary sphincter complex. Ureteral tailoring is often necessary and can be done using any one of a variety of techniques (see Chapter 39 on megaureters).

Duplex System: Salvageable Function

In cases where the upper pole is obstructed, yet provides salvageable function, its ureter can be anastomosed to the adjacent lower-pole renal pelvis (ureteropyelostomy) or ureter (ureteroureterostomy). The lower ureteral segment can be mobilized to the pelvic brim and excised, and the remainder left alone. Concerns about discrepancy in size between the ectopic and recipient ureter are usually unfounded.[93] The long-term efficacy of this approach is

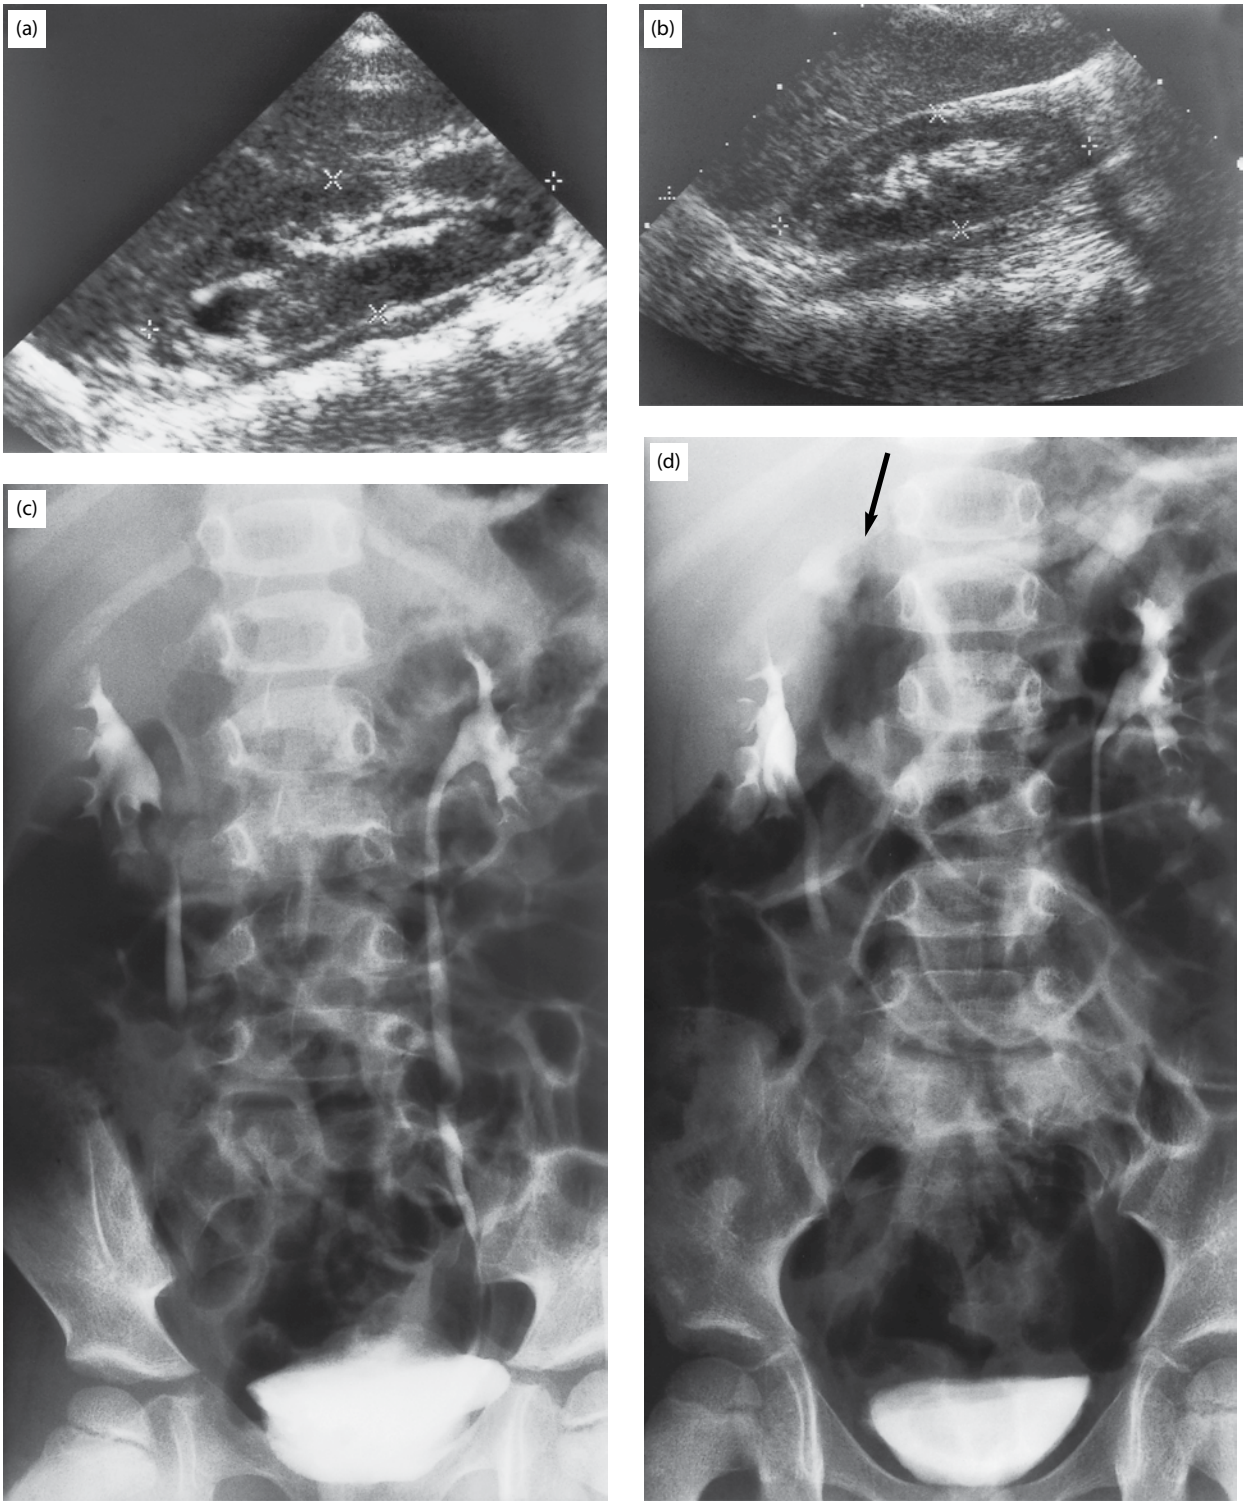

FIGURE 40.33 Utility of EU. Studies in a 13-year-old girl with continuous wetting were strongly suggestive of ectopic ureter. Sonograms for the past 7 years read as normal. (a) Initial ultrasound at 6 years old suggests mild upper-pole dilatation. (b) Current ultrasound is essentially unremarkable. Retrieval and review of early excretory urogram confirms the clinical impression. (c) Note the deviated axis of the right kidney and ureteral displacement on early sequence of the excretory urogram. (d) A later film shows delayed uptake of contrast in the upper pole.

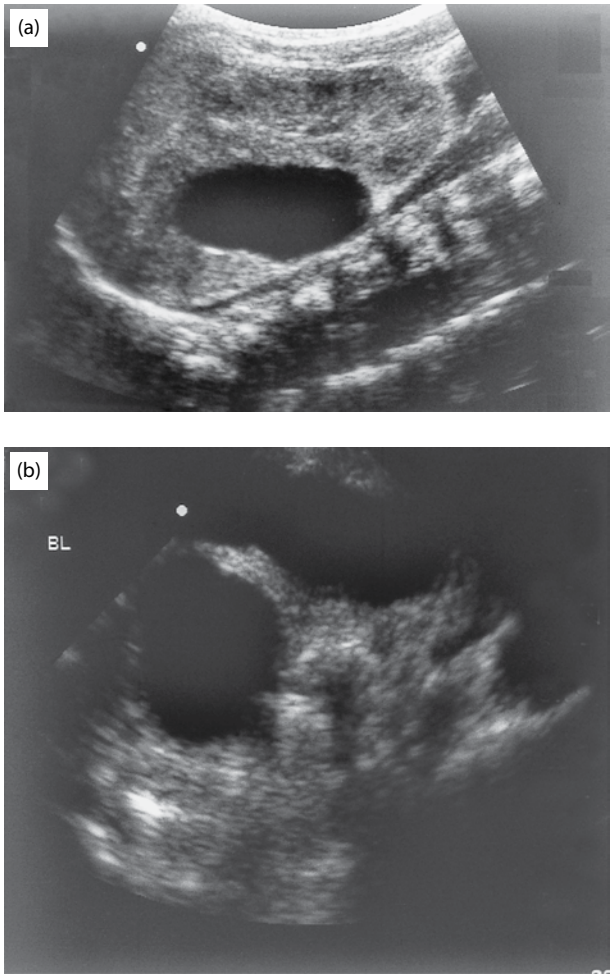

FIGURE 40.34 Infant boy with UTI. The role of EU. (a) Ultrasonogram initially felt to represent single-system hydronephrotic right kidney. (b) A pelvic sonogram demonstrates a markedly dilated ureter behind the bladder. (c) EU shows the displaced lower pole of the right kidney.

TABLE 40.4 Excretory urography

Findings suggesting occult duplex kidney with ectopic ureter

1. *"Drooping lily sign"*—Inferior and lateral displacement of lower pole by minimally/nonfunctioning upper pole. Delayed films may show function, although most are "silent." Axes of the kidneys should normally cross the body of the 10th thoracic vertebrae.
2. *Lateral displacement of lower-pole ureter*—Compared with contralateral ureter, differences in the distance from an adjacent vertebral pedicle.
3. "Missing calyx"—Incomplete complement of calyces with absence of system draining upper pole. A shortened or cutoff infundibulum to the upper-pole calyx, which is normally the longest.
4. More upper-pole parenchyma than expected with increased renal length.
5. Duplex kidney on the contralateral side.
6. Dilated, ectopic ureter appreciated on postvoid film.

documented.[94] These operations are usually no more challenging than the dismembered pyeloplasties required of infants with ureteropelvic junction obstructions. Rates of success should be similar. When technical concerns persist or if the upper-pole moiety exhibits signs of cystic dysplasia, a partial nephrectomy is recommended. Visualization of the upper-pole moiety in assessment of dysplasia is one advantage of this approach. Renal-sparing surgeries could probably be utilized more frequently in this setting. In one study, normal histology was found in 57% of upper-pole partial nephrectomy specimens removed from ectopic ureters.[91]

Another option for obstructed systems is to approach the duplication from below. *When reflux is present in one or both ureters*, a common sheath ureteral reimplantation is the preferred method of treatment.[95] The repair can be technically challenging, especially in smaller infants. Tailoring of the upper-pole ureter

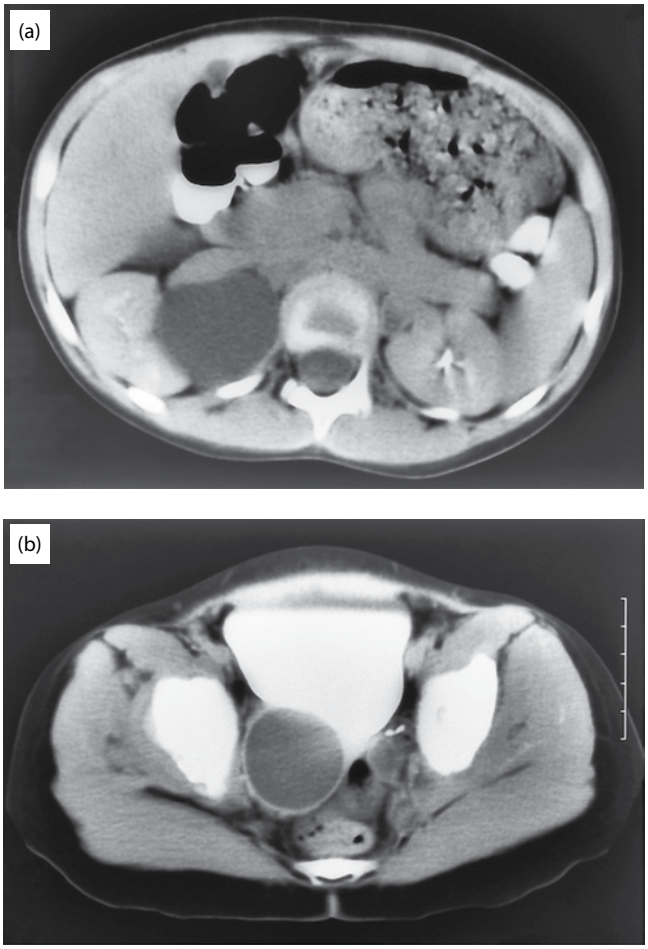

FIGURE 40.35 CT in a female toddler with abdominal pain and palpable mass. (a) Markedly dilated ureter displacing the right kidney associated with duplication. (b) The ureter is shown behind the bladder.

usually becomes necessary to achieve the desired length–diameter ratio required of successful ureteroneocystostomy. Revisions are made along the length of the ureter opposite the common wall, where vascularity is shared by the duplication. Where folding techniques result in excessive bulk with larger ureters, excisional tapering is preferred.[96] A psoas hitch is sometimes necessary to gain additional length for the reimplantation. Another option for duplications with an obstructed upper-pole ureter and refluxing lower-pole ureter is to perform a proximal diversion of the upper ureter (ureteropyleostomy), discard its remainder, and reimplant the lower-pole ureter alone. Although two incisions are required of this approach, it avoids the technical challenge that accompanies ureteroneocystotomy of duplex ureters, where one or both may be dilated.

Recommendations for Management: Ureteroceles

Single System: Minimal or Nonfunctioning Kidney

Nephrectomy is the treatment of choice. Ordinarily, the ureterocele remains collapsed after aspiration and any element of obstruction to the bladder neck or contralateral ureter resolves (Figure 40.37). The latter may unmask reflux into the contralateral, now solitary, kidney. With larger ureteroceles, a significant reservoir for lower UTIs remains, despite their decompression. Although not well defined in the literature, some of these eventually require secondary surgery for their removal. Cystoscopic evidence of the open orifice typically accompanying sphincteric or cecoureteroceles will identify those variants particularly at risk for future problems, especially in females. When this is the case, simultaneous excision of the ureterocele with bladder reconstruction is reasonable, if the age of the patient permits. Otherwise, the patient can be followed medically after nephrectomy and repair of the bladder deferred to a later age, if indicated.

Whether antenatal diagnosis alters the long-term implications of such anomalies is unclear. A nonoperative approach has been taken in a small group of infants whose ureteroceles subtended multicystic dysplastic kidneys. In limited follow-up, the ureterocele collapsed or remained stable in each case, whereas ipsilateral kidneys uniformly involuted. None required surgery.[18]

Selective cystoscopic puncture should probably not be considered for obstructed ureteroceles associated with a nonfunctioning kidney. This risks converting the anomaly from one that can be potentially addressed solely from above to one requiring another incision to correct a refluxing ureterocele. Nonselective cystoscopic "unroofing," as advocated by Tank,[97] remains an option for decompressing obstructed ureteroceles in children who are extremely ill and unable to tolerate open surgery. Interestingly, 50% of renal moieties that showed no function on EU subsequently demonstrated excretion of contrast after their decompression. These data suggest that some kidneys may recover function after being vented, but more likely point to the shortcomings of EU compared with radionuclide studies in infants with obstructed kidneys. Reflux is an expected sequela of this predecessor of selective puncture.[98] Decompression can also be achieved with percutaneous drainage, which can serve to temporize until the ureterocele can be definitively addressed.[99]

Single System: Functioning Kidney

The experience with *selective incisions or puncture* of these ureterocele variants has been encouraging enough that it should be considered the procedure of choice, when obstruction warrants (Figure 40.38).[72,100] In one series, for example, endoscopic decompression was successful in 22 of 25 patients (88%) with single-system intravesical ureteroceles.[101] Reflux tends to appear in larger ureteroceles whose associated detrusor defects result in very little backing to the anomaly. Ureterocele excision, ureteral reimplantation, and correction of any detrusor defects may become necessary when reflux appears, although a trial of medical management, similar to that used with primary VUR, is reasonable, especially in younger children, providing infection can be avoided.

Duplex System: Minimal or Nonfunctioning Upper Pole

An upper-pole partial nephrectomy is a very reasonable option but might not finalize the problem (Figures 40.39

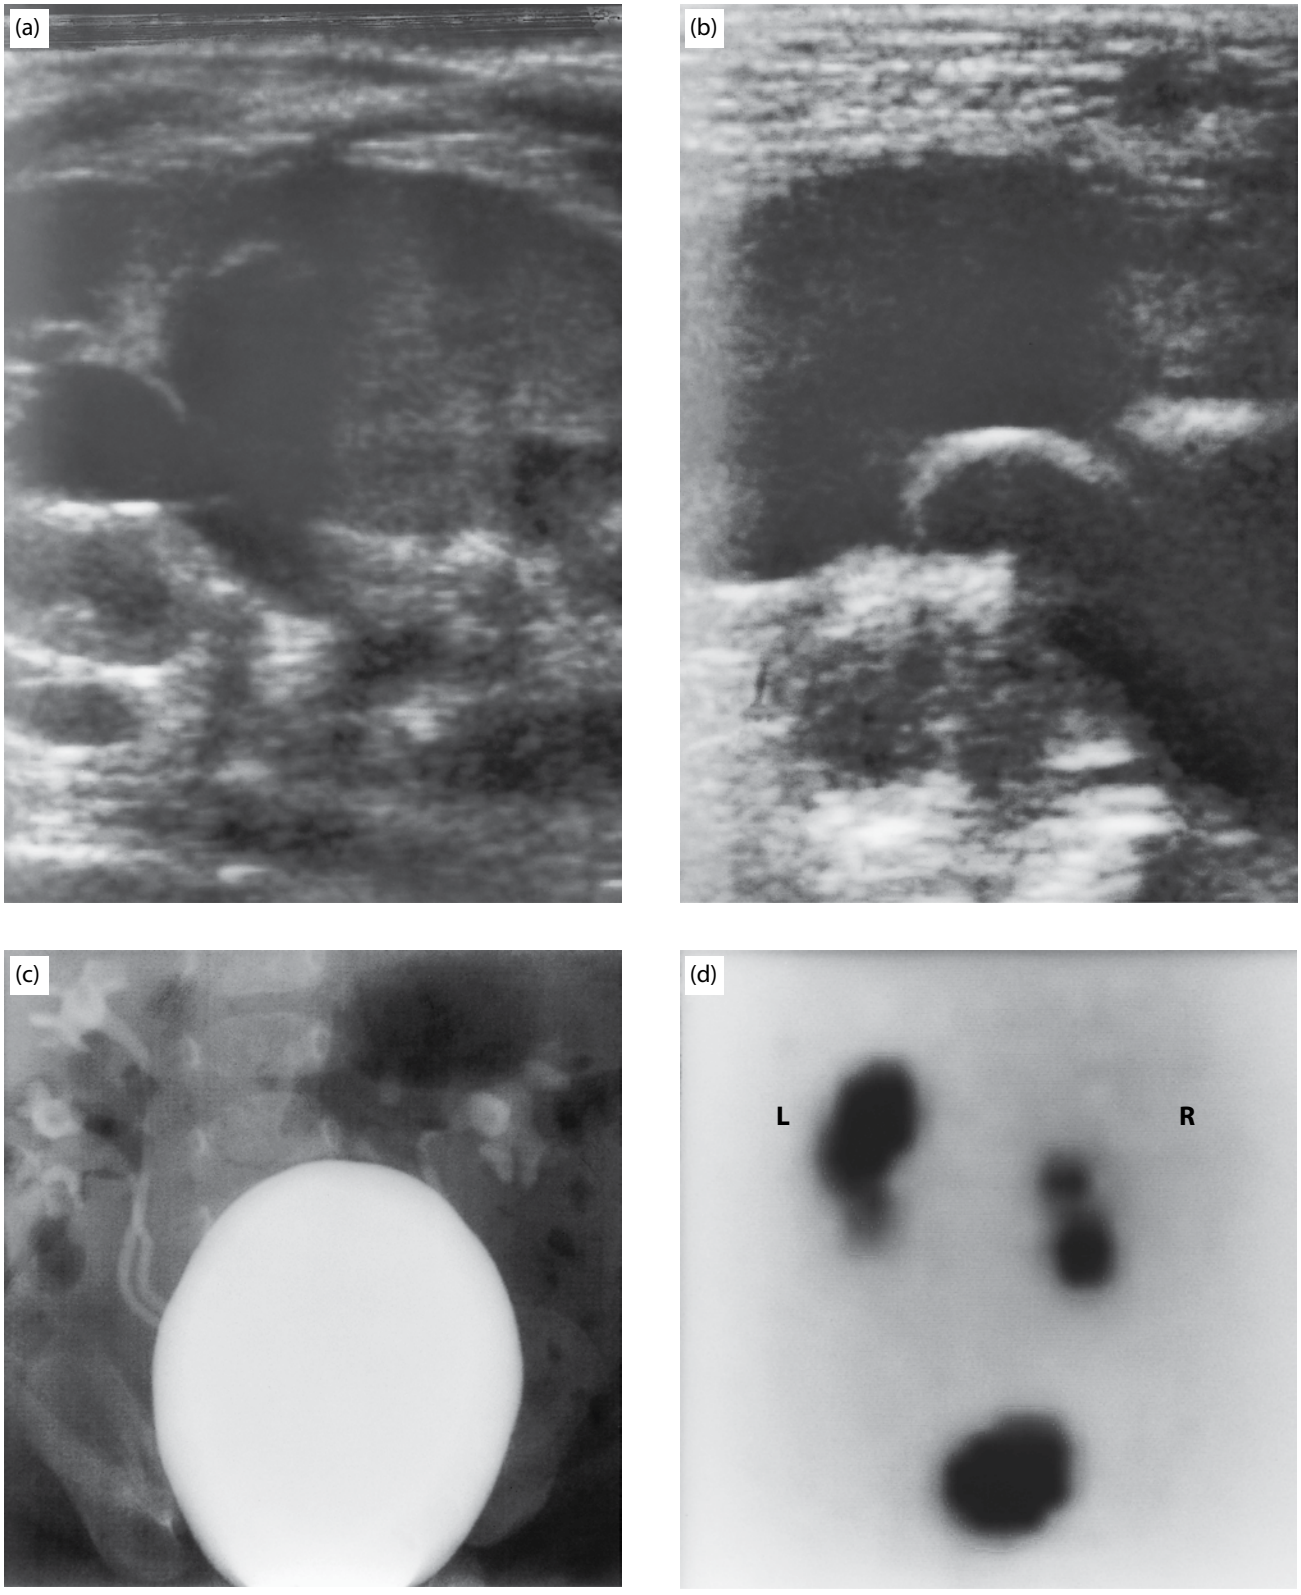

FIGURE 40.36 Antenatally diagnosed ureterocele in a newborn girl. (a) The sonogram shows a dilated upper-pole segment of the duplex left kidney. (b) Pelvic view of the ureterocele projecting within the bladder. (c) A cystogram demonstrates reflux into the contralateral duplex ureters and lower-pole ureter on the left. (d) A renal scan shows preservation of function and hydronephrosis of the left upper-pole moiety.

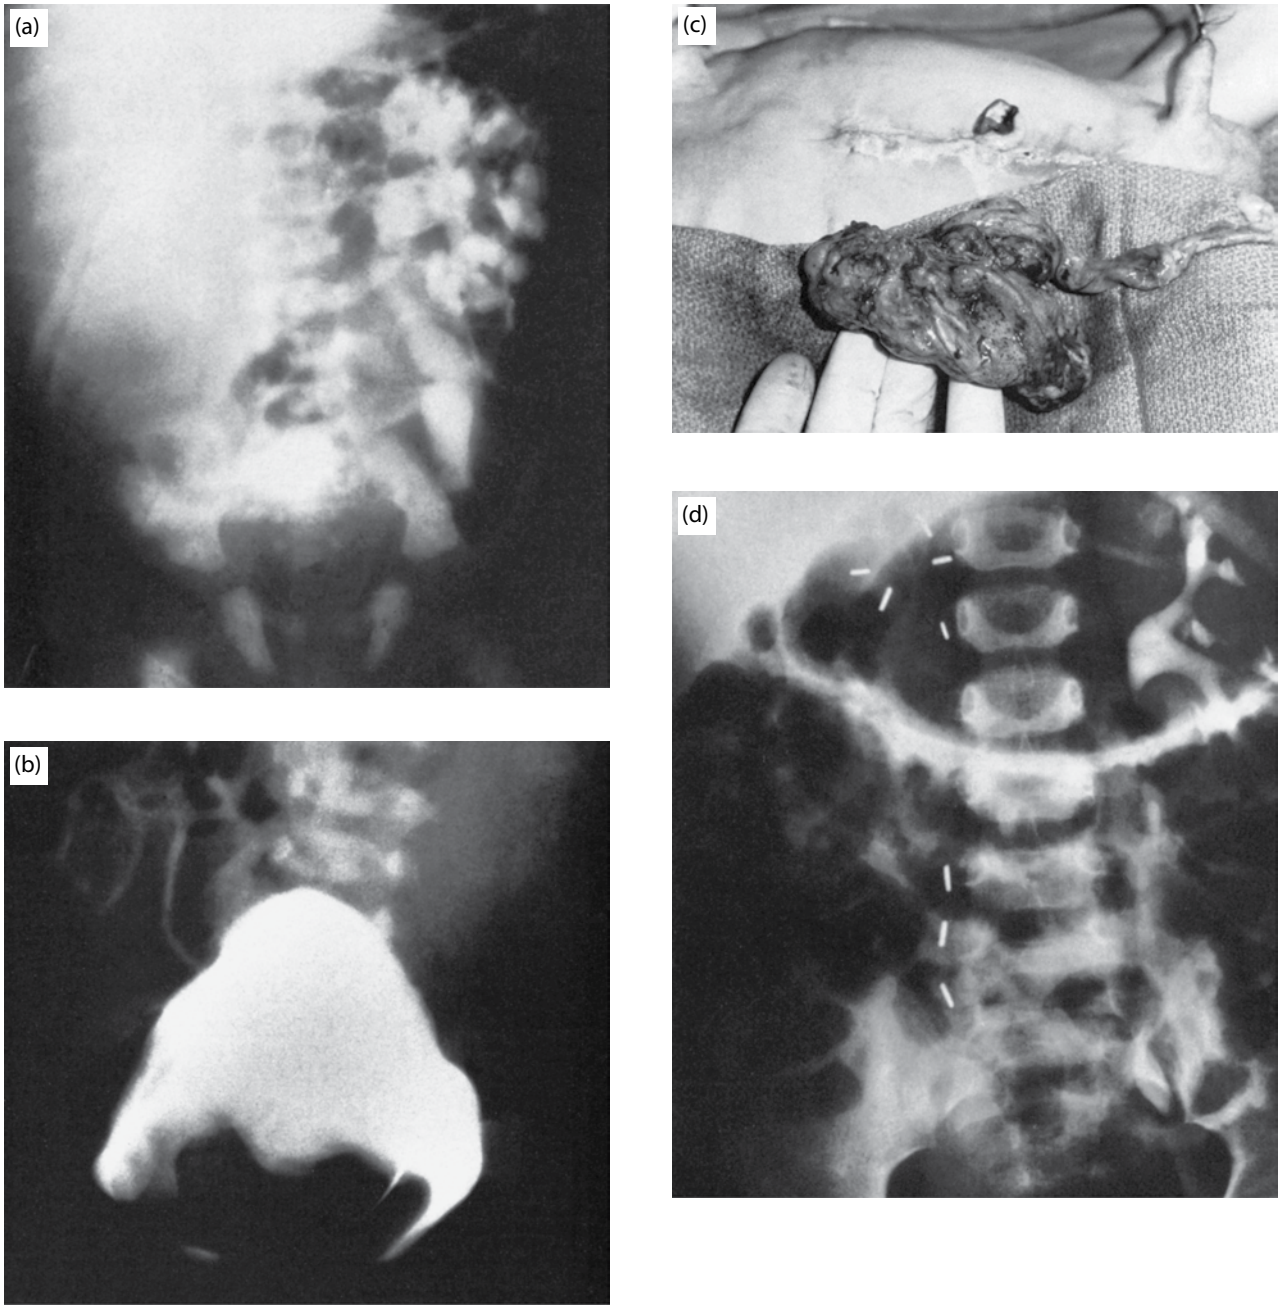

FIGURE 40.37 Newborn male with large single-system ureterocele of the right side. (a) An excretory urogram shows poor visualization of the right collecting system and hydronephrosis of the left. (b) A cystogram shows a large ureterocele filling the bladder and extending through the bladder neck. (c) At surgery, the grossly dyplastic hydronephrotic kidney was removed and extravesical dissection of the ureterocele was completed. (d) A postoperative excretory urogram shows significant improvement of the left-sided hydronephrosis and collapse of the ureterocele.

and 40.40). This *upper tract approach* usually effectively decompresses the ureterocele, potentially restores trigonal anatomy, and may be the only treatment needed for some patients.[102,103] In the series reported by Caldamone et al.,[15] 7 of 36 patients (19%) ultimately required secondary procedures for persistent reflux (3 patients) or bladder outlet obstruction (4 patients). VUR appeared in 10 cases after decompression, where none was present beforehand. The reflux resolved in three patients. Long-term outcomes into adulthood are unavailable in the literature. Other clinicians report similar rates (about 20%) of persistent reflux into ipsilateral lower-pole or contralateral ureters after partial nephrectomy alone.[42,104] In another series of 19 patients reported by Scherz et al.,[105] 9 patients (47%) required secondary intravesical surgery for UTI or VUR (Figure 40.41).

These types of outcomes led some clinicians to advocate a *combined "up-and-down" approach* where heminephrectomy, ureterocele excision, and ureteral reimplantation are completed in a single surgery.[44,106] The need

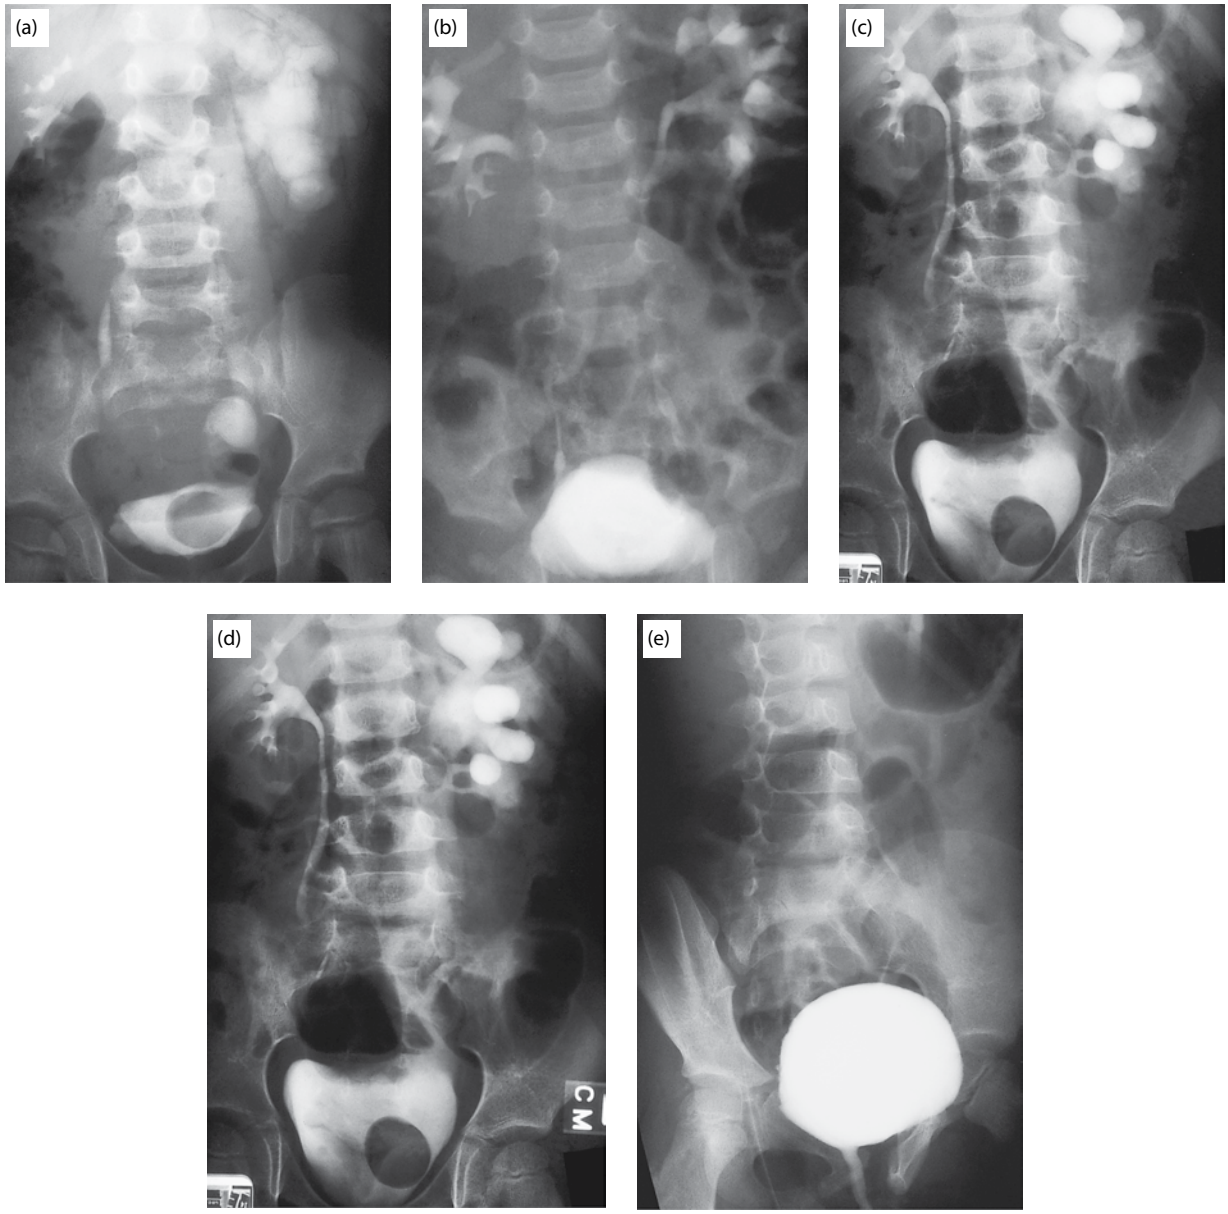

FIGURE 40.38 (a) Single-system intravesical ureterocele causing significant hydroureteronephrosis of the left collecting system. (b) After incision, marked improvement in the degree of dilatation is seen. No reflux was present before or after surgery. (c) A similar variant with hydronephrosis of the left kidney treated with selective incision. (d) Significant improvement shown after surgery. (e) The voiding cystourethrogram is unremarkable.

for secondary surgeries is far less common with the combined approach. For example, only 14% of patients in the Scherz series[105] required reoperations for persistent reflux after the combined approach. To its detriment, ureterocele excision and duplex ureteral reimplantation can present a technical tour-de-force in infants and small children. In addition, intravesical repairs are unnecessary in perhaps half of these patients. The characteristics of ureteroceles that ultimately require excision and bladder reconstruction remain to be fully defined. Such selection criteria would help identify patients whose problem would be best finalized by the upper tract approach and limit the combined approach for those that truly need it.

The review by Husmann et al.,[107] which assessed response to treatment based on renal unit jeopardy, offered insight in this regard. Of 87 patients with a ureterocele and nonfunctioning upper pole treated by heminephrectomy, subtotal ureterectomy, and observation (initial upper tract–alone approach), 54 (62%) required additional surgery to correct reflux. Notably, the need for additional surgery was directly related to the number of renal moieties that had VUR present. When ureterocele alone was present, 21 of 21 patients required no further surgery. If low-grade reflux (less than III/V) was present in only one ureter, 8 of 15 patients (53%) did well with the upper tract–alone approach. Finally, and most significantly,

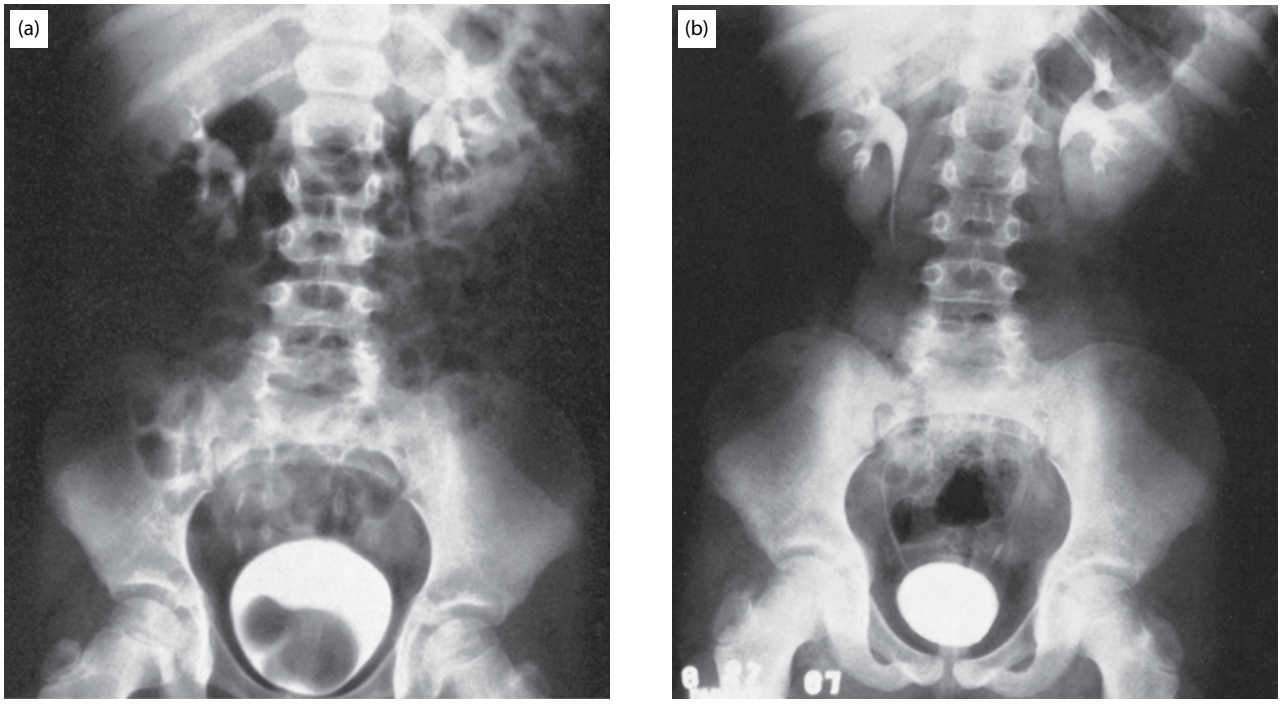

FIGURE 40.39 (a) A preoperative view shows minimally functioning upper-pole moiety of the right kidney. (b) A postoperative view shows decompression of the ureterocele and an essentially normal right kidney.

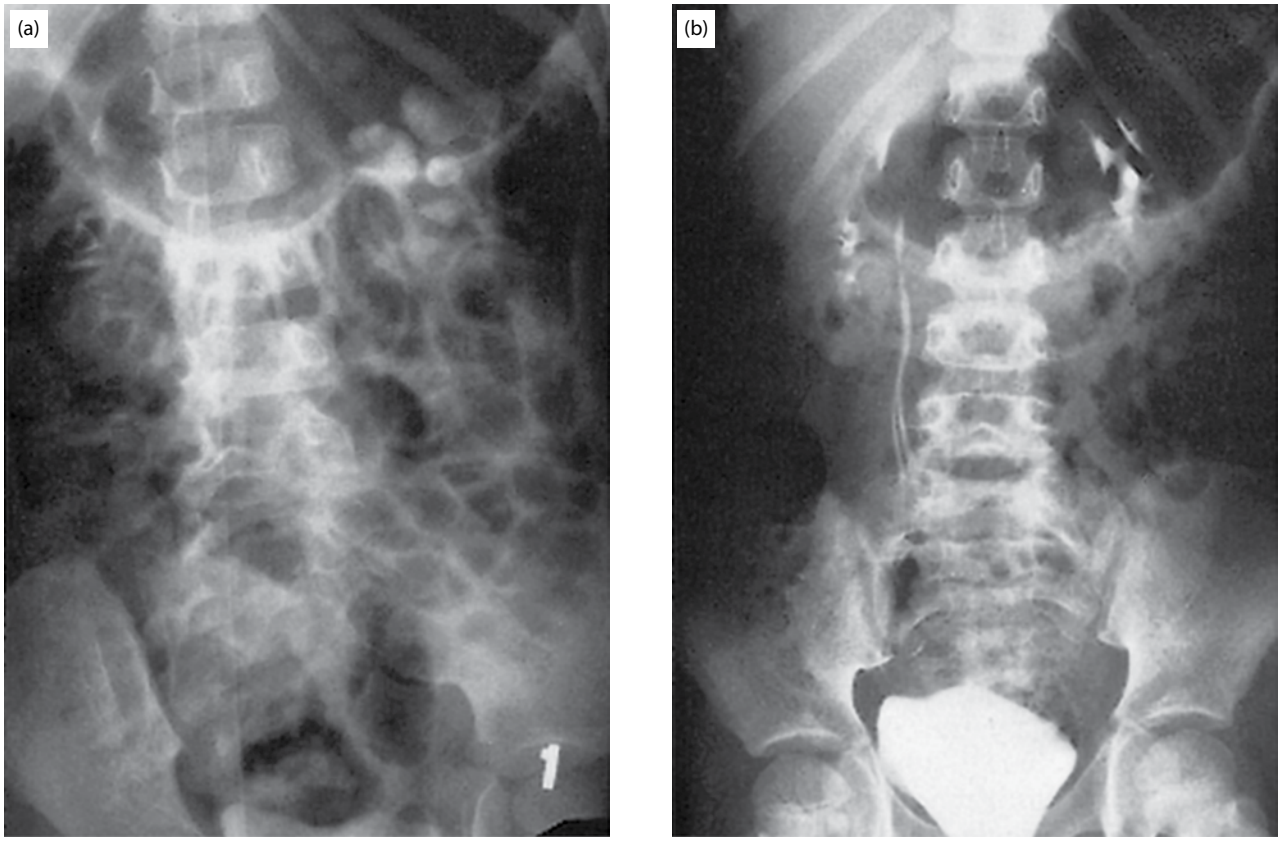

FIGURE 40.40 Extravesical ureterocele treated by heminephrectomy and subtotal ureterectomy. (a) A preoperative excretory urogram shows a left-sided anomaly and markedly hydronephrotic lower pole. (b) Postoperative view. Preservation of the function and appearance of the remaining kidney is often surprisingly good. The ureterocele is fully decompressed.

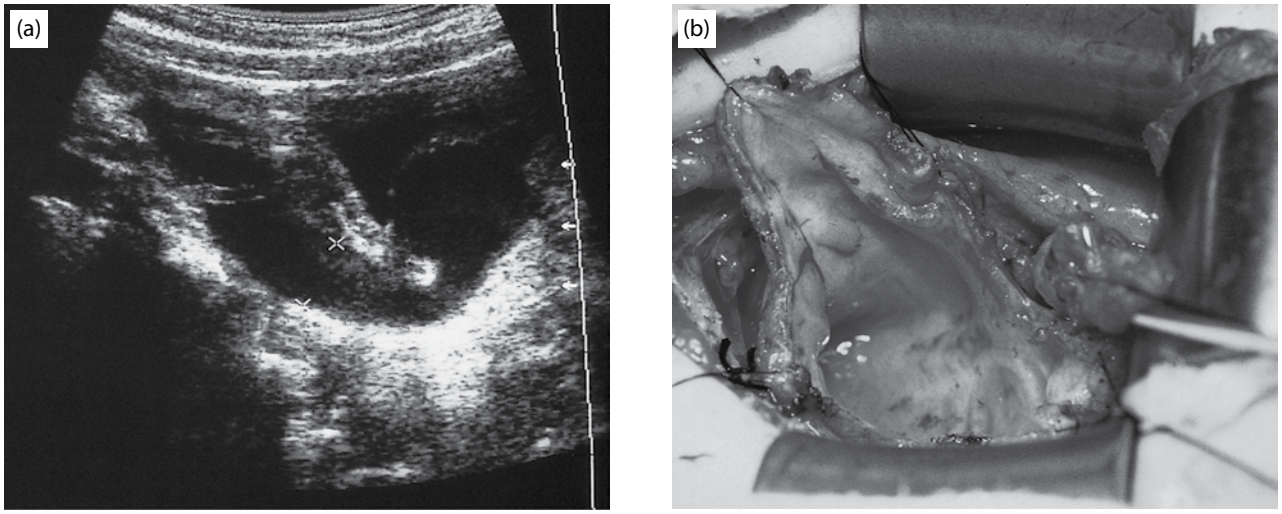

FIGURE 40.41 (a) The stump of the residual ureter and ureterocele remain after heminephrectomy. The patient presented with recurrent urinary infections. (b) Large ureterocele opened at surgery.

when high-grade reflux was seen in one ureter or reflux was associated with more than one moiety, regardless of grade, surgery became inevitable for 48 of 50 (96%) patients. A subsequent review by DeFoor et al.[108] echoed similar findings. Simply put, ureteroceles whose bladder involvement affects other renal segments are more likely to require secondary surgery. Ureterocele prolapse is another finding that inevitably portends bladder reconstruction.[109] In addition, the occasional ureterocele that itself refluxes at presentation will, by default, require a combined up-and-down approach for management.

Given these data, families and patients can be better informed as to the likelihood of needing lower urinary tract surgery if an upper tract approach is initially used. In addition, strong consideration is given to a complete urinary tract reconstruction if the preoperative workup returns such ominous prognosticators and the patient's size permits. Finally, nonselectively unroofing the ureterocele becomes a very real option in newborns and small infants who are destined to require up-and-down surgery anyways, if the "clinical staging" of their anomaly is strongly suggestive. Eliminating obstruction significantly lessens the threat of urinary infections, and decompression of the ureterocele simplifies the bladder repair (Figure 40.42).[166]

Most children can be effectively managed with antibiotic prophylaxis until they are old enough to have definitive reconstructive surgery. However, infections can still occur. In one series of 15 neonates with ureteroceles, 8 developed infections during the first few days of life, including 3 who were receiving prophylactic antibiotics.[110] Assessment, with considerations to surgery, should be done at an early age to optimize the care given to children whose anomalies have been discovered antenatally.[111] The advantage of prenatal detection is demonstrated by one retrospective study comparing the occurrence of UTIs in 95 children with ureteroceles in duplex systems. UTIs occurred much less frequently with antenatal detection (12% vs. 84%) both before and after (15% vs. 27%) surgery.[112] Secondary procedures were also less common (20% vs. 46%).

The report by Gran et al.[113] offers a unique alternative in management. The *lower tract–alone approach* eliminates the long-term follow-up required of residual ureteroceles that remain after the upper tract–alone approach. Rather than remove the nonfunctioning renal moiety, sole reconstruction of the involved ureters and the bladder was successfully completed in 16 patients. No morbidity (mean 5 years' follow-up) has been associated with the nonfunctioning portions of the kidney that remain. Detractors, concerned with the preservation of possibly dysplastic tissue, will argue that families are now offered extended follow-up of such kidneys in exchange for that of the bladder. However, if parallels are drawn with the relative benefits of removing asymptomatic multicystic dysplastic kidneys, the argument may ultimately prove to be a weak one. Future management may see many children with ureteroceles initially punctured and decompressed during the newborn period until they are old enough for bladder reconstruction, if reflux persists or appears, regardless of the status of their kidneys.

Finally, and to further cloud the recommendations in management, an expectant "observation-alone" approach has been used with success in some children with a nonfunctioning upper-pole moiety and low-grade lower-pole VUR. In a group of 52 such patients, whose anomalies were detected antenatally, 14 (27%) were managed expectantly and did well, with a median of 8 years of follow-up.[114] Each was kept on prophylactic antibiotics until the completion of toilet training, and none required surgery through a median follow-up of 8 years. Watchful waiting has also been used in children whose ureteroceles subtend functioning renal units. In most cases, dilatation and reflux both improved with time.[115] This appears to be especially true of ureteroceles that are not significantly obstructed, as shown by scintigraphy.[116] Patients whose ureteroceles subtend dysplastic moieties in duplications have also been followed conservatively.[18] The long-term

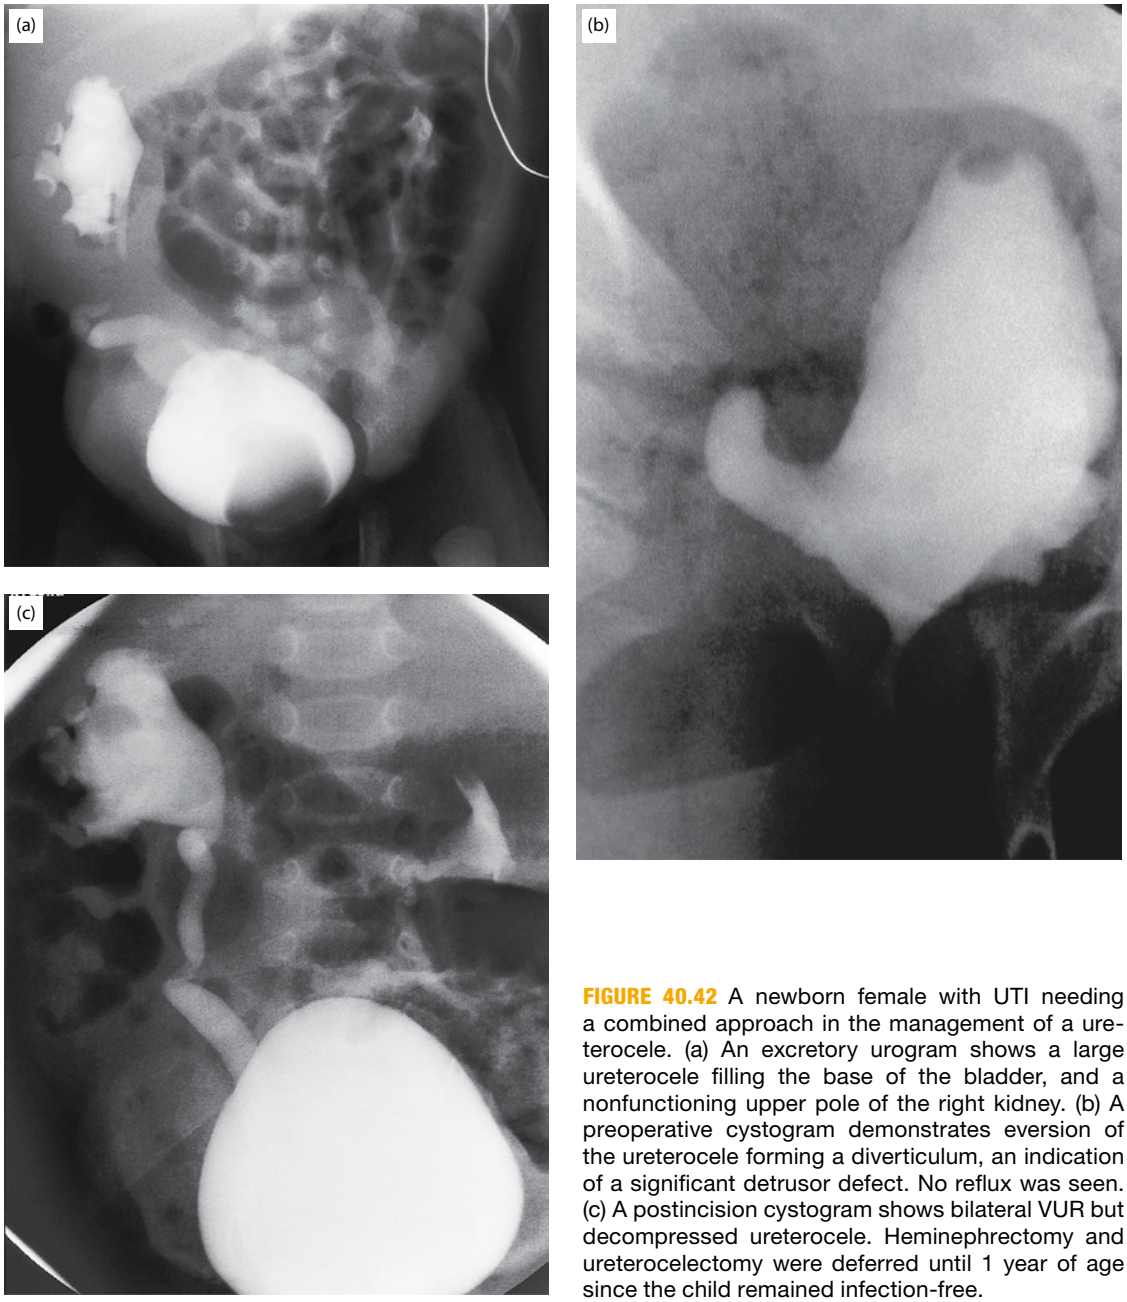

FIGURE 40.42 A newborn female with UTI needing a combined approach in the management of a ureterocele. (a) An excretory urogram shows a large ureterocele filling the base of the bladder, and a nonfunctioning upper pole of the right kidney. (b) A preoperative cystogram demonstrates eversion of the ureterocele forming a diverticulum, an indication of a significant detrusor defect. No reflux was seen. (c) A postincision cystogram shows bilateral VUR but decompressed ureterocele. Heminephrectomy and ureterocelectomy were deferred until 1 year of age since the child remained infection-free.

implications of these findings raise more questions than they answer. Affected children would appear to continue to be at risk for the morbidity seen before the advent of antenatal detection. However, prenatal detection appears to be rewriting the natural history of some ureteroceles, as it has with other congenital urinary anomalies.

Duplex System: Functioning Upper Pole

Like their nonfunctioning partners, these conditions too can be addressed with an upper tract–alone approach. It should be remembered that upper-pole duplications optimally contribute perhaps 16% of overall renal function. Because of this somewhat marginal contribution, some clinicians recommend partial nephrectomies for the majority of functioning duplications, whether they function or not. This avoids the potential complications of the reconstruction, risks to the lower pole, and the unknown long-term implications of upper-pole parenchymal salvage.[31] The other option is salvage of the upper pole by creating a diverting ureteropyelostomy or ureteroureterostomy in combination with a subtotal ureterectomy. A study similar to that cited above for nonfunctioning duplications treated with an upper tract approach has not been reported. Nevertheless, there is every reason to believe that the same risk factors for persistent reflux and recurrent urinary infections exist and result from the size and position of the ureterocele and its implications for the trigone and adjacent ureters. With this in mind, the upper tract approach is usually reserved for ureteroceles

presenting without reflux into the ipsilateral lower and contralateral ureters and should offer a high likelihood of success.

In patients whose variants have associated VUR, it seems reasonable to address the majority solely at the bladder level, removing the ureterocele and correcting the reflux, thus eliminating the need for secondary surgery. Such an approach is ideal for the older child whose bladder is large enough to allow a complex reconstruction with a high likelihood of success. The reality is, however, that the majority of ureteroceles are diagnosed antenatally. After birth, such babies remain at significant risk, as UTIs associated with obstruction are much more threatening to the child and kidney than those that occur with reflux alone. In addition, the affected kidney potentially incurs progressive damage because of distal ureteral obstruction. As a result, medical management with prophylactic antibiotics should be considered a short-term approach in management rather than an extended panacea. Such an approach may not allow a sufficient enough interval of time until the bladder can be safely reconstructed.

As an alternative, endoscopic treatment provides an effective option for many newborns and infants, particularly those who present with significant UTIs. Surgeons should hold realistic expectations for this approach, however, since it rarely provides the final solution for these types of ureteroceles, even with selective incision. The success of endoscopic decompression and the need for reoperation appear to be dependent on the location of the ureterocele.[117] Selective endoscopic decompression is definitive for 80%–90% of intravesical ureteroceles. In contrast, only 25%–30% of extravesical variants are effectively treated. For most patients with the latter then, the maneuver should be considered a temporizing measure used to vent the obstructed system. This increases the likelihood of success with medical management, thus allowing for additional growth of the child until a definitive bladder reconstruction can be completed (Figure 40.43). VUR persists or appears after decompression in the majority of cases. For example, in one series 18 of 21 (86%) patients with extravesical ureteroceles treated endoscopically required additional surgery. By contrast, the results with intravesical variants were strikingly different, with 14 of 16 children successfully treated with incision alone.[118] In a larger series reported by Husmann et al.,[101] the performance of selective incision was also discouraging. Ectopic ureteroceles preoperatively associated with reflux into one or more moieties required further surgery for persistent reflux in 37 of 44 (84%) cases. An identical reoperation rate occurred when partial nephrectomy was used for

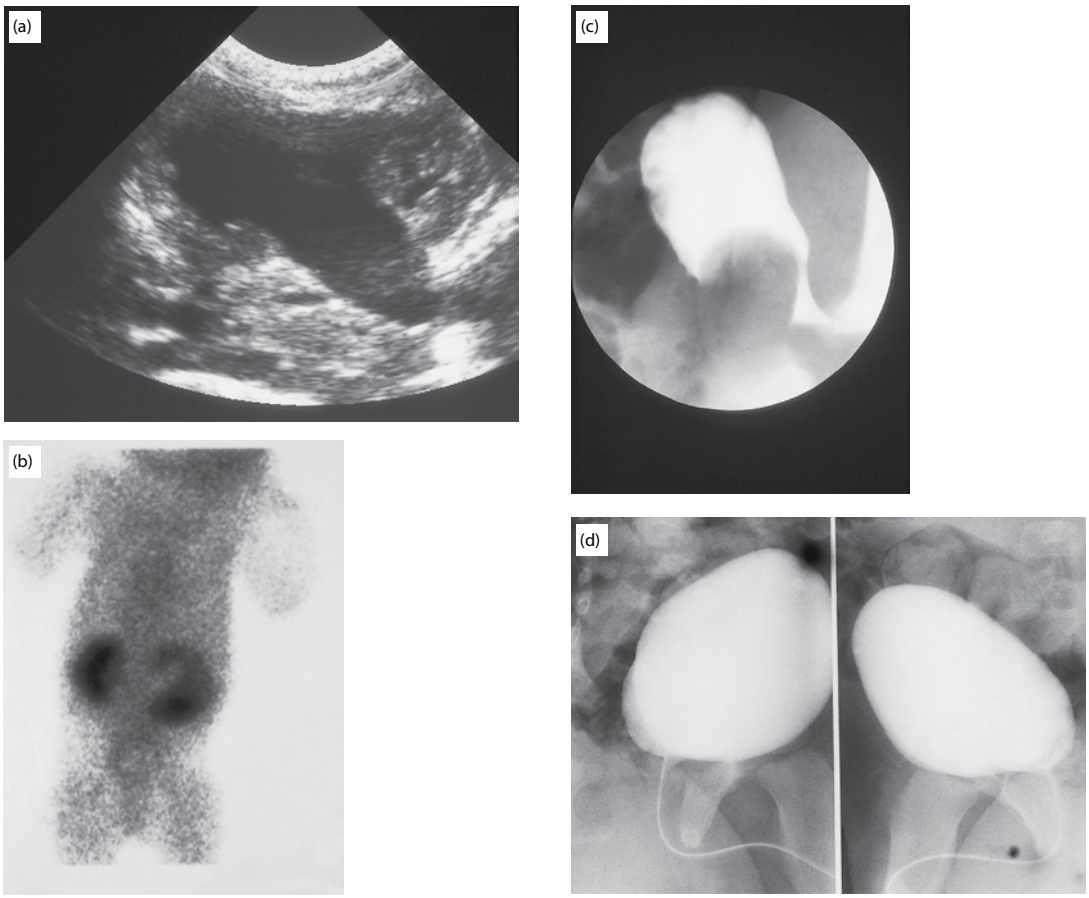

FIGURE 40.43 Selective incision of duplex-system ureterocele with salvagable upper-pole function. (a) Ultrasonic appearance in a newborn diagnosed antenatally. (b) A radionuclide scan shows function to the upper pole and filling defect within the bladder. (c) The bladder defect shown in the cystogram appears largely intravesical, which may have been a factor in success. (d) A postincision cystogram shows no evidence of reflux. Hydronephrosis had virtually resolved.

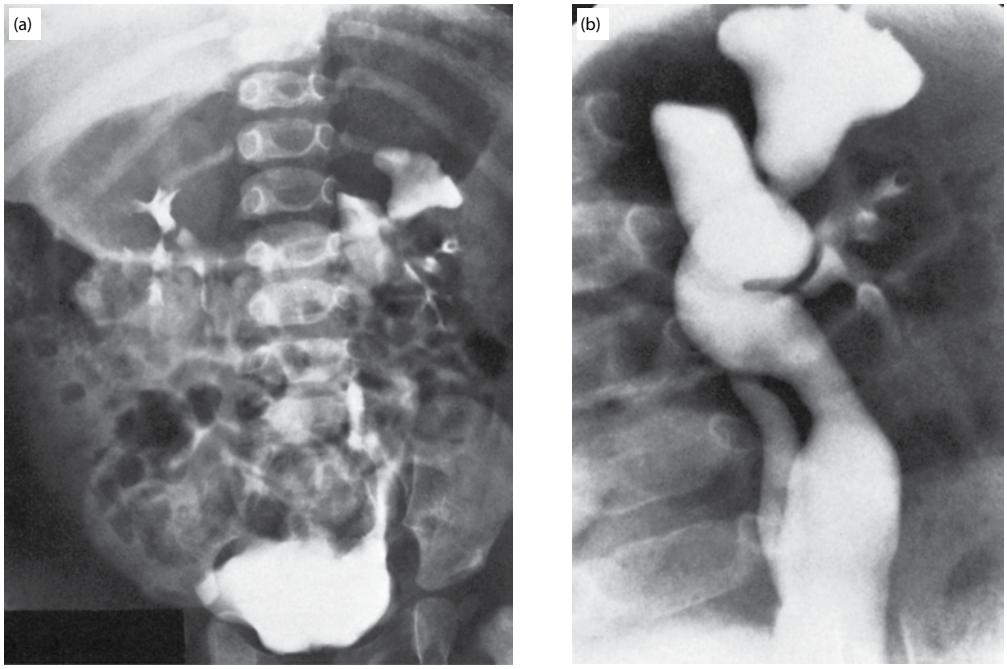

FIGURE 40.44 Risk of ureterocele incision. (a) Duplication of the left kidney associated with an extravesical ureterocele seen on EU. (b) After incision, the previously "obstructed" system converted to one that significantly refluxes into both ureters.

similar variants. In contrast, however, when VUR was not present prior to treatment, incision was more likely than partial nephrectomy to result in the appearance of reflux (64% vs. 15%). Based on this observation, it may be that diverting the ureterocele with a ureteropyelostomy or ureterostomy is the treatment of choice when a salvageable duplex system is not accompanied by reflux.

Whereas success rates with endoscopic incision vary, its weaker performance with extravesical and ectopic ureteroceles is repeatedly borne out in the literature[72,100,119,120] and is more likely a reflection of the anatomic and functional characteristics of the ureterocele and bladder rather than the technique used (Figures 40.44 and 40.45). An unpredictably variable response was offered by the retrospective series reported by Jesus et al.[121] of 50 patients with duplex-system ureteroceles. New-onset VUR occurred postoperatively in 24 patients (40%), mainly to the ipsilateral lower pole or contralateral kidney, findings felt to be unrelated to the puncture itself. Resolution or improvement of reflux occurred in 16 of 22 patients (72%) having prepuncture VUR.[121] Close surveillance is warranted after puncture, and a number of cases of postpuncture VUR will improve.

When VUR persists, the endoscopic injection of bulking agents has been shown to be effective in some cases.[122] Ureterocele puncture was completed in a large series of 109 children, 97 (89%) of which were part of a duplex system. VUR was seen in 85 units before puncture (lower-pole ipsilateral in 53, contralateral in 32). Reflux resolved in 36 (42%) of these. When significant VUR persisted, endoscopic injection therapy was successful for 31 of 44 (70%) units after a single injection and resolved after a second injection in 9 (21%) others. The long-term efficacy of an all-endoscopic approach is unclear, but the attractiveness of its minimally invasive nature is readily obvious.[123]

SURGICAL TECHNIQUES

Although many of these techniques are described elsewhere, observations of their application to the treatment of ectopic ureters and ureteroceles in children deserve comment.

Ureterocele Prolapse

The prolapsed ureterocele is not the surgical emergency once supposed. Manual reduction back into the bladder is sometimes possible, but because of the nature of the defect, it is likely to recur. Heminephrectomy to decompress the ureterocele is another option. However, because of the size of these defects, affected bladders will uniformly require secondary reconstructions as well. A simpler solution is to incise the ureterocele at the bedside with a disposable ophthalmic cautery unit. This technique is usually effective and serves the same purpose as cystoscopic incision. In occasional cases, the latter still becomes necessary to treat the intravesical portions of a prolapsing ureterocele that sometimes fail to decompress because of bladder neck obstruction.

Selective Cystoscopic Incision

The cystoscope is initially passed under vision to avoid traumatizing the ureterocele. For *intravesical variants*, a distally positioned puncture at the ureterocele's medial base is usually sufficient to decompress the structure yet preserve enough submucosal length to maintain the characteristics required of an effective flap valve to avoid reflux (Figures 40.46 and 40.47).[124] *Cecoureteroceles and sphincteric ureteroceles* can be unobstructed by vertically incising

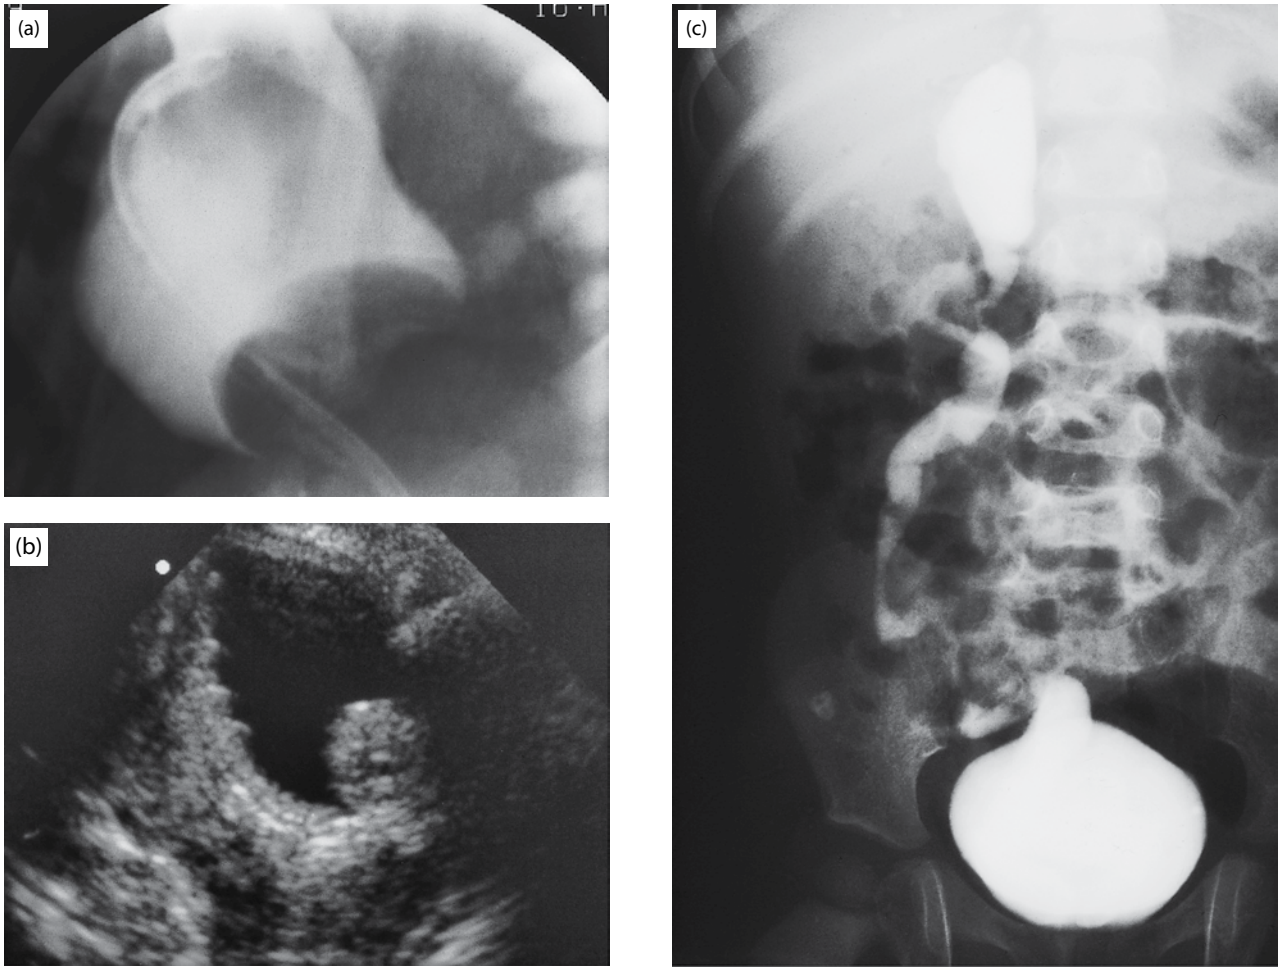

FIGURE 40.45 (a) Large extravesical ureterocele shown during cystography. Both poles functioned and no reflux was seen. (b) Successful decompression is seen by ultrasound, but (c) reflux into upper-pole moiety is documented on a postoperative cytogram.

the meatus and extending its opening above the bladder neck (Figure 40.48). Cutting current is applied across a No. 3 Fr bugbee electrode to provide a clean, full-thickness puncture of the ureterocele wall. A laser incision can also be considered.[125] Aggressive hydration and minimal instillation of irrigation help keep the ureterocele distended to aid in placement of the puncture. Surgery can be done as an outpatient, depending on age. An ultrasound obtained 10–14 days later should document resolution of hydronephrosis and ureterocele decompression. The decompressed ureterocele typically appears as a pseudomass or mucosal thickening.[126] A VCUG is performed 3 months later to demonstrate whether reflux has been created.

Partial Nephrectomy

The key to success with partial nephrectomy at any age, but especially in the infant, is complete and careful mobilization of the kidney. The vessels of babies are prone to spasms and intimal tears (Figure 40.49).[104] Undue traction must be avoided as the organ is gently cleared from the surrounding pararenal fat. It helps to intermittently discontinue the manipulation of smaller kidneys. In cases where vascular spasm persists, topical vasodilatory agents, such as papaverine, can be applied. The loss of small amounts of function is a common finding. A mean decrease of 6.8% occurred in 60 kidneys of children undergoing open partial nephrectomy in one series.[127]

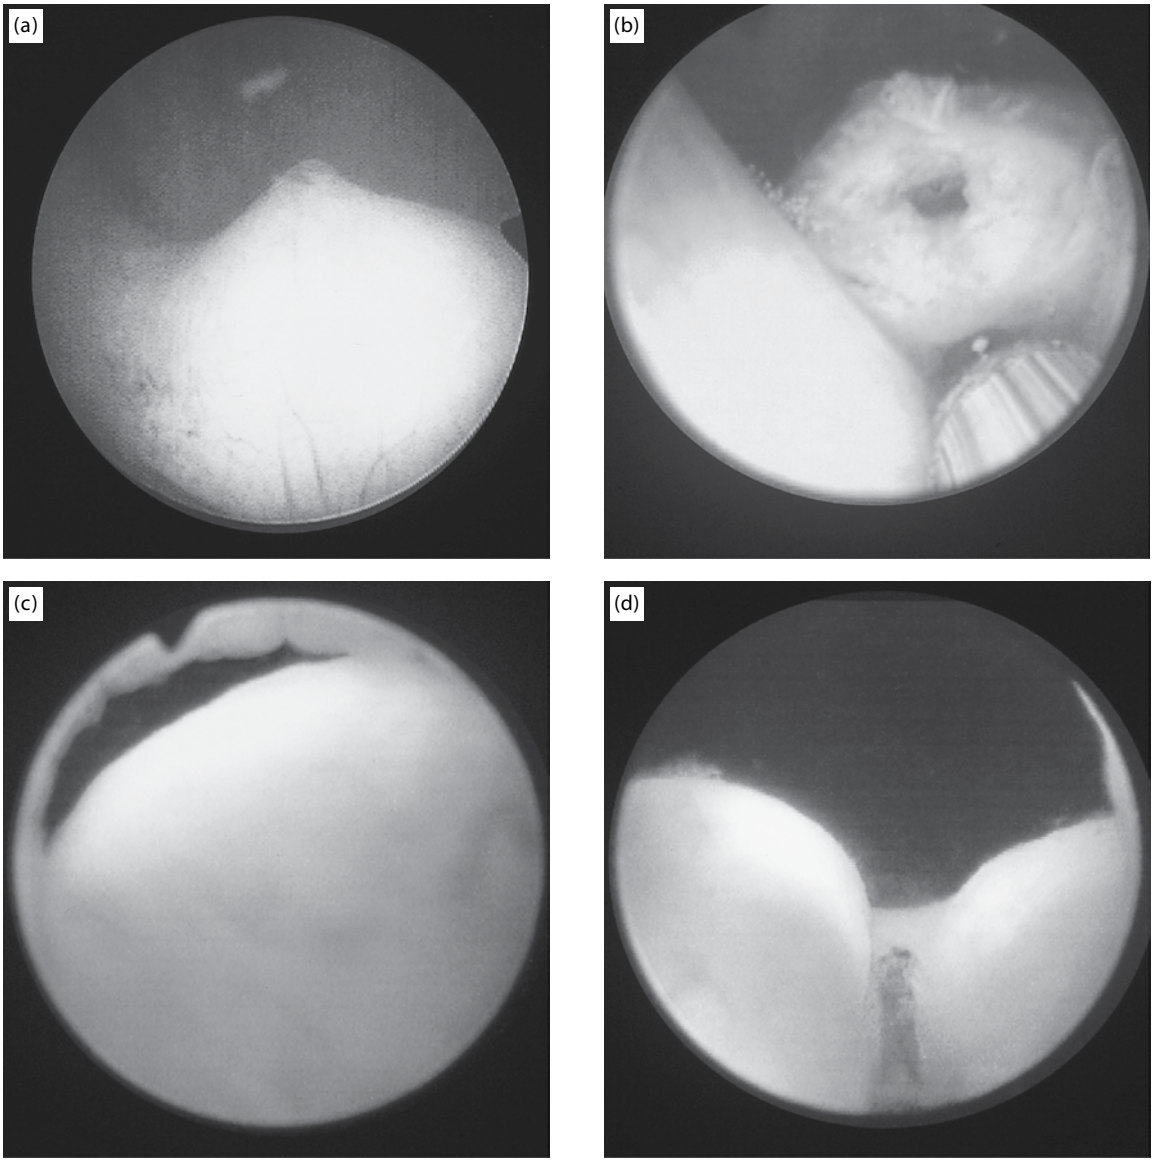

FIGURE 40.47 (a) Cystoscopic appearance of intravesical ureterocele. (b) The ureterocele is decompressed after incision by fine bugbee. (c) The extravesical ureterocele is seen occluding the bladder neck. (d) Wire applied at medial base with intent of preserving the flap valve effect.

In some cases, the vascular pedicle to the upper pole is isolated from that of the lower, making it easily discernable. In others, branching of the two occurs near the renal hilum, making identification of the upper-pole vessels more difficult. After the vessels are identified, vessel loops are placed around them. The ureter is transected at its midsection and mobilized superiorly, posterior to the anteriorly positioned renal vessels. Once freed, the ureter can be swung beneath the vessels and used as a handle on the upper pole, providing traction during its separation from the lower. Upper-pole blanching will occur after its vessels are ligated (Figure 40.50). Clamps on the lower vessels are avoided. Instead, the kidney is gently grasped between the thumb and index finger to help control bleeding. A rim of the renal capsule can be peeled off the upper pole and preserved to serve as reinforcement of the lower pole closure. The poles are then separated with cautery (high settings) along the line of vascular demarcation (Figure 40.51).

When a fish-mouthed defect remains in the lower pole, it can be closed with chromic mattress sutures that incorporate parenchyma and capsule. Otherwise, a flap of pararenal fat can be mobilized and tacked into position to cover the defect. Suturing the capsule of the remaining lower pole to the adjacent muscle is also recommended to avoid postoperative torsion. A drain is left in the renal fossa.

Ureteropyelostomy and Ureteroureterostomy

The principles of successful ureteropyelostomy and ureteroureterostomy are identical to those of

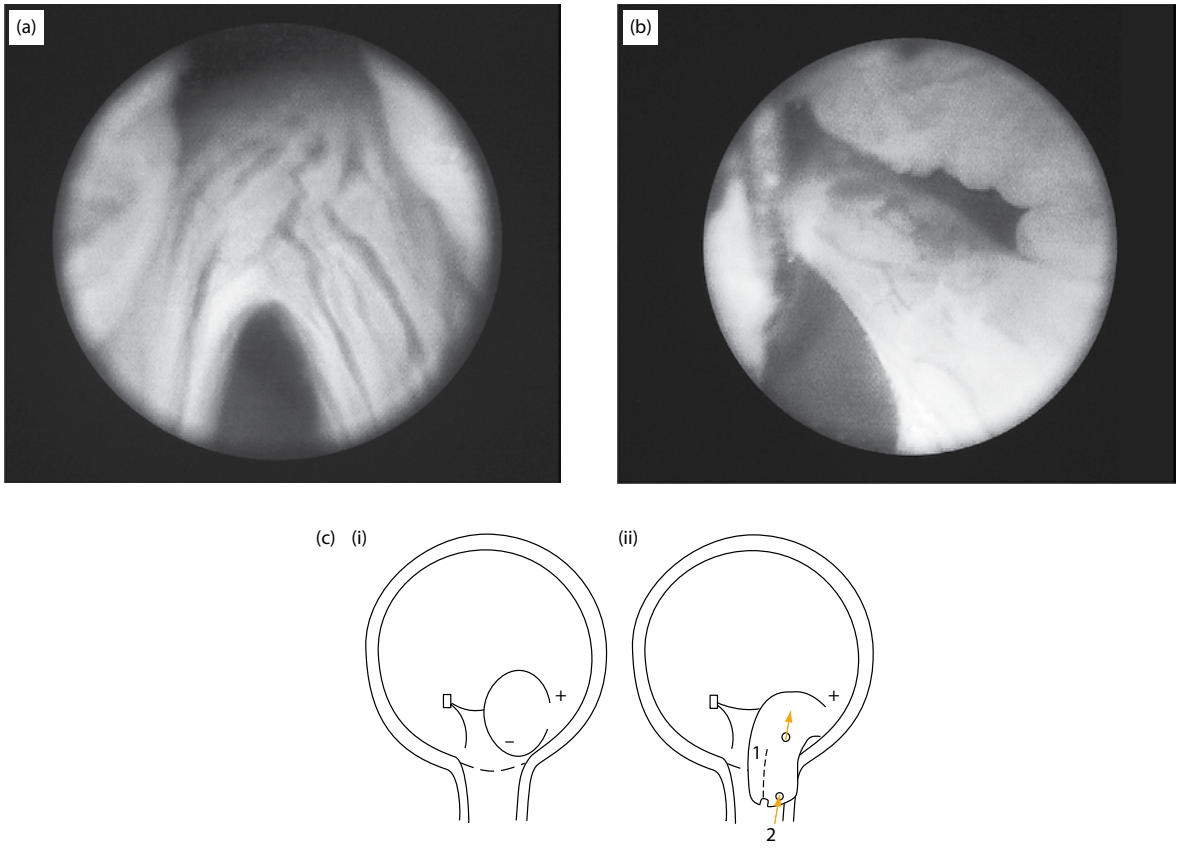

FIGURE 40.48 (a) Cystoscopic view of the sphincteric ureterocele having a widely open orifice (six o'clock position) distal to the bladder neck. (b) Vertical extension by wire eliminates the element of obstruction that accompanies the variant until definitive bladder reconstruction can be done at a later age. (c) The diagram depicts differences in incisions between intravesical ureteroceles (i) and sphincteric varieties (ii). (Adapted from Blythe B et al. *J Urol* 1993;149:556.)

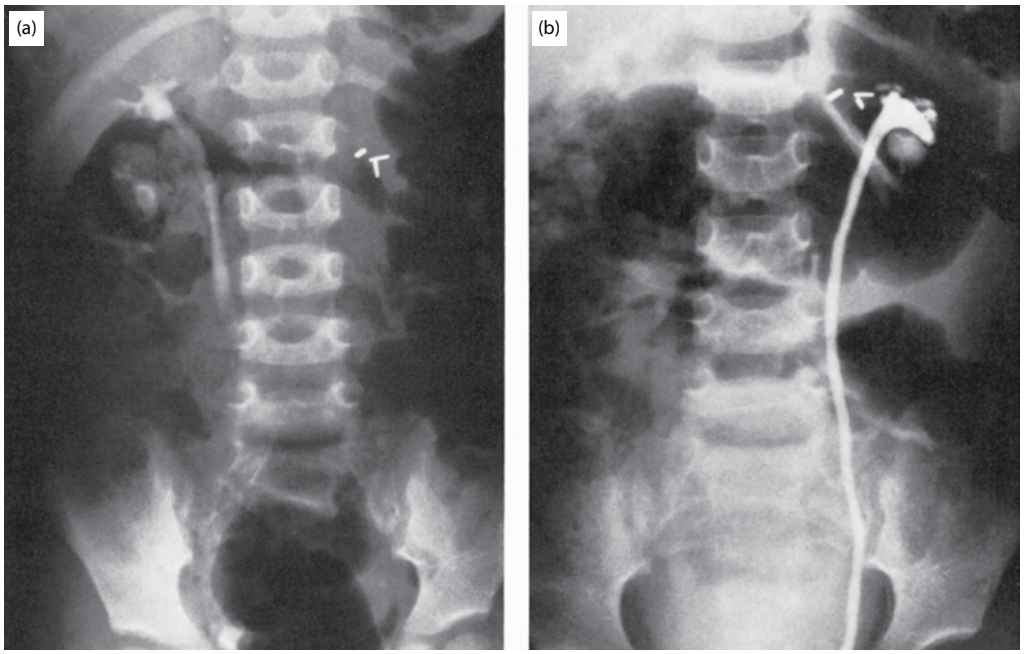

FIGURE 40.49 Vascular injury after left upper-pole heminephrectomy and partial ureterectomy. (a) After surgery, failure of contrast excretion by the remaining lower pole of the kidney, although the segment had been well vascularized prior to surgery. (b) A retrograde pyelogram demonstrates a shrunken unobstructed lower-pole moiety.

FIGURE 40.50 Mobilization is completed before excising the upper-pole segment. The ureter has been transected and carried behind the vessels to the lower pole of the kidney, providing a useful handle and guide to demarcation for heminephrectomy.

dismembered pyeloplasty: minimal handling of the ureters and maintenance of their orientation. Luminal disparity between the recipient collecting system and upper-pole ureter is rarely a cause for concern[128] (Figure 40.52). In most cases, the anastomosis is anteromedially positioned. Traction sutures define the extent of the ureterotomy or pyelotomy on the recipient ureter. An oblique incision of the donor ureter is marked to match. Running 6-0 polydiaxanone sutures are used to complete the repair. Urinary drainage tubes are unnecessary, although a drain is left in the region of the repair (Figures 40.53 and 40.54). When VUR is absent, ureteroureterostomy can also be completed through an inguinal incision using similar surgical principles. Concerns about residual hydroureteronephrosis and urinary stasis as a consequence of the "yo-yo" phenomenon appear to be unfounded.[129] A temporizing cutaneous ureterostomy is utilized in cases where the recipient ureter is felt to be too small.

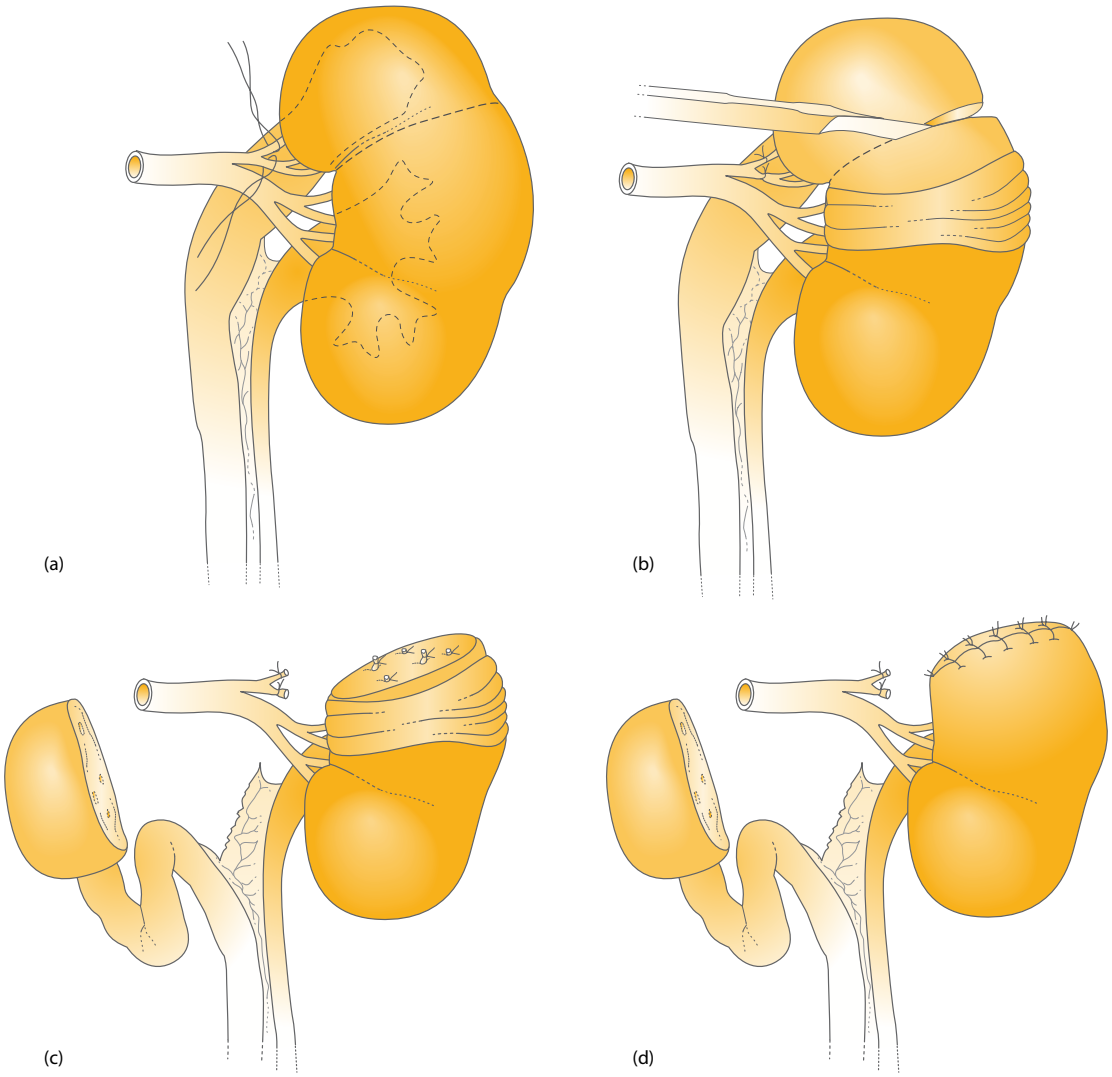

FIGURE 40.51 Technique of heminephrectomy. (a) Vessels to the upper pole are identified and ligated. At this point, the ureter can be fully mobilized from the area of the lower-pole hilum and swung posteriorly and superiorly. (b) The capsule is peeled away from upper pole and preserved for closure. A cautery offers less bleeding than the knife. (c) Significant vessels are ligated. (d) Closure incorporates the capsule and parenchyma.

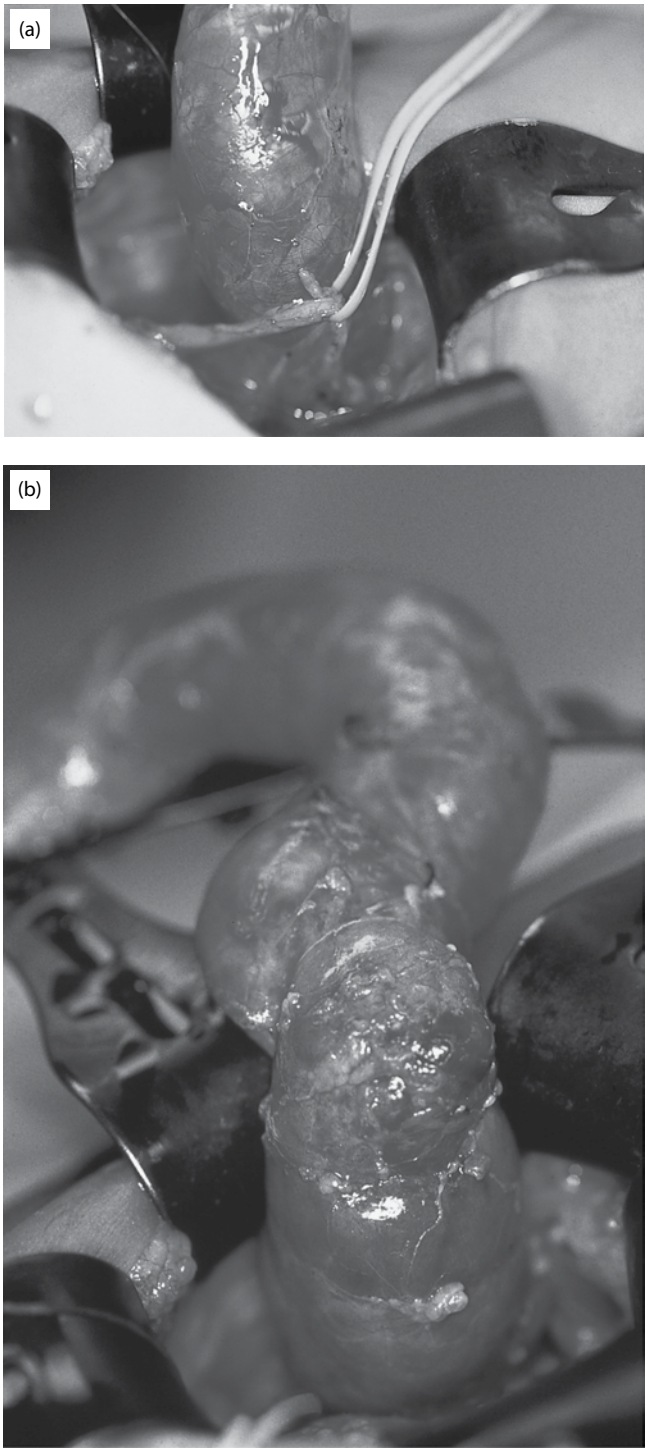

FIGURE 40.52 (a) Disparity in size between the obstructed ureter of the upper-pole moiety and the lower ureter (vessel loop) sometimes poses problems for ureteroureterostomy. (b) Since the upper pole shown grossly provided only moderate function, a heminephrectomy was performed.

Subtotal Ureterectomy

As much of the abnormal ureter as possible should be removed in concert with a heminephrectomy or renal salvage procedure. After dividing the ureter, a 12 F red rubber catheter is sutured within to provide traction during its dissection. The ureter to the lower pole is identified and minimally handled. Long, narrow retractors are used to lift away the peritoneum as the adventitia and periureteral tethers to the upper ureter are taken down with selective cautery. The dissection is ended near the level of the pelvic brim, where the ureters become more intertwined. Ligation is done with 00 or 000 polyglycolic acid suture after aspiration of the obstructed ureter.

Lower Ureterectomy

When a lower ureterectomy is necessary, a transverse Gibson-type incision is made along a lower abdominal crease. The obliterated hypogastric artery is identified and ligated. This is followed posteriorly until the ureter is encountered medially. The proximal portion of the ureter is pulled into the wound and acts as a handle during the remainder of the dissection. The ureter should be mobilized from within its adventitial sheath, avoiding the adjacent peritoneum and vas deferens. Once the mobilization is complete, the ureter is ligated and transected just outside the bladder. When urethral ectopy is being addressed, a catheter is placed to aid in the dissection. The ureter is mobilized to just above the pelvic floor, where it is ligated and transected. The distal insertion can be left alone and undue dissection of the sphincter avoided. In the case of duplication, the shared wall of the upper-pole ureter is left attached to that of the lower pole, avoiding damage to the blood supply. After resecting the ureter at the level of the bladder, several sutures are placed to obliterate its lumen at the hiatus (Figure 40.55).

Ureterocelectomy

The goals of this aspect of ureterocele surgery—removal of the ureterocele itself, correction of associated reflux, and repair of any bladder defect—can be achieved by a number of different approaches. A *transvesical approach* gives the best opportunity to assess the problems associated with the anomaly and to surgically respond accordingly.

The bladder is opened and the submucosal extent of the ureterocele is appreciated after incising its dome. Laterally and medially, the planes between the ureterocele lining and overlying bladder mucosa are better defined using fine cautery dissection. Some bladder mucosa should be preserved for coverage of the resultant defect. As the enucleation or excision is carried posteriorly, the ureterocele lining is excised by defining its plane with the underlying detrusor. Proximally, one or both ureters are circumferentially mobilized at their entrance to the bladder. Mobilization is identical to that of ureteroneocystostomy. Lumenal tailoring is usually necessary for the ureter associated with the ureterocele. The bladder defect that remains after the dissection is closed with interrupted sutures. Ureteral reimplantation is completed with ipsilateral advancement-type (Glen–Anderson) or cross-trigonal (Cohen) reimplantation techniques (Figure 40.56).

Distally, ceco- and sphincteric ureteroceles present a special challenge because of their urethral projections.

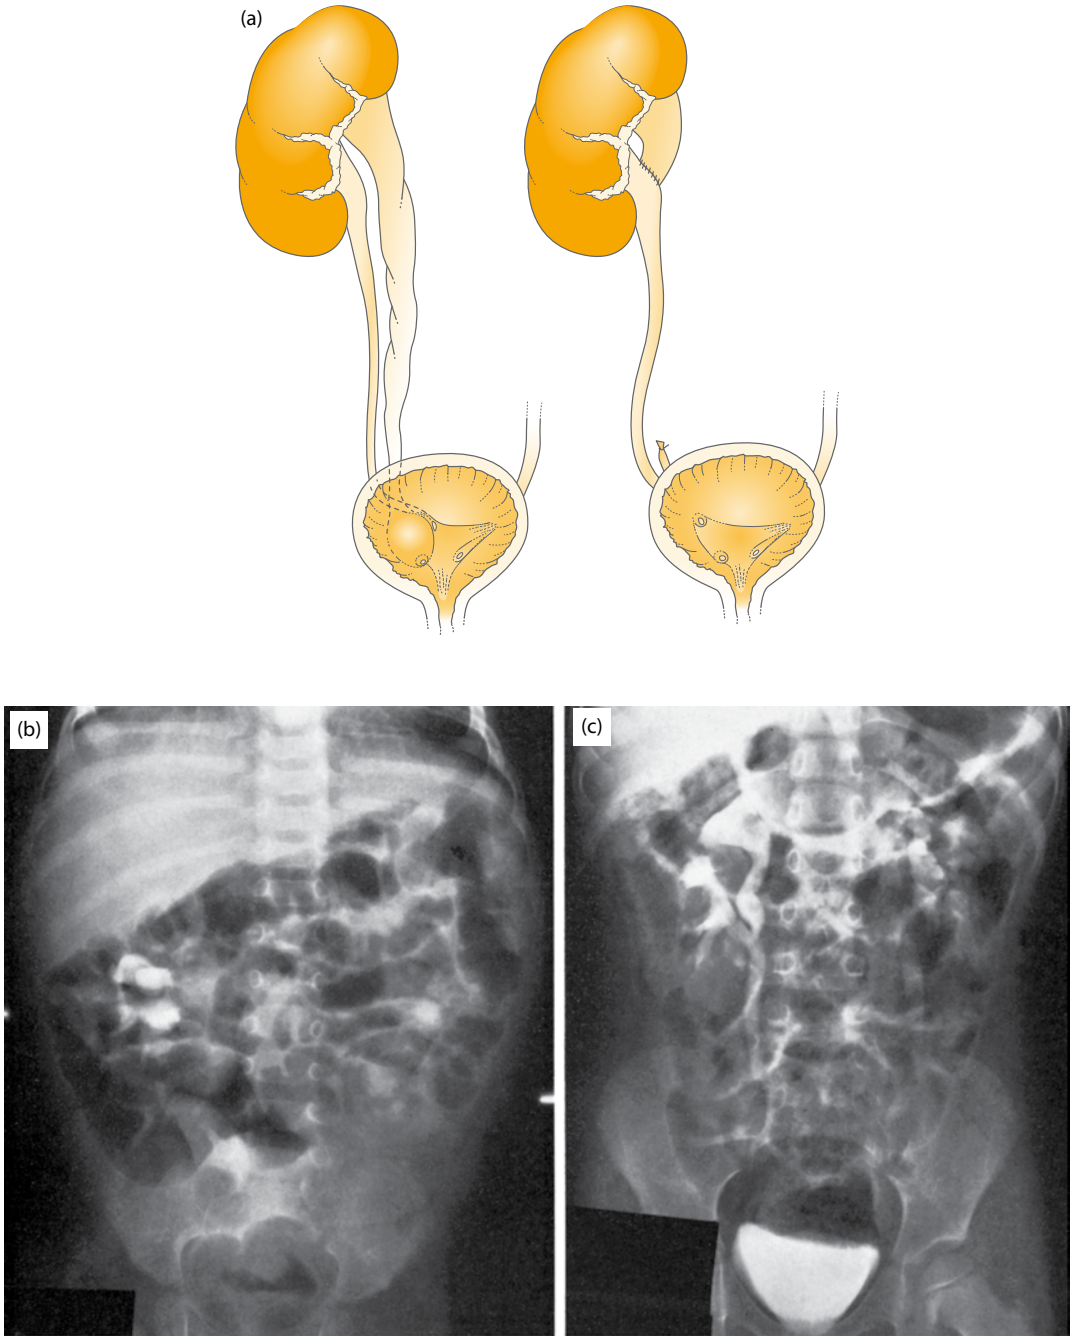

FIGURE 40.53 (a) Pyeloureterostomy and subtotal ureterectomy can be used to treat ureteroceles or ectopic ureters. (b) EU shows bilateral duplication and ectopic ureteroceles. A poorly functioning right upper moiety showed salvageable function by radionuclide scan. (c) An excretory urogram after the right pyeloureterostomy and left heminephrectomy shows return of function in the right upper segment and decompression of both ureteroceles below.

Flap valve obstruction of the bladder can result if tissue is left to balloon into the urethra during voiding.[131] However, extensive dissection should be discouraged to avoid damage to the sphincter mechanism. Instead, when the distal extent of the projection can be appreciated, it can be filleted open and its edges trimmed flush with the urethra. Otherwise, the opening to the projection can be defined and closed at the bladder neck, leaving the lumen intact where it rarely poses a problem. The efficacy of ureterocele excision and ureteral reimplantation with bladder reconstruction is shown by a series of 54 patients with ectopic ureterocele. After long-term follow-up (9.6 years), almost all patients were continent ($n = 51$). Ten required subsequent intervention for persistent VUR.[132] In cases where the detrusor muscle is attenuated, the overlying mucosa should be excised or fulgurated and the muscle plicated to shore up the defect.

Ureteroceles can be corrected by other approaches. *Marsupialization* has been successful in some cases, excising the intravesical outpouching of the anomaly and

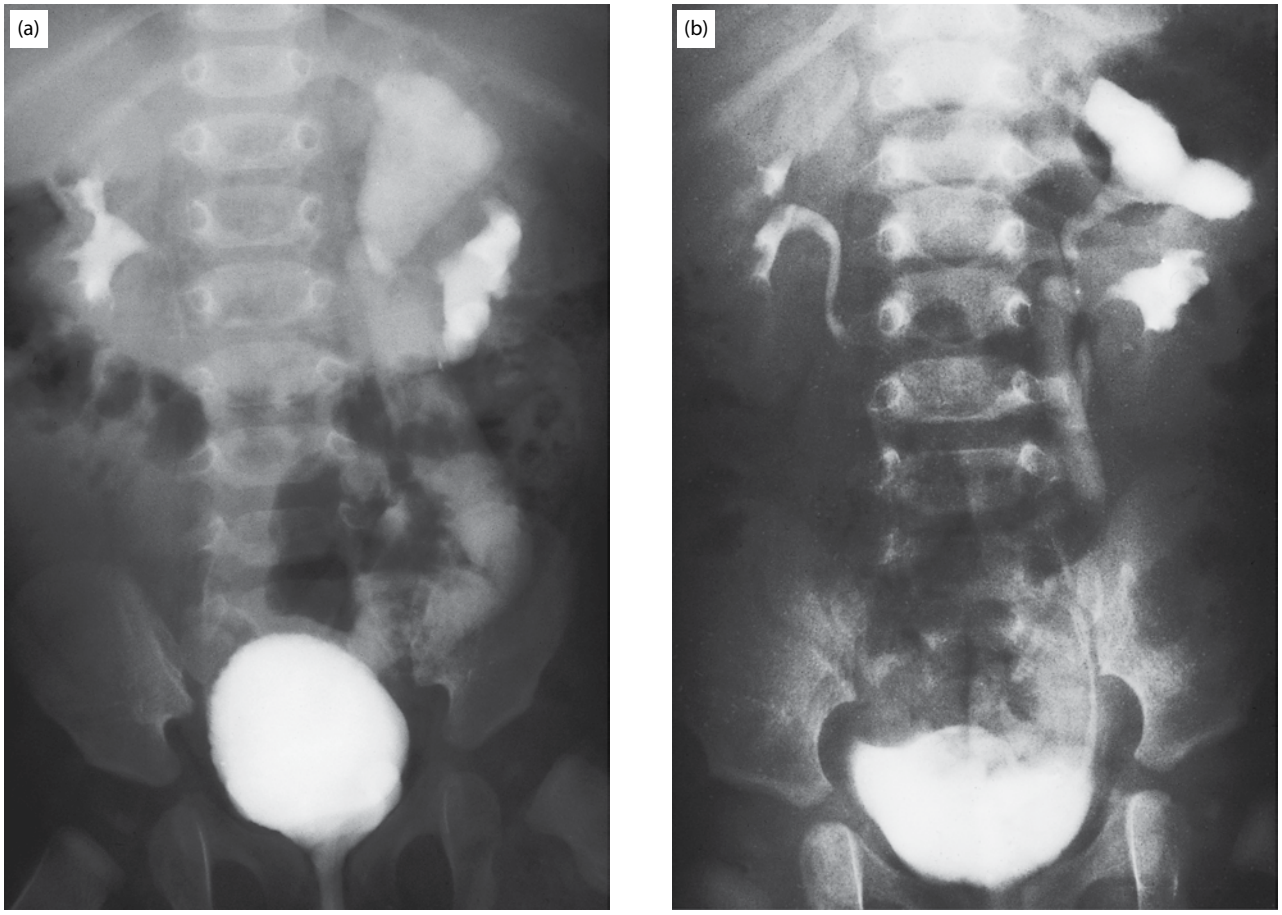

FIGURE 40.54 Nine-month-old female with intravesical ureterocele. (a) A preoperative excretory urogram shows good function to the upper pole. (b) Decompression of the upper pole after successful ureteroureterostomy.

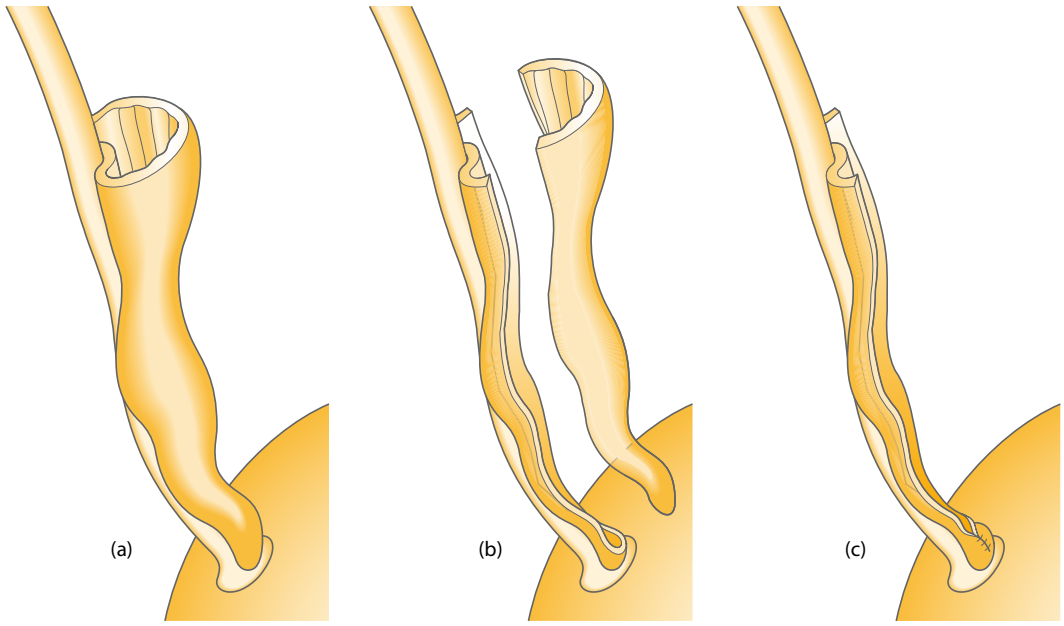

FIGURE 40.55 Lower ureterectomy. (a) It is often difficult to separate the two ureters as they near the bladder. (b) The outer wall of the dilated ureter associated with ectopia or ureterocele can be excised to the bladder, preserving a strip of common wall with the lower-pole ureter. (c) Transfixing sutures obliterate its lumen, with care being taken not to injure the orthotopic ureter. (Adapted from Schlussel R, Retik A. Anomalies of the ureter. In Walsh PC, Retik AB, Vaughan ED Jr, Wein AJ, eds., *Campbell's Urology*, 7th edn. Philadelphia: WB Saunders, 1998, 1820–9.

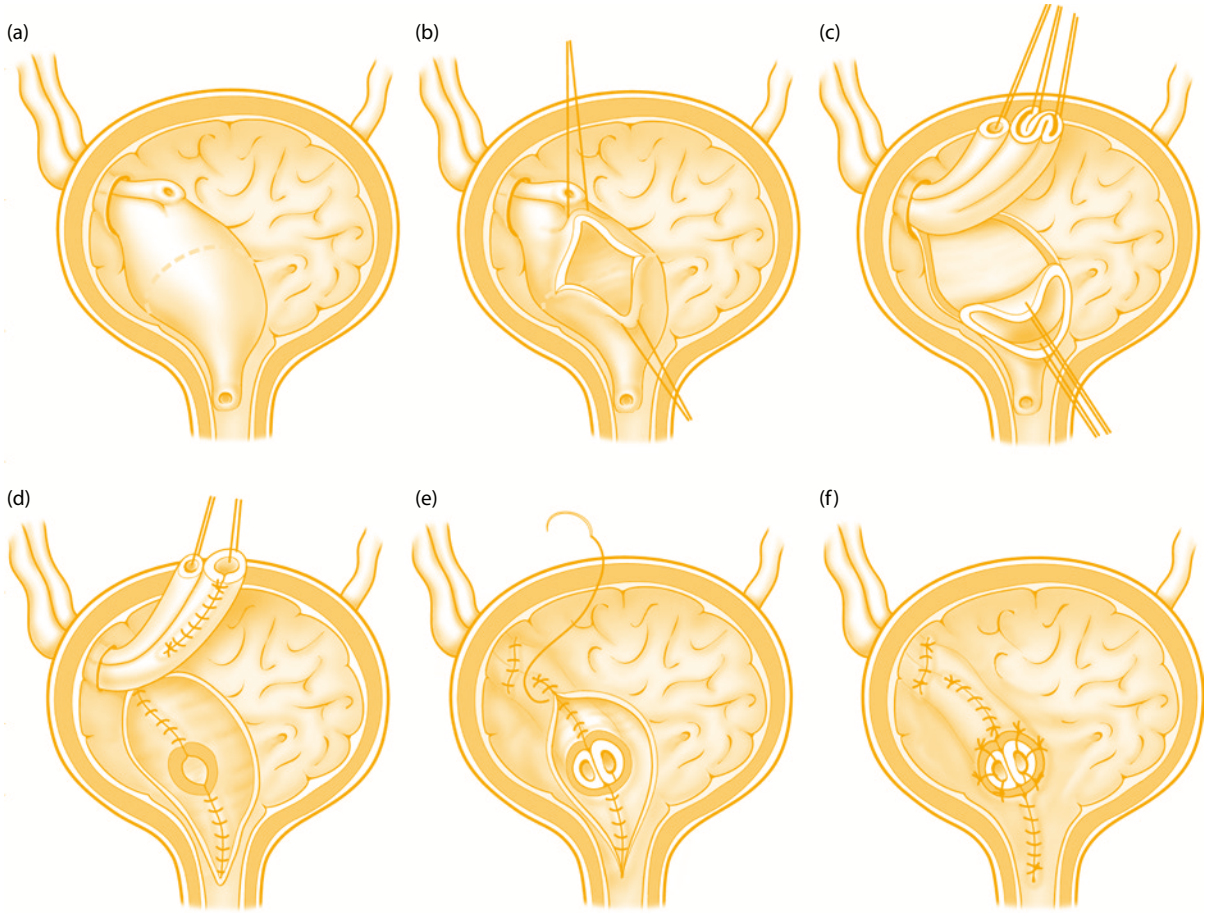

FIGURE 40.56 Technique for excision of ectopic ureterocele with common sheath reimplantation of both ureters. (a) Right-sided ureterocele. Contralateral ureter in close proximity. (b) Ureterocele can be opened transversely (as shown). A vertical incision can sometimes offer better visualization of the urethra. In many cases, the mucosa overlying the ureterocele is thinned out and must be discarded. (c) The posterior wall is incised and dissected away for underlying detrusor. The dissection is carried around to the bladder mucosal edges to enable complete removal of the ureterocele. Ureteral orifices are circumscribed and mobilized. (d) Ureteral mobilization completed. The dilated ureter tapered opposite the common wall. (e) Both ureters brought through the new hiatus in the bladder wall, although the cross-trigonal method can also be used. (Adapted from Schlussel R, Retik A. Anomalies of the ureter. In Walsh PC, Retik AB, Vaughan ED Jr, Wein AJ, eds., *Campbell's Urology*, 7th edn. Philadelphia: WB Saunders, 1998, 1820–9.)

leaving its back wall in continuity with the adjacent bladder as coverage (Figure 40.57).[105] Reimplantation can be done beneath the marsupialized ureterocele, although it is often necessary to create a trough by incising its mucosa, which is more intimately attached to the posterior musculature than in normal bladder. Marsupialization is probably less likely to cause sphincter damage than enucleation. To its detriment, the modification is unable to correct defects in the detrusor and/or sphincter, and thus is most applicable to smaller ureteroceles. In a multi-institutional study of 57 cases of complete excision versus marsupialization, no significant difference was seen in the clinical outcomes.[133]

Another approach is to address the ureterocele extravesically. This can be combined with a heminephrectomy or a distal ureteroureterostomy done through the same incision (Figure 40.58).[134] A portion of the ureterocele wall can be excised extravesically without opening the bladder mucosa and any significant detrusor defect closed. Reimplantation of an upper-pole ureter can also be successfully performed. The extravesical approach may lessen the chances of developing postmanagement bladder dysfunction, especially in children with unilateral variants.[135] Although less invasive, this approach cannot address the suburethral extensions found with some ureteroceles and does not provide a solution to the contralateral or ipsilateral reflux sometimes seen after correction of the anomaly.

Laparoscopy and Robotic-Assisted Management

Partial nephrectomies, ureterectomies, and reconstructive ureteral surgery can be done laparoscopically. Shortened hospitalizations and decreased morbidity are noted when compared with open procedures. Magnification also aids in the dissections.[136–140] Laparoscopy also provides another option in locating ectopic ureters associated with small dysplastic kidneys that cannot be identified

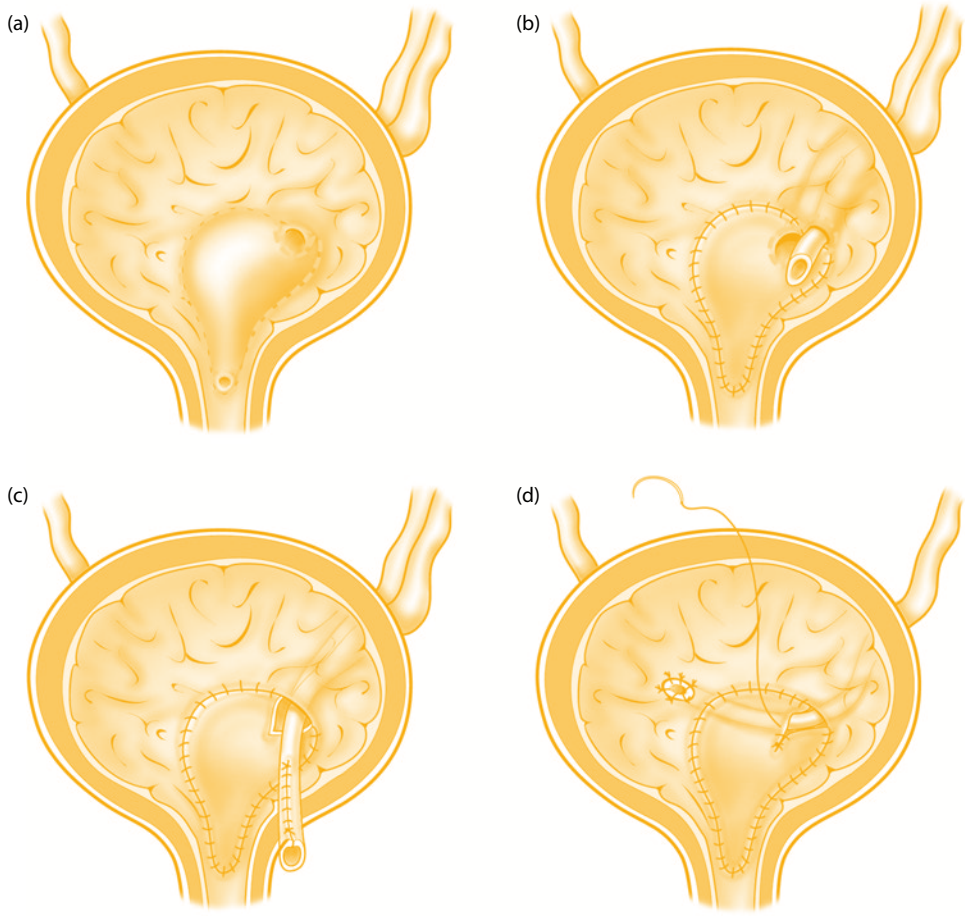

FIGURE 40.57 Marsupialization of ureterocele. (a) Ureterocele is incised at its junction with the normal bladder and sutured to mark edges and secure hemostasis. (b) Completed marsupialization. Mobilization of the duplex ureters is begun as a common sheath. (c) Ureteral mobilization is complete and the bladder defect from dissection is repaired. The dilated ureter has been excised (as shown) or can be tapered opposite the common wall. diagnostically.[141] Reports of increasingly larger groups of children treated with the so-called minimally invasive approach cite results that are comparable to the surgical outcomes offered by conventional open surgery.[142,143] The prolonged lengths of surgery cited in most reports are felt to be a concession to the learning curves required of the techniques early in the experience. And like open surgery, serious complications have occurred,[144] including loss of function of a lower-pole moiety after partial nephrectomy and urinoma formation.[145] Nevertheless, the role for laparoscopy in the management of duplication anomalies, as well other urologic anomalies, will only continue to expand.[146] In addition, robotic-assisted management of these anomalies, until now largely limited to adults, will undoubtedly extend to include children.[147,148]

POSTOPERATIVE CONCERNS

An ultrasound or functional study is obtained 6 weeks after surgery, depending on the procedure used to address the anomaly. The status of salvaged upper-pole kidneys or remaining lower-pole moieties and the effects of surgery on the bladder are assessed. Improvement in the degree of dilatation is to be expected of most patients, although residual hydronephrosis, the consequence of congenital obstruction, is a common postoperative finding. This typically improves with time.[149] Where concerns of obstruction persist, a nuclear renal scan is obtained. Voiding studies are performed 3–6 months after bladder construction to document the adequacy of the repair. Prophylactic antibiotics are continued in the interim. Children with complex urologic histories require periodic follow-up. The need for more prolonged serial radiographs depends on the remaining urinary configuration. In cases where the anomaly is presumably corrected, an ultrasound 2 and 5 years later is probably adequate. Primary physicians complete periodic checks of the urine, blood pressure, and interval somatic growth. Patients who remain at risk, because of persistent reflux, for example, require more frequent evaluation and, if necessary, secondary surgery.

Ureteroceles are particularly challenging in this regard. The length of an adequate trial of medical management

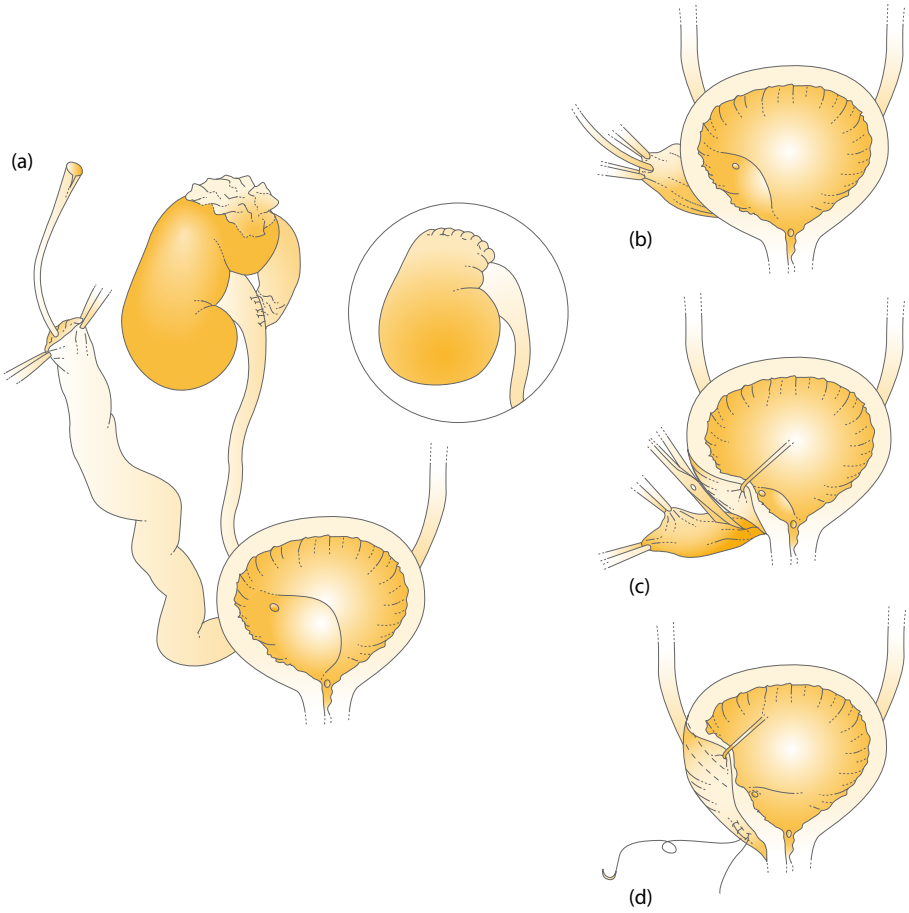

FIGURE 40.58 (a) The technique of extravesical ureterocele excision can be used after either upper-pole heminephrectomy or ureteroureterostomy. The remainder of the upper-pole ureter is cannulated and approached through the lower incision. (b and c) Extravesical dissection can be completed and the detrusor defect repaired (d). Both ureters can be detached to allow for easy separation of their common wall and the lower-pole ureter reimplanted using a Lich-type repair after repairing the detrusor defect.

for VUR that persists after an upper tract approach or selective incision has not been defined. Although spontaneous resolution of reflux associated with ureterocele occasionally occurs, it appears to do so at rates significantly lower than those seen with primary reflux. Most bladders are large enough to reconstruct as the child approaches his or her first birthday. Although it would seem preferable to address ureteroceles before the onset of toilet training, there may be no optimal age for surgery. In one series, bladder dysfunction appeared in 22 of 33 (67%) of patients whose ectopic ureteroceles were excised and bladders repaired at a mean of 10 months of age. Infrequent voiding, large capacities, and significant postvoid residuals were commonplace. The appearance of voiding dysfunction had no correlation with ureterocele size or location,[150] although children with bilateral ectopic ureteroceles may be particularly prone in this regard.[151] Whether these findings are surgically acquired or an inherent component of the anomaly is unclear. Similar rates of dysfunction in patients treated with upper tract surgery alone suggest a congenital component.[152] Regardless, the observation is an important one and may account for the lower rates of success with ureteral reimplantation in these children, when compared with ureteroneocystostomy for primary reflux. Bladder dysfunction should be considered a contributing factor in any child who continues to have persistent VUR after ureterocele surgery. Urodynamic testing and an assessment of bladder emptying should be obtained before considering any additional surgery.

RELATED CONDITIONS

Bilateral Single Ectopic Ureters

Bilateral single-system ectopic ureters are far more common in girls, who present with significant urologic problems as a consequence. The trigone and bladder neck is wide and poorly defined because of the aberrant insertions of the ureters. These usually drain into the distal urethra, although genital ectopy has also been described. Sphincter deficiency and bladder outlet incompetence result. The presentation is very similar to that in patients with epispadias. In addition, the bladder is typically small and the detrusor thin walled, in theory because it has never been required to store urine during development (Figure 40.59). Renal dysplasia or varying degrees of

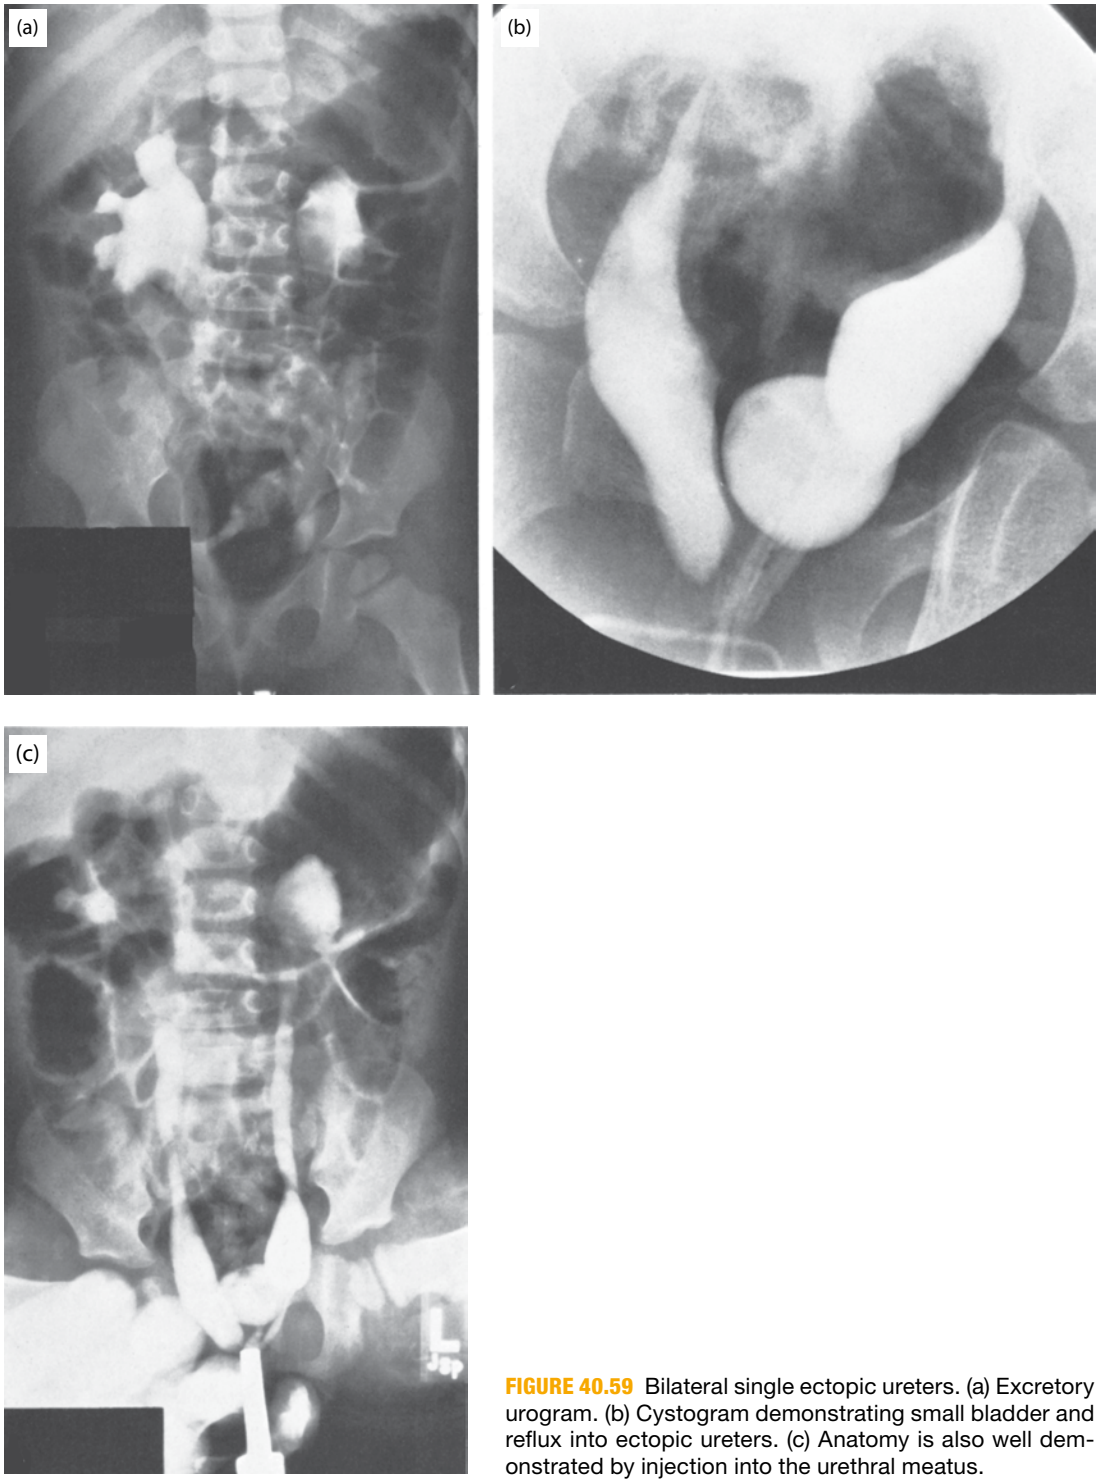

FIGURE 40.59 Bilateral single ectopic ureters. (a) Excretory urogram. (b) Cystogram demonstrating small bladder and reflux into ectopic ureters. (c) Anatomy is also well demonstrated by injection into the urethral meatus.

hydronephrosis are usually present. Reimplantation alone does not correct these glaring urodynamic abnormalities in most patients,[40] although there have been exceptions.[153] Augmentation cystoplasty is often required, and bladder neck reconstruction becomes necessary to increase outlet resistance. Boys are also occasionally affected by bilateral single-system ectopia, which inserts into the prostatic urethra. Bladder dynamics are more favorable, presumably because the better-developed external sphincter helps to retain the urine necessary to stimulate bladder capacity.[154]

Ureteral Triplication

Triplication of the ureter is one of the rarest anomalies in the urinary tract.[155] The individual takeoff of three ureteral buds from the Wolffian duct or the presence of two buds with early fission of one of the two accounts

FIGURE 40.60 Ureteral triplication.

for the variants of complete or partial triplications that have been described. The most common is a trifid configuration with all three ureters uniting and draining through a single orifice (Figure 40.60). Triplicate ureters are more common in females and occur more often on the left side. Common presentations include UTI and/or signs of ureteral obstruction. Ureteral triplications can be associated with ureteroceles, ectopia, and renal fusion anomalies.[156–158] The principles in management are similar to those of duplication anomalies.

Lower-Pole Ureteropelvic Junction Obstruction

Proximal ureteral obstructions occasionally involve duplicated ureters at the renal pelvic junction.[159] These almost always affect the lower-pole ureter. Because of their similarity, most problems that affect the ureters of single-system kidneys can affect the lower-pole ureters of duplications. The configuration and size of upper-pole ureters more closely mimic those of a calyx, making them much less prone to obstruction (Figure 40.61). Ultrasonography demonstrates lower-pole hydronephrosis in the absence of ureteral dilatation. Renal scintigraphy is used to assess function and document obstruction (Figure 40.62). When the lower pole is salvageable, its pelvis is anastomosed to the adjacent upper-pole ureter (pyeloureterostomy) (Figure 40.63). The remainder of the ureter is ligated above the bifurcation and discarded.

Yo-Yo Reflux

The phenomenon of yo-yo reflux remains poorly defined and its clinical implications unclear. Ureteral dilatation of bifurcated ureters was noted in 41% of cases in one series.[160] This raised the question of disordered peristalsis

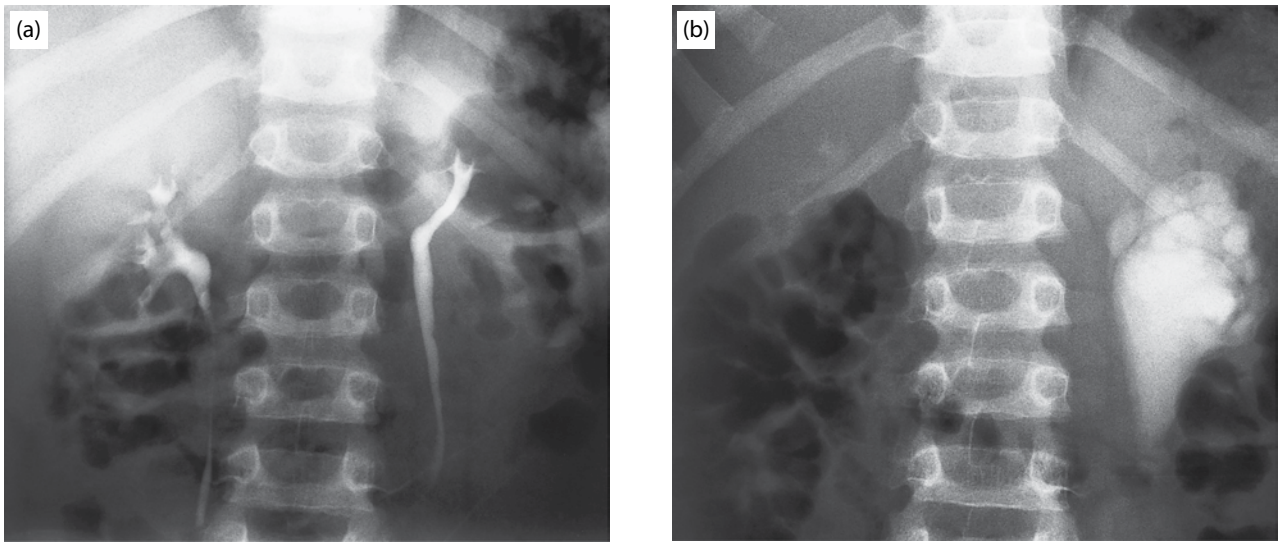

FIGURE 40.61 Difference in upper- and lower-pole configuration shown in different phases of an excretory urogram in a teenage boy with lower-pole ureteropelvic junction obstruction. (a) The early phase shows the upper pole with the appearance of a calyx. (b) The later phase shows the typical pelvic appearance of the lower pole. Note the kink form crossing the vessel.

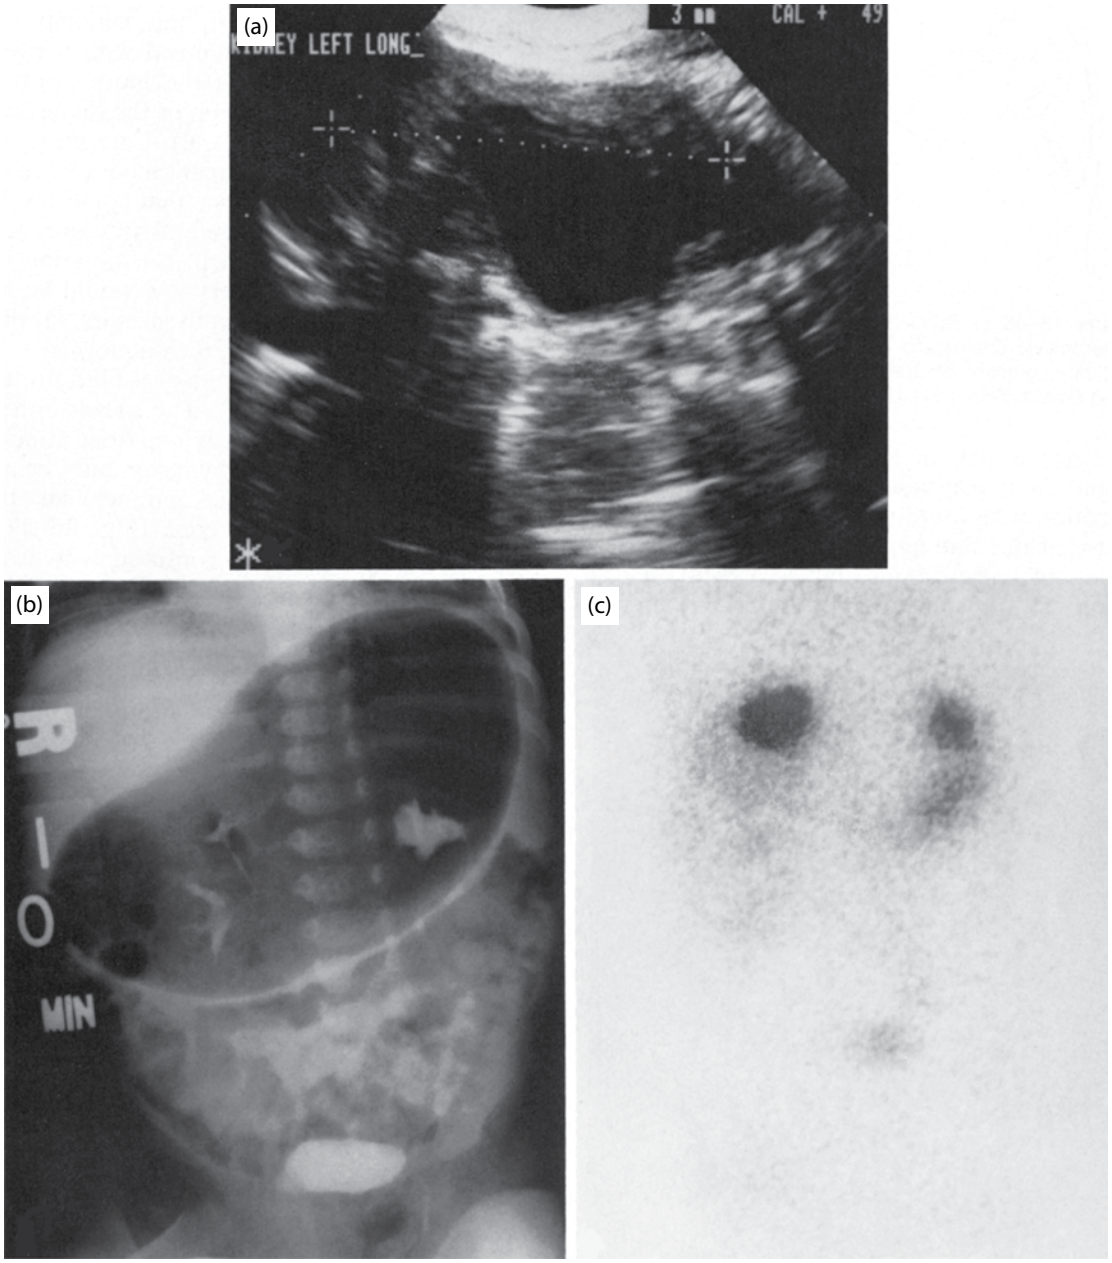

FIGURE 40.62 Lower-pole ureteropelvic junction obstruction diagnosed prenatally. (a) A renal sonogram demonstrates lower-pole hydronephrosis with better-developed renal parenchyma in the upper pole. (b) An EU shows opacification of the upper-pole structures on the left displaced superiorly and laterally. (c) A radioisotope scan demonstrates reduced but salvagable function in the left lower pole.

causing partial ureteral obstruction. In theory, antegrade peristalsis that begins in one ureteral limb initiates a reverse peristalsis in the other once it reaches the junction.[161] High-grade obstruction is rare, and an increased tendency to infections seems unlikely in most cases (Figure 40.64). In addition, despite altered to-and-fro peristalsis at its junction, the overall direction of urinary flow is still antegrade. In the rare patient in whom a clinically significant yo-yo is suspected, a high ureteroureterostomy is recommended, discarding as much of abnormal ureter as possible (Figure 40.65).[162] The preferred option for low-confluence bifurcations is to excise the shared segment and complete a common sheath ureteral reimplantation.

Remnant Ureters

A blind-ending branch of a bifid ureter is occasionally found in a child, although they are more often discovered in adults. These occur more commonly in females and on the right side. Most are associated with low-confluence bifurcations that are prone to reflux, although the anomaly can

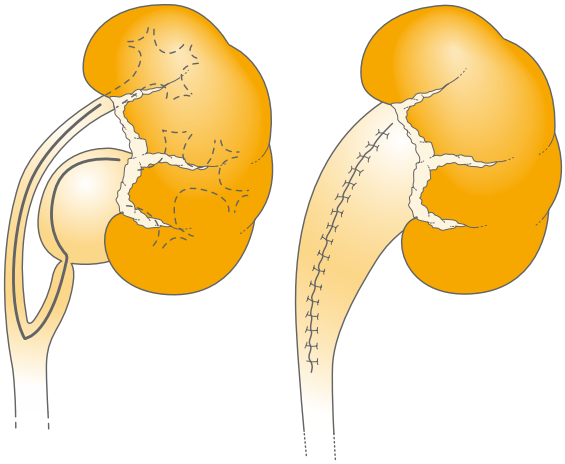

FIGURE 40.63 Surgical treatment of the lower-pole ureteropelvic junction obstruction in duplication. Joining two systems as shown brings less risk than attempting an isolated dismembered pyeloplasty of the lower system.

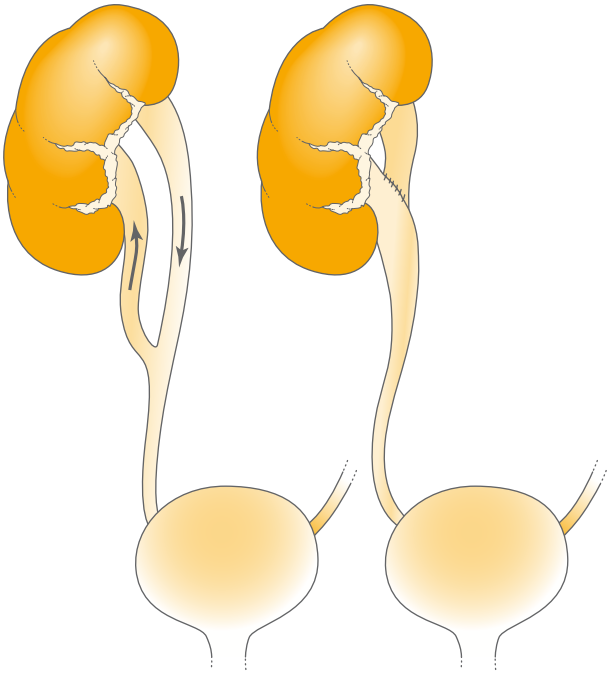

FIGURE 40.65 A high ureteropyelostomy with elimination of one limb of the yo-yo is occasionally required to treat ureteroureteral reflux.

also occur with complete duplications (Figure 40.66).[163,164] Proximally, the ureter ends blindly or may be associated with a small segment of poorly functioning kidney. For larger segments, excision is occasionally warranted. Otherwise, surgery is not indicated unless recurrent infections become problematic, in which case a common sheath

FIGURE 40.64 (a) Yo-yo reflux in a 2-year-old female may contribute to the mild dilatation of the two branches of the incomplete duplication shown. (b) An unusual duplication variant in a 4-year-old boy with lower-pole ureter ending as a saccular dilatation beneath the normal kidney. Although both children are possibly at risk from to-and-fro peristalsis, both are being followed expectantly and have done well.

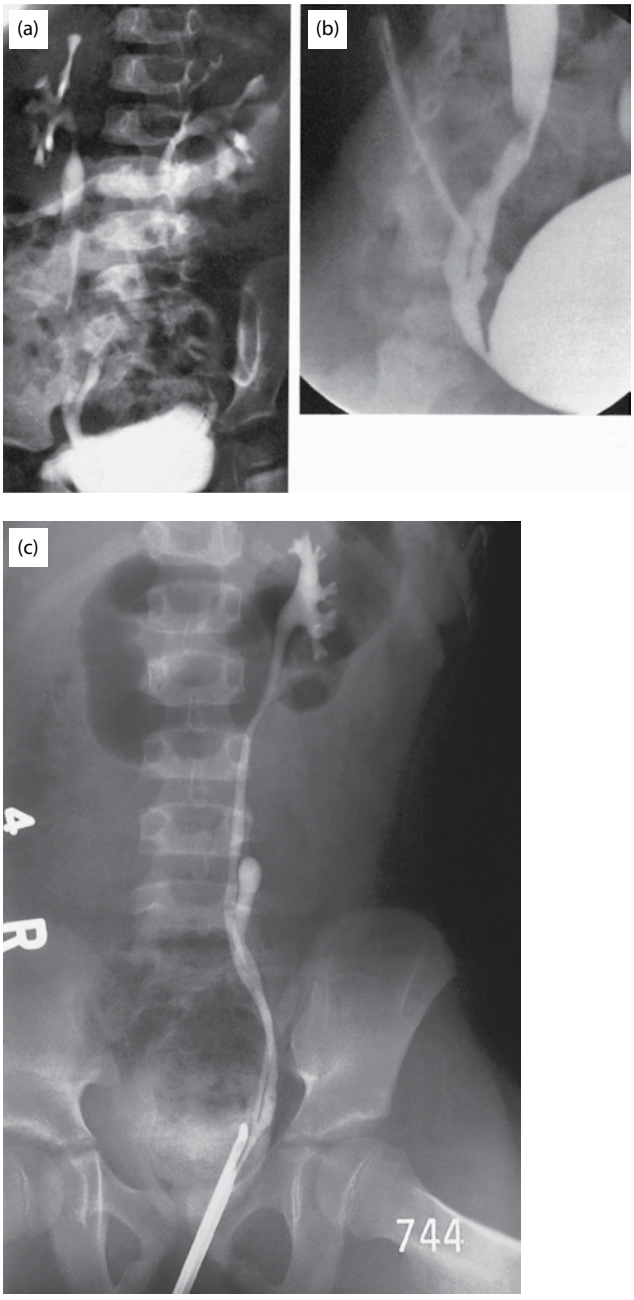

FIGURE 40.66 Blind-ending bifid ureter. (a) An excretory urogram outlines the blind-ending bifid ureter on the right side. (b) A voiding cystourethrogram shows reflux and bifurcation. (c) Retrograde study of similar abortive duplication whose orifice was seen at preoperative cystoscopy. When encountered unexpectedly, these can be safely reimplanted using a common sheath technique.

reimplantation is recommended. In occasional cases, an unsuspected duplication is discovered at cystoscopy or even during ureteral reimplantation. The ureter can be cannulated and a retrograde ureteropyelogram obtained. In nearly every case, the surgeon should still proceed with reimplantation unless the segment is short and easily excised. Complications from the retained renal parenchyma associated with remnant ureters have yet to be described.

CHAPTER
41

Laparoscopic Management of Duplication Anomalies

Aaron D. Martin and Craig A. Peters

INTRODUCTION

The continued progression of laparoscopic techniques applicable to children has presented the opportunity of managing complex renal duplication anomalies using less invasive methods, without compromising surgical efficacy and safety. This chapter reviews the specific laparoscopic methods appropriate to the management of congenital duplication anomalies. Familiarity with the anatomic and functional implications of these anomalies, as well as of their appropriate evaluation, is presumed. The indications for laparoscopic correction of various duplication anomalies are the same as for open surgery. The principal determinants of the need for surgery, as well as the nature of the surgery needed, are the status of the affected renal moiety and the contralateral kidney and the presence or absence of reflux, obstruction, or incontinence. The options are upper- or lower-pole heminephrectomy, vesicoureteral reimplant, pyeloureterostomy, and ureteroureterostomy (U-U).

LAPAROSCOPIC OPERATIONS IN DUPLICATION ANOMALIES

In the setting of duplication anomalies, the most common operation performed is partial nephrectomy, predominantly of the upper pole. The usual indication to perform an upper-pole heminephrectomy is an upper pole with minimal or no demonstrable function. This is typically associated with a dilated corresponding ureter from distal obstruction, as in an ectopic ureter or ureterocele (UC), or incontinence from an ectopic ureter. In some ectopic ureters with incontinence, there is minimal to no dilation in the affected dysplastic upper pole. Laparoscopy provides excellent exposure to the hilum, and this particular operation is carried out more efficiently in laparoscopy than in open surgery.[1] The approach may be transperitoneal or retroperitoneal. The transperitoneal approach offers a wider operative field and is preferred for nephroureterectomy and when there is need for concomitant abdominal surgery (orchiopexy and ureteral reimplant); otherwise, the retroperitoneal approach is widely used. This may be in the prone or lateral position.[2–4] The instruments required are 5 or 3.5 mm cameras, scissors with cautery, a curved fine grasping or dissection instrument, a large grasping instrument for retraction, a clip applier (5 mm), an irrigating and aspirating device, and a harmonic scalpel or hook cautery. We have used 2 mm instruments, but now feel these do not provide adequate control.[2]

In the prone retroperitoneal approach, the patient is prone and the first incision is at the costovertebral angle (Figure 41.1). Blunt dissection is carried out until Gerota's fascia is exposed and entered. The retroperitoneal working space is developed using a balloon filled with saline. The balloon can be created from a finger of a surgical glove tied to a silastic catheter, or commercial devices are available. Developing the retroperitoneal space is accomplished with volumes from 90 mL in an infant to 150 mL in a school-aged child. After removal of the balloon, the first trocar is placed, secured, and insufflated to about 12 mmHg for school-aged children and 8 mmHg for infants. The surgeon is positioned at the ipsilateral side of the patient (affected kidney) or at the feet of the patient in smaller children. Secondary ports are placed under direct vision above the iliac crest lateral to the sacrospinalis muscle and at the posterior axillary line (Figure 41.1). The prone approach offers excellent exposure of the hilum with less concern for inadvertent pneumoperitoneum (Figure 41.2).

The lateral retroperitoneal approach (Figure 41.3) provides easier access to the distal ureter. However, it requires extensive mobilization of the peritoneum and retraction of the kidney for optimal exposure of the hilum.[5] The patient is positioned in the flank position, and the first incision is made at the lower border of the 12th rib. The working space is developed similarly to the prone approach, and accessory ports are placed one finger width from the top of the iliac crest and posteriorly in front of the lumbosacral muscle. Alternatively, they can be placed in a fashion similar to that of the prone approach.[6,7]

In the transperitoneal approach, the patient is supine and the first trocar is placed at the umbilicus with the open technique and secured in place. Two additional ports are placed under direct vision, one in the midline between the umbilicus and the xiphoid process and one in the midclavicular line in the lower quadrant (Figure 41.4). A fourth port for liver retraction may be placed at this time for a

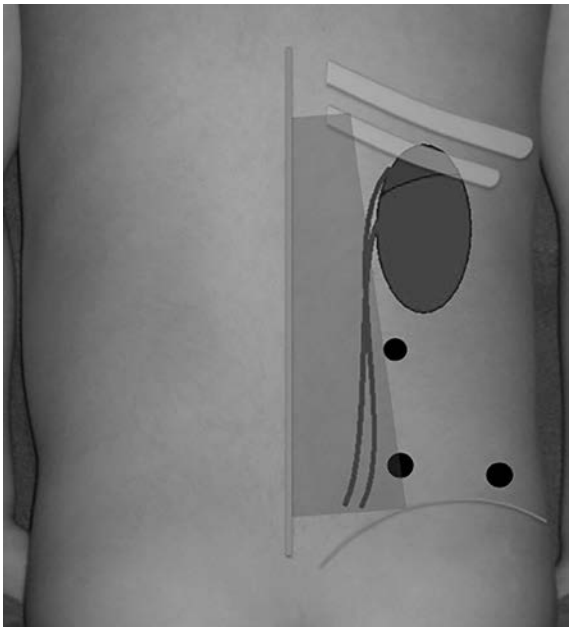

FIGURE 41.1 Port placement for prone retroperitoneal partial nephrectomy. The camera is usually placed in the port at the costovertebral angle.

right-sided operation. The table is then rotated so that the patient is in an oblique position, which allows the bowel to fall out of the operative field. Access to the retroperitoneum and kidney begins with mobilization of the right or left colon.[8]

Once access to the retroperitoneal space is obtained, the lower pole of the kidney is identified and mobilized until the two ureters can be identified. It is preferable to gain control of the hilum as soon as it may be adequately

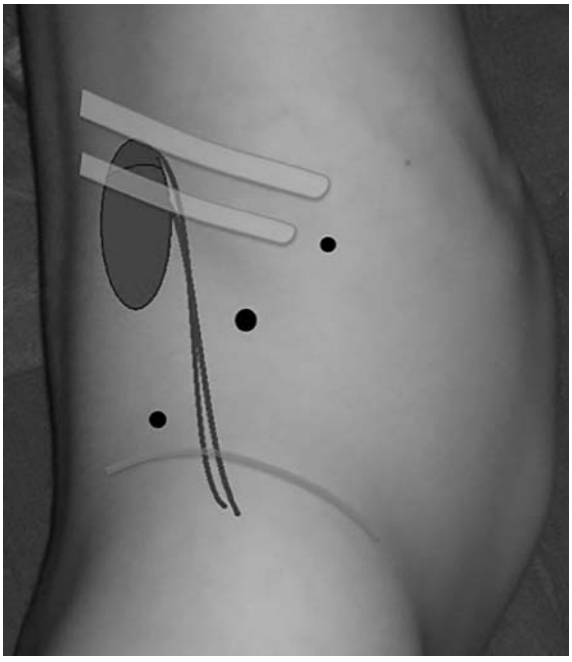

FIGURE 41.2 Port placement for the lateral retroperitoneal approach to the kidney.

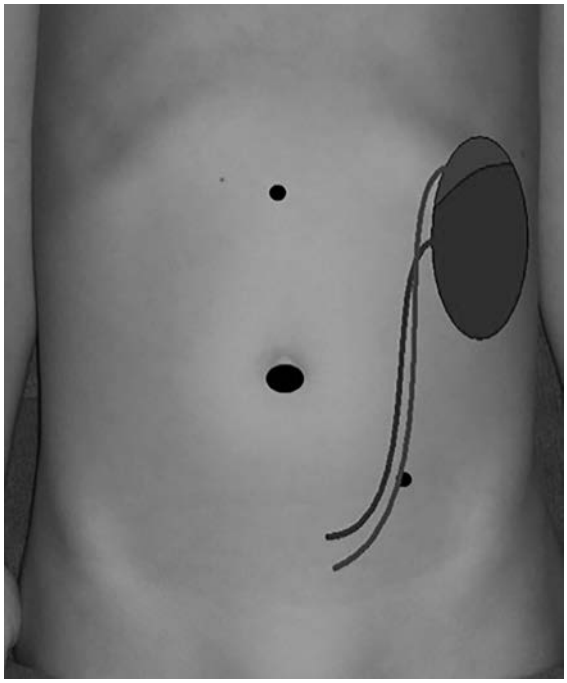

FIGURE 41.3 Port placement for the transperitoneal approach to the kidney, which provides excellent access to the distal ureter when this must be resected.

visualized. In the prone position, the kidney tends to fall laterally and anteriorly, exposing the vascular pedicle. The appropriate polar vessels are identified and clipped individually using a 5 mm clip applier. With the patient prone, the artery comes first in view and is taken first (Figure 41.2). Two clips are used on the proximal side and one on the distal end. Alternatively, a harmonic scalpel can be used if the vessels are small in caliber. Subsequently, the corresponding ureter is mobilized, transected just below the lower pole, and used as a handle to facilitate isolation of the corresponding pole. Occasionally, mobilization of the ureter is required prior to obtaining complete visualization and control of the vessels. Transection of the renal

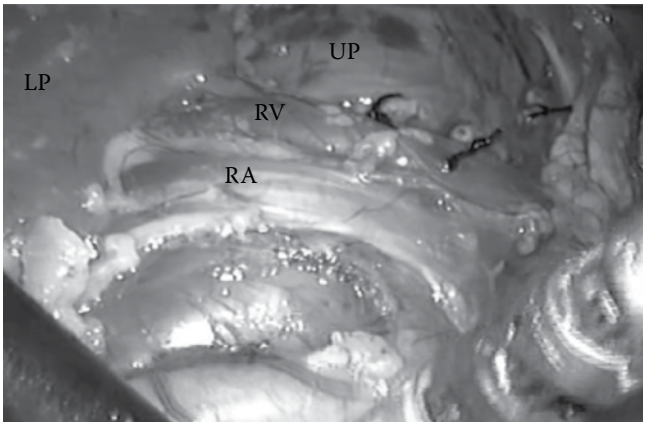

FIGURE 41.4 Exposure of the renal hilum and lower-pole (LP) renal vessels (RA, RV) during robotically assisted partial nephrectomy. The markedly dilated upper-pole collecting system is indicated (UP) passing posterior to the vessels.

parenchyma is then carried out with the harmonic scalpel or with the bipolar cautery.[9] The remainder of the ureter is then dissected away from the remaining ureter by staying very close to the ureter being removed to avoid devascularization of the remaining ureter. The distal ureteral stump should be suture ligated when reflux is present. In the ectopic ureter with both obstruction and reflux, usually those entering the bladder neck, the entire ureter should be removed and the defect closed with sutures. The specimen is removed from the largest port incision. Large cysts in dysplastic upper poles may need to be aspirated before the specimen can be removed.

The typical indication for lower-pole heminephrectomy in duplicated anomalies is a severely compromised lower pole as a result of high-grade vesicoureteral reflux (VUR) or, less often, severe ureteropelvic junction (UPJ) obstruction. The procedure can be undertaken transperitoneal or retroperitoneal, and prone or lateral, in a fashion similar to that of an upper-pole partial nephrectomy. It is best to expose the entire hilum first in order to positively identify the lower-pole vessels. In lower-pole partial nephrectomy, the plane between the upper- and lower-pole pelves is not as distinct and may be difficult to develop. Also, the calices of the dilated lower pole often protrude into the upper pole and may be entered during separation of the two moieties. All remnants of the calices and parenchyma must be removed in order to prevent formation of a urinoma (Figure 41.5). If the upper-pole collecting system is inadvertently entered, suture closure is recommended, as well as drainage. Removal of the lower pole through the initial incision may require morcellation.

RESULTS OF LAPAROSCOPIC PARTIAL NEPHRECTOMY

Table 41.1 shows the results of several series of pediatric laparoscopic partial nephrectomies. In general, the operative times are acceptable and the conversion rate to open surgery is low. In comparative studies of transperitoneal and retroperitoneal approaches, there is a minimal difference in times or outcomes. In studies comparing laparoscopic and open approaches, there is typically a shorter hospital stay, less blood loss, and less postoperative analgesic use with comparable outcomes.[4,10–15] Even in the infant, laparoscopic approaches for complex renal surgery are both safe and efficient.[12,13]

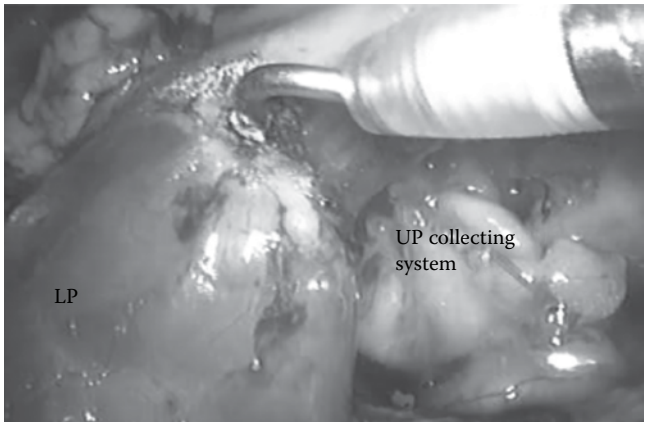

FIGURE 41.5 Transection of margin between the upper (UP) and lower (LP) poles during robotically assisted partial nephrectomy. The plane between the upper-pole collecting system has been developed to facilitate exposure of the thin connection that is being cut with cautery.

COMPLICATIONS

Possible intraoperative complications of laparoscopic partial nephrectomy include bowel, liver, and spleen injuries; abdominal wall vessel injuries; and vascular injuries.[16] On the right side, the duodenum can be injured while exposing the upper pole. It is important to recognize that what looks like the renal vein may in fact be the vena cava if proper orientation of the camera is lost. It is important to briefly reorient oneself prior to any definitive clip placement. Arterial injuries require prompt control of bleeding and repair. Conversion to open surgery may be necessary, depending on the severity of the injury and the experience of the surgeon. Although there is less need to manipulate the remnant pole during a laparoscopic partial nephrectomy, the possibility of arterial spasm in the remnant pole must be recognized and anticipated. This is more likely in infants, but can occur at any age. Any tension on the remnant pole vessels should be released and a syringe of papaverine prepared. If the affected pole does not "pink up," 0.5 mL of papaverine should be forcefully squirted at the affected artery. If no effect is seen, a second bolus of 0.5 mL should then be instilled. Alternatively, lidocaine (without epinephrine) may be useful to correct the vasospasm. Several recent series have reported loss of the lower pole with laparoscopic heminephrectomy, and it is unclear if this represents part of the learning curve or a specific risk.[17] Postoperative complications have been limited to urinoma formation, although none have been clinically significant. Simple aspiration is usually associated with rapid recurrence. If there is concern about a remnant pole leak, a double-J stent may be placed for several weeks. We have not seen any long-term problems with these and have usually simply observed them without untoward outcomes.

URETERAL SURGERY ASSOCIATED WITH DUPLICATION ANOMALIES

Laparoscopic vesicoureteral reimplant has limited indications in duplication anomalies. Isolated VUR of the lower pole is best managed by ipsilateral U-U. If the upper pole is also refluxing, typically as a result of previous incision of a UC, a common sheath reimplant is appropriate. An isolated lower-pole reimplant is considered when the upper moiety has been previously removed. In unilateral cases, simple or common sheath reimplant can be accomplished laparoscopically with a Lich–Gregoir extravesical reimplantation.[18]

For ureteral reimplantation, the patient is positioned supine, and ports are placed at the umbilicus and

symmetrically in the midclavicular lines. Their level is determined by the size of the patient, being above the umbilicus in infants and below in the older child. The ureter is exposed by incising the peritoneum behind the bladder, permitting mobilization. A hitch stitch is placed to hold the bladder anteriorly to aid exposure. A detrusor incision of 3.5–4 cm is made with the hook cautery to permit creation of a submucosal tunnel for the ureter. The muscle is then brought around the ureter with interrupted sutures. No ureteral stenting is required. In bilateral cases, a laparoscopic intravesical approach can be used; however, urinary retention is rare with laparoscopic bilateral extravesical reimplantation compared with the open approach.[19,20] Laparoscopic UC excision has also been described, including extravesical reimplantation of the remnant ureter.[18]

In the case of an ectopic or obstructed upper pole with reasonable function, an ipsilateral U-U can be performed at the lower pole of the kidney or at the pelvic brim, assuming the lower pole is nonrefluxing.[21] For proximal U-U, which is generally useful when one ureter is markedly larger than the other, the positioning is identical to that for a lower-pole partial nephrectomy. For a distal U-U, the ports are placed similarly to those for a ureteral reimplantation and the ureters are exposed at the level of the pelvic brim. The donor ureter is transected obliquely with a length matching an incision in the recipient ureter. Running anastomosis is performed, and the ureters are stented only in the recipient ureter. In some clinical scenarios, it is more efficient to perform a U-U, even when there is little to no function of the associated upper pole, as the procedure is simpler and there is little risk to the remnant pole if well drained.

Associated lower-pole UPJ obstruction is best treated by creating a wide anastomosis between the lower-pole pelvis and the upper-pole ureter (pyeloureterostomy). On occasion, however, an isolated lower-pole dismembered pyeloplasty can be considered. This can be performed transperitoneally or retroperitoneally.[22] Ports are placed as in a transabdominal partial nephrectomy, but the retroperitoneal space can be exposed through a transmesenteric incision. The operation is carried out as an open

TABLE 41.2 Summary data for robotically assisted partial nephrectomy in children, with complication rates

dismembered pyeloplasty, with resection of the stenotic segment, spatulation of the ureter, and reanastomosis. A double-J internal stent is left in the repaired ureter. This operation requires significant skill in laparoscopic suturing and knot tying. For this reason, it can be more efficiently accomplished by using the da Vinci robotic surgical system (Intuitive Surgical, Sunnyvale, California).[23–25]

ROBOT-ASSISTED LAPAROSCOPY FOR DUPLICATION ANOMALIES

The use of robotics potentially expands the number of laparoscopic cases, enabling surgeons with limited laparoscopic experience to perform complex laparoscopic reconstructions requiring extended suturing skills. The da Vinci robotic surgical system is composed of three main parts: the robotic unit, with three (or four) robotic arms that hold the camera and instruments; the video–insufflation–light source unit, as in conventional laparoscopy; and the remote console, from where the surgeon controls the robotic arms.[26] It is equipped with a three-dimensional camera. The instruments presently available are 8 and 5 mm in diameter, the larger ones permitting the greatest maneuverability and options. Robotic laparoscopy presents significant advantages in terms of visualization, fine suturing capabilities, accuracy, and speed of surgery over freehand laparoscopy. In the small child, care must be taken in terms of patient preparation and positioning, setup, and port placement, yet renal surgery has been performed safely in children as small as 5 kg. Extravesical ureteral reimplantations, pyeloplasties, U-Us, and partial nephrectomies have been performed robotically in children.[27–29] In pyeloplasties and partial nephrectomies, the approach is typically transperitoneal, as retroperitoneal access can be difficult due to increased space needs for the robotic arms. For renal surgery, the robot is brought in from the side and angled from the shoulder. To perform a ureteral reimplant, the robot is brought in from the feet of the patient. Port placement is identical to that described above for laparoscopic transperitoneal surgery. While the surgeon sits at the console, the assistant will remain scrubbed at the patient's side, taking care of instrument changes. With the da Vinci robot, current instruments include a hook cautery, scissors, Debakey forceps, larger grasping forceps, two sizes of needle holder, and an articulated suction–irrigation device. These instruments are integrated with conventional laparoscopic clip appliers, irrigation and aspiration devices, scissors, and graspers. Dissection is carried out mostly with the hook cautery, as is the parenchymal resection in a partial nephrectomy. Vessels are clipped with a traditional clip applier maneuvered by the assistant. For a partial nephrectomy, it is recommended that the renal defect be closed, as was typically done with open surgery (Figure 41.6), to limit the risk of development of a urinoma, although these are rarely clinically problematic (Table 41.2).[30] The operations are carried out as previously described. Operation times are usually reduced, compared with conventional freehand laparoscopy, although overall time may be equal due to the preparation and docking time required with the robot. This time can be greatly reduced by training a dedicated robotic surgery team. Despite increased use, publications of comparison studies using the robot-assisted approach are still sparse.

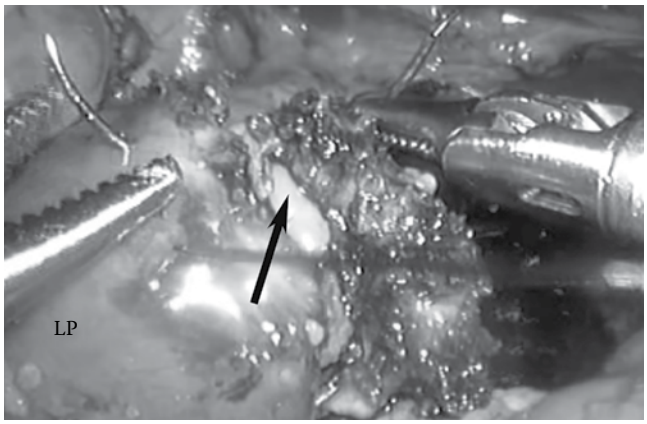

FIGURE 41.6 Closure of the defect after upper-pole removal in a robotically assisted partial nephrectomy. Mattress sutures of monofilament absorbable suture are placed to close the defect. The arrow indicates a pad of retroperitoneal fat that has been placed into the defect to facilitate hemostasis and prevent urinoma formation. LP, lower pole.

Innovative new technologies integrated within the DaVinci system may permit even greater accuracy and safety in certain procedures, particularly partial nephrectomy. Arterial patterns may be mapped out with use of IV indocyanine green, which shows the arterial phase under infrared light.[31]

CHAPTER 42

Vesicoureteral Reflux: Etiology—Anatomical and Functional

Nina F. Casanova and John M. Park

Vesicoureteral reflux (VUR), a retrograde flow of bladder urine into the upper urinary tract, is one of the most commonly encountered pediatric urological anomalies. It occurs normally in some animal species but is generally considered abnormal in humans. Traditionally, VUR has been categorized etiologically into *primary* and *secondary*. *Primary VUR* is thought to represent an abnormal anatomy and function of the ureterovesical junction (UVJ), whereas *secondary VUR* implies an acquired condition as a result of increased intravesical pressure in the setting of neurogenic bladder dysfunction, nonneurogenic bladder dysfunction, or outlet obstruction. The clinical association of VUR and urinary tract infection (UTI) that leads to pyelonephritis, renal scarring, hypertension, and chronic renal insufficiency (*reflux nephropathy*) has been the primary impetus for diagnostic and therapeutic interventions for VUR. However, various clinical and experimental studies seeking to establish a causal relationship between the pathophysiologic components of VUR, UTI, and other clinical sequelae have led to many contentious debates rather than a unifying consensus. In fact, most pediatric urologists and nephrologists now consider VUR not as a disease in and of itself, but rather as a marker of a heterogeneous condition of the whole urinary tract. It includes congenital renal hypoplasia and dysplasia (in addition to acquired pyelonephritic renal damage), primary reflux caused by incompetent UVJ, altered lower UTI, and inherent predisposition to UTI. In this chapter, the etiological components of VUR—both anatomic and functional—are discussed to establish the conceptual framework within which clinical management issues are presented in the subsequent chapters.

HISTORICAL PERSPECTIVE

Galen and Leonardo da Vinci were the first to propose that a normal UVJ allowed unidirectional flow of urine into the bladder, and that VUR might be abnormal in humans.[1,2] In 1893, Pozzi reported that VUR could occur in humans after noting an unexpected urine leakage from the distal end of an accidentally severed ureter during a pelvic gynecological procedure.[3] Initially, VUR was not thought to be a significant clinical problem for humans. However, in 1903 Sampson began looking closely at the anatomy of the ureter and the pathology associated with ureteral reimplantation after gynecologic procedures. He noted an oblique ureteral entry into the bladder that, upon filling, caused a locking mechanism of the orifice, effectively occluding the lumen from reflux and protecting the kidney from ascending infection.[4] The anatomic relationship was further elucidated in 1929 when Gruber published his work demonstrating that the incidence of reflux varied in relation to the length of the intramural ureter and the muscularity of the detrusor backing.[5]

The systematic identification of VUR came as the result of technological advances in contrast radiography, namely, voiding cystourethrography (VCUG). Consequently, in 1924 Bumpus speculated that VUR was related to UTI and that in children, unlike adults, VUR was not associated with other urinary tract pathology.[6] In 1930, Campbell found VUR in 12% of more than 700 VCUGs but assumed that there was other underlying pathology as the cause of VUR.[7] In 1944, Prather proposed that VUR was abnormal in children,[8] and this notion gained increasing acceptance, after accumulating evidence suggested that VUR was typically absent in normal neonates and children.

The modern era of clinical VUR management was ushered in by Hutch's observation that VUR and pyelonephritis might be causally related in paraplegic patients.[9] Hodson, applying Hutch's concept to children, noted that VUR was more common in children with UTI and renal parenchymal abnormality.[10,11] Expounding upon that relationship, Ransley and Risdon demonstrated the relationship between pyelonephritic scarring, reflux, and infection, effectively defining the pathophysiology of reflux nephropathy.[12] In the era of the VCUG and the accepted pathophysiology of reflux, the grading system for reflux was published by the International Reflux Study Group in 1985.[13] Other clinical and experimental observations soon followed, providing additional anatomical and functional bases for the UVJ mechanism and the etiology of VUR.

DEMOGRAPHIC FEATURES OF VESICOURETERAL REFLUX

In most cases, VUR is discovered clinically after investigation of either UTI or antenatal hydronephrosis. In children without UTI or any other urological problems, the true incidence of VUR is difficult to ascertain but may be

in the order of 0.4%–1.8% of the overall pediatric population.[14,15] In contrast, the incidence of VUR in children with UTI is typically around 30%–50%, with an even higher incidence in infants with UTI.[16–18] Of the 1 of every 500–1200 live births detected to have antenatal hydronephrosis, VUR is identified in about 15%–38% of those infants, with the highest incidence noted in infants with persistent postnatal renal abnormalities.[19,20] Infants with VUR diagnosed from antenatal hydronephrosis show a male preponderance,[21] in contrast to older children who are diagnosed with VUR after presenting with UTI, in which females predominate. Boys tend to present at a younger age, and often have more severe degrees of VUR, especially if diagnosed in infancy.[22] Additionally, urodynamic studies of infants with VUR suggested that high voiding pressures and small functional capacity are more common in boys,[23] which may be explained by a transient urethral obstruction causing high intravesical pressures.

VUR appears to be a heritable disorder, as identical twins have been observed to have a higher incidence of VUR, nearing 80%–100% concordance.[24] VUR occurs in other siblings of affected children as well and is seen at a significantly higher rate than that in the general population (as high as 40%–50%).[25–27] Various studies suggest a dominant inheritance pattern with a variable penetrance. These include an approximate 50% incidence of sibling VUR in the first 2 years of life and a high incidence (about 60%) of parent-to-child transmission.[28] Evidence of genetic heterogeneity has also been published, suggesting that different genes act on different families.[29] These findings bring to light interesting discussions regarding the utility of screening siblings or children of the index patient given the potential increased renal morbidity.

Furthermore, the incidence of VUR varies among races. Children of African ancestry have a lower rate of VUR than those of Caucasian genetic background (ratio of 3.4 to 1),[30,31] and girls of Asian ancestry are suggested to be less likely to have scarring associated with reflux than Caucasian girls.[32] Additionally, studies suggest that the reflux in female children of African descent also resolves at a faster rate[33] and presents with a lower grade.[34] After the age of 10, these rates of reflux seem to equilibrate, suggesting a potential for a delay in antireflux mechanism maturation in Caucasian patients.[35]

ANATOMICAL FEATURES AND EMBRYOLOGIC ORIGINS OF THE URETEROVESICAL JUNCTION

The UVJ is anatomically and functionally adapted to allow intermittent passage of the urinary bolus from the ureter into the bladder while preventing the retrograde flow of bladder urine back toward the kidney during storage and micturition. To achieve these functions, the ureter enters the bladder wall with an oblique intramural path (*intramural ureter*) and extends through a submucosal tunnel of appropriate length (*submucosal ureter*) to open onto the trigone in a correct location. This "flap valve" configuration causes the intramural and submucosal ureter to be compressed with progressive bladder filling against the detrusor muscle backing, as if one were stepping on a compressible straw on the ground (Figure 42.1). This passive action is coupled with an active ureteral–trigonal mechanism, resulting in maintenance of an intact UVJ and the prevention of reflux.

The active component of the UVJ mechanism requires a functional integration of the ureter with the bladder and trigone. Functional components of the UVJ were first appreciated when Bell, in 1812, noted that extension of the ureteral longitudinal muscle fibers into the trigone (*Bell's muscle*) was important in the preservation of intramural ureter obliquity.[37] An anatomic description of these intravesical fibers was then further elucidated by Tanagho and Pugh,[38] demonstrating that the inner longitudinal ureteral fibers formed the superficial trigone, down to the level of verumontanum in males and the dorsal surface of the

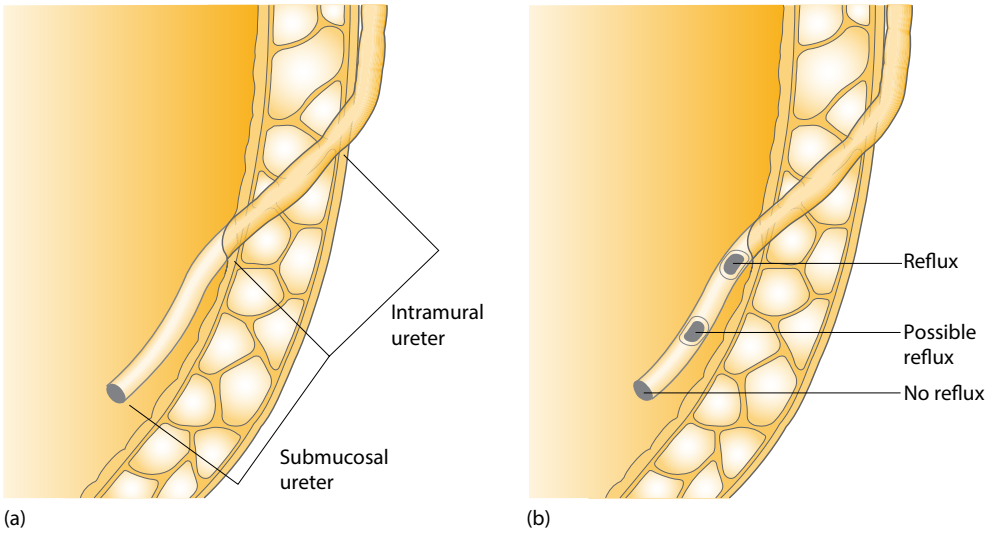

FIGURE 42.1 (a) Normal UVJ: Demonstration of the intravesical ureter (intramural + submucosal). (b) Refluxing UVJ: In contrast to nonrefluxing orifice, there is an inadequate length of the intravesical ureter, compromising the flap valve mechanism. (From Politano VA. Vesicoureteral reflux. In Glenn JF, ed., *Urologic Surgery*, 2nd edn. New York: Harper & Row, 1975, 272–93.)

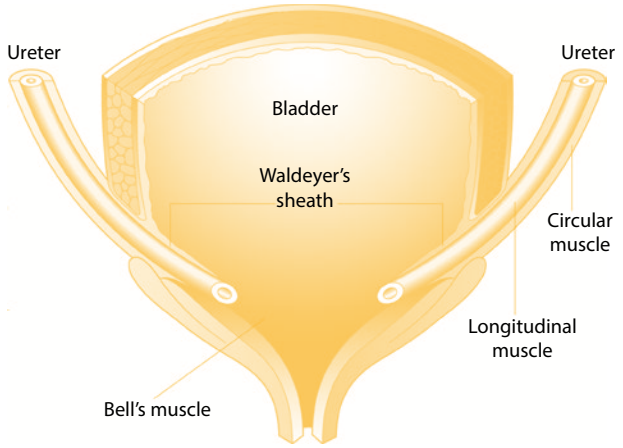

FIGURE 42.2 Passage of the distal ureter through the ureteral hiatus in the bladder wall. Ureteral inner longitudinal muscle fibers extend into the trigone to form Bell's muscle. The Waldeyer sheath anchors the distal ureter at the hiatus. (From Mathisen W. *Surg Gynecol Obstet* 1964;118:965–71.)

urethra in females. Here the muscle fibers extend fanwise and, at the midline of the trigone, intermingle with those of the contralateral ureter. The middle circular ureteral muscle is not seen beyond the level of the ureteral hiatus, and the adventitia of the distal ureter just outside the bladder wall fuses with the fibromuscular sheath that encircles the ureter (known as the *Waldeyer sheath*). The Waldeyer sheath is thought to anchor the ureter within the hiatus while allowing the intramural ureter to slide freely within the hiatus during bladder filling and emptying (Figure 42.2). This is essential to the ureter's ability to efflux, as this mobility allows for the shortening and widening of the ureter in response to a bolus of urine.

In 1972, Elbadawi[40] (and later confirmed by Stephens[41]) identified a separate intermediate layer extending from the ureter into the deep trigone. Immunohistochemical studies also confirmed these intermediate ureteral muscle extensions into the deep trigone and noted that they are richly innervated by noradrenergic receptors, similar to vasa deferentia,[42] and fan out into the trigonal region along with the muscle fibers.[43] Interestingly, this intermediate layer may be important in the overall development of the ureteral trigonal relationship, and embryologically, ureteral maldevelopment may be linked with an abnormal trigonal development. (This thought is supported by a recent study of vitamin A signaling–deficient mice demonstrating an abnormal development of trigone, thereby resulting in a high incidence of distal ureteral anomalies.[44])

Despite somewhat conflicting opinions about the precise anatomical details of the ureter–trigone relationship, there is sound physiologic evidence to suggest that a functional integration of the ureter and trigone is important in the normal UVJ mechanism. From a neuroanatomical standpoint, Tanagho's series of elegant experiments in dogs helped define these roles in preventing VUR[45] and suggested an important neuronal involvement, as a unilateral sympathectomy at L3–5 uniformly induced reflux. These findings were consistent with earlier observations by Langworthy in 1938, where unilateral sympathectomy in cats induced unilateral dilated ureter with ipsilateral widening of the ureteric orifice. Smooth muscle integration has also been found to be necessary in this process, as studies suggest distal ureteral smooth muscle atrophy, dysplasia, and architectural derangement and extracellular matrix remodeling in refluxing ureters.[46,47] Additional experiments demonstrated that increasing the trigonal tone and contractility using electrical stimulation, epinephrine injection, bladder distention, and micturition all resulted in functional occlusion of the ureteric orifices. Furthermore, surgical incision of ureter–trigone continuity below the ureteric orifice resulted in VUR, which then disappeared after healing of the incision.

In addition to the experimental observations noted above, clinical findings lend further support for the importance of the flap valve mechanism in preventing VUR, specifically in relation to the length of the intravesical ureter and the lateral displacement of the ureteric orifice. The intravesical ureter (the intramural segment plus the submucosal tunnel) has been estimated to lengthen with age, providing rationale for spontaneous VUR resolution with maturation. In neonates, the average length of the intravesical ureter was 0.5 cm, while in adults, it was 1.3 cm,[48,49] and the mature length was thought to be achieved by 10–12 years of age. Trigonal competency also plays a critical role in maintaining the adequate length and obliquity of the intravesical ureter during bladder distention and micturition, further supporting the importance of this relationship. Inadequate trigonal function allows the ureteric orifice to displace laterally and migrate away from the bladder neck during bladder filling, leading to reduction of the intravesical ureteral length.

The lateral displacement of the ureteric orifice and its abnormal appearance in association with VUR are well established (Figure 42.3). The classic explanation proposed by Mackie and Stephens suggests that the lateral displacement may occur as the result of abnormal ureteric

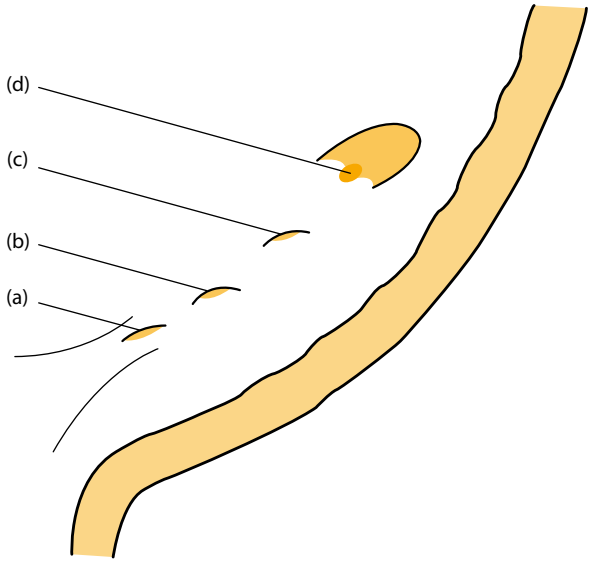

FIGURE 42.3 Four different ureteric orifice positions. (a) Normal. (b) Moderately lateral. (c) Very lateral. (d) Orifice at the mouth of a diverticulum. (From Glassberg KI, Hackett RE, Waterhouse K. Congenital anomalies of the kidney, ureter, and bladder. In Kendall AR, Karafin L, Goldsmith HS, eds., *Urology*. Philadelphia: Harper & Row, 1987, 158.)

bud origin along the developing mesonephric duct.[51] They found a correlation between the lateral displacement of ureteric orifice and the degree of renal dysplasia and hypoplasia. They postulated that the ectopic origin of ureteric bud during the metanephric development was the primary embryological error leading to anomalous renal differentiation and an abnormally located ureteric orifice. This view is most plausible when applied to duplex system anomalies but may also be pertinent to the congenital renal anomalies associated with VUR. An alternative embryological view of the VUR may be the concept of primary trigonal disorder, as previously discussed. The trigone develops as a result of common nephric duct and the distal ureter incorporation into the developing bladder, and it is reasonable to postulate that the lateral displacement and the abnormal ureteral anchoring may occur as a result of functional disorganization of the trigone during development.[44]

Endoscopic observations have helped in confirming the importance of the flap valve mechanism in preventing VUR as well. Specifically, the ratio of the submucosal tunnel length to the ureteral diameter appears to be a critical factor that determines the effectiveness of UVJ function.[48,49] Paquin noted that in children without VUR, the ratio of tunnel length to ureteral diameter was 5 to 1, whereas in children with VUR, the ratio was 1.4 to 1. Cussen documented the relationship between intravesical ureteral length, submucosal ureteral length, and ureteral diameters in normal infants and children (Table 42.1).[49] The relative position and shape of the ureteric orifice also seem to correlate with the length of the intravesical ureter. Orifices that are placed laterally, away from the bladder neck, are associated with a higher incidence of VUR and probably reflect poor trigonal anchoring and short intravesical ureteral length. Lyon and colleagues described four basic orifice shapes that reflect the competency of the UVJ anatomy: cone, stadium, horseshoe, and golf hole.[52] VUR was seen in 4% of patients with a normal cone configuration, in 28% of those with a stadium orifice, in 83% of those with a horseshoe orifice, and in 100% of those with a golf-hole orifice. Heale confirmed Lyon's observations by reporting a higher prevalence and grade of VUR, as well as renal scarring, in patients with more laterally placed and abnormal ureteric orifices.[53] Stephens described another orifice configuration—the lateral pillar defect—which probably represents a type of ureter–trigone abnormality between horseshoe and golf-hole orifices.[54] Although an endoscopic appearance of ureteric orifices is no longer considered a particularly reliable clinical indicator of VUR (especially in low- to moderate-grade

situations), these observations provide insight into the overall mechanism of competence of the UVJ (Figure 42.4).

The anatomical mechanisms of the UVJ combining active and passive mechanisms can be summarized as follows. The natural tone of ureteral muscle provides a mild passive closure of the intramural ureter except during the efflux of the urinary bolus. As the bladder fills and becomes distended, there is a progressive obliquity of the intramural and submucosal ureter, creating a "flap valve" mechanism, provided that there is a sturdy back wall support of the detrusor muscle. The tone and contractility of the trigone increase steadily during bladder filling as it becomes stretched, and it provides a secure anchoring of the ureteric orifices, further augmenting the flap valve mechanism. Micturition also stimulates the trigonal tone via a complex integration of muscle and neuronal mechanisms, anchoring the ureter and preventing the lateral displacement of the orifice. The critical factor of this flap valve mechanism is the effective occlusion of the intramural and submucosal ureter as the rising intravesical pressure compresses it against the detrusor muscle. The anatomical and functional integration of the ureter and trigone is a remarkable piece of bioengineering, which allows an unimpeded unidirectional flow of urine at the UVJ.

PRIMARY VERSUS SECONDARY VESICOURETERAL REFLUX AND THE ROLE OF LOWER URINARY TRACT FUNCTION

The distinction between *primary* and *secondary* VUR is important in the conceptualization of contributing

pathophysiology and relevant anatomic and functional etiologies that need to be addressed clinically. In certain cases, the distinction is not entirely clear in that some forms of primary VUR may be associated with bladder anomalies, which contribute to the progression of the underlying UVJ malfunction. The clinical reality is that in all patients presenting with VUR, the proper management must include a global view of the entire urinary tract, including UVJ mechanism, bladder dysfunction, predisposition to UTIs, and renal anomalies. A short intravesical ureter or a marginally competent ureter–trigone complex may increase the likelihood of VUR in unfavorable conditions, such as bladder hypertonicity, high-pressure voiding, and UTI. On the other hand, an extremely competent UVJ may resist VUR even in cases of challenges by an abnormal bladder until there is an irreversible deformation of the UVJ structures.

The concept of secondary VUR is critical in that understanding the dynamic process of reflux would be incomplete without considering the effect of the bladder. In a normal, mature urinary tract, increasing the intravesical pressure alone does not necessarily induce VUR. However, VUR can be acquired secondary to bladder anomalies, such as neurogenic bladder disorders and various types of bladder outlet obstruction (as in boys with posterior urethral valves). The chronic elevation of bladder pressure and the subsequent distortion of the bladder wall at the UVJ (such as paraureteral diverticulum) may be critical in the formation of secondary VUR as the pressure elevation overwhelms the flap valve mechanism. The structural and neurological perturbation of the trigone in the abnormal bladder is likely to be important as well.

The most common anatomic cause of secondary VUR is seen in boys with posterior urethral valves, which are associated with VUR in more than 50% of patients.[55] Reflux may resolve in 30%–70% of these patients at 6 months with valve ablation and relief of the high-pressure voiding.[56] Anatomic obstructions causing VUR in girls are rare and may occur in the setting of an obstructing ureterocele. Again, this VUR often resolves after decompression of the ureterocele.

Overall, any child with an altered bladder function is at risk for secondary VUR. A poorly compliant bladder, along with its abnormal interaction with dyssynergic urinary sphincters, can lead to increased intravesical pressures, which then weaken and alter the UVJ to cause VUR. McGuire et al. demonstrated that if the bladder pressures exceeded 40 cm H_2O, the incidence of VUR was seen in more than 80% of patients with myelodysplasia and neurogenic bladders.[57,58]

In infants and children, abnormal lower urinary tract function often coexists with VUR without any apparent neurogenic or anatomic pathology. These observations further suggest a role of lower urinary tract function in the pathogenesis of VUR and its implication in the clinical management of the condition. To start, elevated voiding pressures, especially in infants, may play a central role in VUR pathophysiology. Infantile bladders have been shown to have high voiding pressures. Urodynamic studies have shown that this may be the result of imperfect coordination between detrusor contraction and sphincter relaxation.[59,60] This pattern of immaturity typically disappears after 2 years, and is thought to result from a lack of integration between the bladder, the external urethral sphincter, the brainstem, and the higher cortical centers. Compared with normal infants, those with VUR have an even higher voiding pressure and abnormal bladder function, even in the absence of UTI.[59] A discoordinated pattern of voiding was the most common urodynamic abnormality in both male and female infants with VUR. Additionally, abnormally high voiding pressures with small functional bladder capacity or poor bladder contractility with inadequate emptying was seen primarily in boys. Others have also noted an increased incidence of bladder "hypercontractility" in infant boys with VUR.[61] This higher voiding pressure and its association with a higher incidence of high-grade VUR in infant males has been attributed to transient urethral obstruction, especially when intravesical ureteral tunnels are not fully mature.

In a fetal sheep model of VUR, defunctionalization of UVJ (surgical unroofing of the submucosal ureter) was insufficient to produce VUR reliably in females, who also required a partial ligation of the urethra in order to reproduce a similar degree of VUR as seen in males with UVJ unroofing only.[62] Such experimental observations, along with VUR-associated urodynamic abnormality analogous to that seen in boys with posterior urethral valves, led to a speculation that transient urethral obstruction may be the cause of infantile VUR in some cases.

The abnormal urodynamics seen in infants with VUR may also imply a global maldevelopment of the trigone and proximal urethral mechanism, which needs to funnel open in coordination with detrusor contraction in order to induce efficient, low-pressure emptying. Godley and colleagues studied the clinical outcome of infants with VUR in relation to the overall renal status and the bladder function and found that those with abnormal kidneys were more likely to have an abnormal bladder function, as well as failure of VUR resolution.[63] These observations further support the notion that the entire spectrum of VUR disorder—reflux, renal anomaly, and bladder dysfunction—may result from the primary maldevelopment of the ureter–trigonal complex.[44,51]

Symptoms of pediatric voiding dysfunction—frequency, urgency, and enuresis—lie on a spectrum with detrusor instability (DI) and/or detrusor sphincter dyssynergia (DSD), and they are often found in patients with UTI and VUR. In a study of more than 360 children with dysfunctional voiding, 60% had UTI and 20% had VUR.[64] The European branch of the International Reflux Study found the presence of dysfunctional voiding in 18% of more than 300 children with VUR and UTI,[65] and urodynamic investigation showed that DI may be found in up to 60% of children with VUR.[66,67] Despite these well-documented associations, it is unlikely that VUR is directly caused by DI in most cases. Many more children have DI than VUR. There are also reports showing no statistical causal association between DI and VUR.[68] However, in patients with marginally competent UVJ, DI may exaggerate the VUR. It is generally accepted that unrecognized DI can delay the resolution of VUR, and there are reports that the treatment of DI with anticholinergics can facilitate the VUR resolution.[66,69] Some studies, however, have

not shown any beneficial effect of anticholinergic therapy in the elimination of VUR.[70]

Although DI may not induce VUR directly, it plays an important role in the overall pathophysiology of the VUR–UTI–nephropathy complex. The presence and severity of dysfunctional voiding symptoms correlated significantly with the persistence of VUR during medical management and further correlated with the UTI recurrence regardless of surgical correction of VUR.[65] In fact, the mutual association of DI and VUR to UTI may explain its clinical coexistence in many clinical scenarios.

ROLE OF UTI IN VESICOURETERAL REFLUX

Tanagho and colleagues proposed that lower urinary tract inflammation might affect the mildly deficient UVJ and induce VUR.[45] New VUR was reportedly acquired in six out of seven experimental piglets after *Escherichia coli* infection and bladder inflammation.[71] Some *E. coli* strains have been implicated to affect the activity of urinary tract smooth muscle directly, rather than via inflammatory reaction. Bacterial endotoxin was found to inhibit α-adrenergic receptors of trigonal musculature in cats.[72] Similarly, UTI may cause human ureteral dilatation.[73,74] Such a direct effect of bacterial infection on ureteral smooth muscle function could conceivably induce ureter–trigonal dysfunction, thereby facilitating VUR. Since UTI is also known to induce bladder hypercontractility and lower the compliance, a combined challenge of both ureter and bladder muscle dysfunction by UTI may well cause VUR in patients with marginally competent UVJ.

Clinically, it had been suggested that VCUG performed at the time of ongoing UTI might "falsely" demonstrate VUR, which was not present when the urine was sterile. Gross and Lebowitz surveyed more than 600 children undergoing cystographic evaluation for VUR and found no evidence of increased VUR in the setting of positive urine cultures.[75] In other words, their data did not support the notion that VUR was caused by UTI.

Whether the combined challenge of UTI and abnormal bladder dynamics leads to the *secondary* (or acquired) VUR or merely discloses preexistent *primary* VUR, it is clear that they are critical cofactors to contend with in the overall management of patients with VUR.

CONCLUDING REMARKS

Although VUR remains a significant and commonly encountered clinical problem in pediatric urology, VUR may be a normal transitory phenomenon in many species and in some humans. It is a dynamic process involving anatomical and functional anomalies and maldevelopment of the ureter–trigone complex and the UVJ, as well as the effects of UTI and lower urinary tract dysfunction. The clinical significance of VUR must be interpreted in the context of global urinary tract anomalies, including bladder dysfunction, inherent predisposition to UTI, and congenital or acquired reflux nephropathy.

CHAPTER 43

Nonsurgical Management of Vesicoureteral Reflux

Jack S. Elder and Mireya Diaz

INTRODUCTION

In a child with vesicoureteral reflux (VUR), the primary goal of therapy is to prevent pyelonephritis, because repeated upper urinary tract infection (UTI) can lead to renal scarring and, in some cases, hypertension, reduced somatic growth, renal insufficiency, and end-stage renal disease (ESRD). In addition, reflux-related complications during pregnancy may occur. If a child with VUR already has reduced renal function, then additional treatment may be necessary to preserve existing renal function as the child grows. The clinical factors that place the patient at risk for these complications include high VUR grade, female gender, presence of bladder–bowel dysfunction (BBD), and presence of renal scarring.

Nonsurgical therapy is based on the following principles: (1) higher grades of VUR increase the risk of developing pyelonephritis; (2) VUR often resolves over time; (3) sterile VUR is not harmful to the kidneys, if bladder function is normal; (4) UTI in the presence of VUR can result in acute pyelonephritis, which can result in renal scarring; and (5) the morbidity or complications of VUR can be decreased by preventing UTI. In contrast, the principle of surgical therapy is that the risks associated with VUR and nonsurgical therapy can be minimized or prevented with surgical correction. The benefits and risks of these two approaches must be considered when deciding on a course of therapy.

Options for nonsurgical therapy include

1. Antibiotic prophylaxis
   a. Daily
   b. Intermittent (i.e., treatment of UTIs when they are diagnosed)
2. Bladder training (urotherapy)
3. Treatment of BBD: Timed voiding
   a. Treatment of constipation
   b. Anticholinergic
   c. Alpha-blocker
   d. Biofeedback
4. Periodic assessment of reflux and child well-being
   a. Serial assessment of blood pressure, renal function, and somatic growth
   b. Serial urinalysis or urine culture
   c. Serial voiding cystourethrogram or radionuclide cystogram
   d. Serial upper urinary tract studies

An individualized approach to each child utilizing shared decision making with parents takes into account the child's gender, VUR grade, age, presentation (UTI, sibling screening, and antenatal diagnosis), renal status at the beginning of therapy, compliance with treatment, likelihood of reflux resolution, and parent and child preferences.

REFLUX RESOLUTION

The decision to choose nonsurgical management in a child with VUR is based on the fact that reflux often resolves, and when it resolves, the risk of upper tract infection is reduced. The exact mechanism of reflux resolution is unknown. Presumably, the intramural ureteral tunnel lengthens with bladder growth and with bladder functional maturation.

VUR resolution is most likely in younger children and those with lower reflux grades (Figure 43.1). The 1997 American Urological Association (AUA) Pediatric Vesicoureteral Reflux Practice Guidelines Committee analyzed the raw data from several series in which long-term treatment was nonsurgical to develop these figures.[1–4] At 5 years, approximately 92% with grade I and 81% with grade II VUR showed resolution, irrespective of age at presentation or whether the reflux was unilateral or bilateral. On the other hand, in grade III VUR, resolution was highest for unilateral grade III reflux in children less than 2 years (70%) and lowest for children with bilateral grade III reflux over 5 years at diagnosis (12.5%). In contrast, in a large series by Greenfield et al., for children with grade III VUR, resolution was similar irrespective of age at presentation.[5] In the AUA series, unilateral grade IV VUR resolved in 50% at 5 years, whereas only 10% of those with bilateral grade IV VUR resolved.[1] For grade IV VUR, age was not stratified because of small patient numbers. In a report of 80 infants who were <6 months at diagnosis with grades III–V VUR, resolution of VUR (including reduction of VUR grade to I or II) occurred in 62%.[6] These children

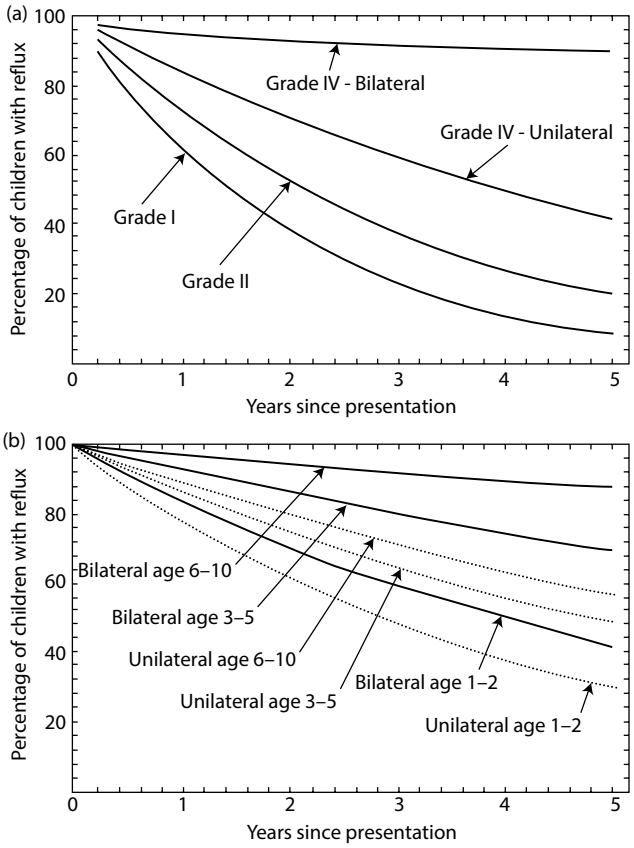

FIGURE 43.1 Percent chance of reflux persistence for 1–5 years following presentation. (a) Grades I, II, and IV reflux (bilateral and unilateral). (b) Grade III reflux by patient age reflux laterality at presentation. (Reprinted from Elder JS et al. *J Urol* 1997;157:1846–51.)

were diagnosed following either an antenatal diagnosis of hydronephrosis or a UTI. Overall, only 25% had surgical correction. A normal initial dimercaptosuccinic acid (DMSA) scan, an initial reflux grade of less than V, and the absence of breakthrough febrile UTIs were predictive of reflux resolution or improvement. There are more recent nomograms for predicting VUR resolution rates,[7] but they include a large number of children that drop out for surgery. This diminishes the number of medically treated children with VUR and might bias the reported resolution rate.

There is little available observational follow-up that is longer than 5 years. Ten-year follow-up of the medical treatment arm of the International Reflux Study showed reflux resolution in 73% of those with unilateral grade III or IV VUR.[8] In children with grade III or IV VUR on one side and grade I or II on the other, 49% had resolved, and in those who presented with bilateral grade III or IV VUR, only 39% resolved. In a series from Children's Hospital of Philadelphia, 10/51 children (19.6%) (mean age 8.6 years) who were taken off antibiotic prophylaxis demonstrated VUR resolution, and 5/51 (9.8%) developed a febrile UTI.[8] It is known that VUR can resolve during adolescence. For example, in the series by Lenaghan, VUR resolution was reported in 20%, but their patients were not studied systematically.[9]

The timing of VUR during a voiding cystourethrogram can predict reflux resolution. If VUR occurs during bladder filling, when bladder pressure is low, it is much less likely to resolve or improve significantly, whereas if VUR is demonstrated only during voiding, when bladder pressure is high, it is much more likely to resolve over time.[10,11] Bladder capacity does not appear to be a relevant factor. Bael et al. demonstrated that bladder capacity varies widely in children with VUR, and that there is no relationship between bladder capacity and reflux grade or likelihood of VUR resolution.[12]

ANTIBIOTIC PROPHYLAXIS

In the past, the cornerstone of UTI prevention was daily antimicrobial prophylaxis. The basis for prophylaxis is that in the 1960s and 1970s, children with VUR were managed by treating each UTI as it occurred, i.e., intermittent therapy. Several retrospective studies of children with VUR suggested that the rate of new renal scar formation was significantly lower in children receiving prophylaxis (as low as 3%).[3,5,13,14] In addition, it was concluded that girls with VUR were more likely to develop renal scars than boys, renal scars can occur at any age, children with mild VUR were at risk for scar formation, and scarring could occur in normal kidneys. Several earlier studies suggested that new renal scarring occurred primarily in children with a breakthrough febrile UTI.[2–5] However, there is also evidence that new scarring can occur in older as well as young children.[15–18] The efficacy of prophylaxis in preventing the ultimate complication of renal scarring, ESRD, was questioned in a review of the Australia and New Zealand Dialysis and Transplant Registry from 1971 to 1998, in which no significant reduction of ESRD secondary to VUR was observed, despite implementation of routine prophylaxis for VUR.[19]

More recently, there has been considerable concern regarding the risk of bacterial resistance resulting from inappropriate use of antibiotics, and many parents question the benefit and safety of continuous antibiotic prophylaxis (CAP). Furthermore, several prospective randomized clinical trials have demonstrated that prophylaxis in children with VUR is often ineffective. These series are summarized in Tables 43.1 and 43.2.[20–27] Four of the seven prospective trials suggested that there was no benefit to prophylaxis in children with VUR. As is common in clinical trials, there was significant variation in the quality of these studies, and most of the children had low-grade VUR. However, the Swedish Reflux Trial, which studied children ages 1–2 years with grades III and IV VUR, demonstrated a clear advantage to prophylaxis in girls.[25] In this study, no child receiving prophylaxis developed a new renal scar.[26] The benefit of prophylaxis in this study of dilating VUR was statistically significant in girls, but not in boys. The study by Craig et al. indicated that the rate of UTI was diminished from 19% (placebo) to 13% (prophylaxis).[24] The most recent trial was RIVUR (Randomized Intervention for Vesicoureteral Reflux). This trial was a randomized prospective double-blind placebo-controlled study of 607 children, ages 2–72 months (median 12 months), 92% of whom were girls.[27] After 2

TABLE 43.1 Randomized trials of antimicrobial prophylaxis for vesicoureteral reflux

Authors	Randomized/ placebo controlled	Patient age	Number studied	Patients included	No. With vur	Vur grade	Urine collection in non-toilet-trained children	Definition of uti	Duration of follow-up (months)
Garin et al.[20]	Yes/no	1 month–18 years	218	UTI ± VUR	113	I–III	Bladder catheterization if unable to void	Pyuria + significant bacteriuria	12

[a] Febrile UTI.

years, trimethoprim-sulfamethoxazole (TMP-SMZ) prophylaxis diminished the risk of UTI by 50%. The benefit was most apparent in children who had had a febrile UTI before entry and in those with BBD. However, the rate of new renal scarring was similar in the two treatment groups (11.9% vs. 10.2%).

A unique aspect of the RIVUR study is that TMP-SMZ resistance of *Escherichia coli* isolates was evaluated by rectal swab at study entry, at 24 months, and following an occurrence of treatment failure.[27] Overall, the authors found an insignificant difference in *E. coli* resistance between the prophylaxis group (27.6%) and the placebo group (19.5%). However, in the children who experienced treatment failure secondary to *E. coli*, 19/30 (63.3%) receiving TMP-SMZ prophylaxis had resistant stool isolates, compared with 11/57 (19.3%). With regard to antibiotic adherence (i.e., compliance), 77% of the families reported having administered the prescribed medication at least 75% of the time. Of the children receiving the prophylactic TMP-SMZ, 91/302 (30%) of the parents reported having discontinued administration of the drug. In a "real-world" study from a national pharmacy claims database, antibiotic adherence was only 40%.[28]

The 2010 AUA VUR guidelines recommended prophylaxis for children less than 1 year of age, whereas in children over 1 year, it was a treatment option.[29] In addition, if a child with VUR not receiving prophylaxis developed a febrile UTI, it was recommended that initiation of prophylaxis should be considered. These guidelines were based on studies reported through 2008 and did not include the Swedish Reflux Trial, which was reported in 2010 and strongly supported prophylaxis in girls with grades III and IV VUR; the Craig trial; or the RIVUR trial.

Consequently, daily antibiotic prophylaxis appears to be beneficial in girls with grades III–V VUR and boys with grades IV and V VUR. On the other hand, children with grades I and II VUR and boys with grade III VUR may not benefit from prophylaxis, unless they have BBD (see below).

Common medications used for prophylaxis include TMP-SMZ, nitrofurantoin, TMP, and cephalexin. Generally, a dosage that is one-quarter to one-half of the full dose is prescribed, and administration at bedtime theoretically yields the optimal benefit. Although it has been assumed that TMP and SMZ are synergistic in the treatment of UTI, it has been demonstrated that TMP alone is as effective as the combination medication, and significantly more effective than SMZ in the treatment of *E. coli* UTI.[30] Edlin et al. demonstrated that in an outpatient setting, *E. coli* resistance to nitrofurantoin was only 1%, vs. 24% for TMP-SMZ.[31] Nitrofurantoin and TMP are excreted only in the urine and do not induce a change in bowel flora.

Antibiotic resistance is receiving significant exposure in the press, and recently, the World Health Organization released an extensive report on its efforts for global surveillance on antibiotic resistance.[32] In this era of shared decision making, parents will be increasingly uncomfortable administering a daily antibiotic or antimicrobial unless there is good evidence for its benefit for their child. In addition, in the case of VUR, parents may choose surveillance or surgical therapy (endoscopic, open, or minimally invasive) over prophylaxis.

Potential adverse effects of nitrofurantoin suspension include gastric upset, nausea, and a very poor taste to the medication. Use of nitrofurantoin macrocrystals in a capsule can obviate these problems. In young children, the capsule may be opened and the macrocrystals can be mixed with food or formula. More serious side effects are rare, with one study documenting only 40 reports out of 8.6 million uses.[33] TMP-SMZ is generally well tolerated, although Uhari et al. reported that the medication was changed because of adverse effects in 15% of children receiving sulfonamides and 8% receiving TMP.[34] The most common adverse effect is allergic skin reaction, usually from the sulfa component. This problem may occur following several weeks or months of therapy, but anaphylaxis is rare. Although neutropenia, thrombocytopenia, and/or eosinophilia occurs in 12%–34% of children receiving full-dose TMP-SMZ for only 10 days,[35] the incidence of these side effects in children receiving prophylactic dosages as long as 1 year is quite low.[36] Photosensitivity is another concern with sulfa-based antimicrobials. An additional potential complication is dental caries secondary to the fructose in the liquid preparation, but this problem can be prevented by having the children brush their teeth after taking the drug. The most serious potential side effect is Stevens–Johnson syndrome, but this reaction is extremely rare.

In babies up to 2 months of age, amoxicillin or cephalexin should be prescribed instead of a sulfa-based antibiotic or nitrofurantoin. Typically, 50–75 mg once or twice daily (either amoxicillin or cephalexin) is prescribed.

BLADDER–BOWEL DYSFUNCTION

BBD is one of the most important clinical factors contributing to recurrent febrile UTI and renal scarring in children with VUR.[29,37] BBD is used to describe children with abnormal lower urinary tract symptoms of storage and/or emptying, which include lower urinary tract conditions, such as overactive bladder and urge incontinence, voiding postponement, underactive bladder, and dysfunctional voiding, and may also include abnormal bowel patterns, such as constipation and encopresis.[29] Many of the terms pertaining to abnormal lower urinary tract symptoms were described in an article on nomenclature published by the International Children's Continence Society (ICCS).[38]

The effect of bladder dysfunction on VUR has been recognized for many years. In 1979, Koff et al. studied 53 neurologically normal children with UTI and detrusor sphincter discoordination and found that 50% had VUR.[39] In 1983, Koff and Murtagh reported that in children with VUR, uninhibited bladder contractions, and voluntary sphincter contraction, treatment with anticholinergics resulted in a threefold increase in VUR resolution and fourfold reduction in UTI.[40] In 1985, Noe retrospectively studied 305 patients undergoing ureteral reimplantation for primary reflux and noted that reflux persisted postoperatively in 11, of whom 6 required a secondary procedure. All 11 children had diurnal and nocturnal enuresis, frequency, urgency, and squatting, while 4 had

straining and an interrupted urinary stream, 2 had significant postvoid residual urine, and 3 had a neurogenic configuration of the bladder on cystography.[41] In 1991, Snodgrass reviewed 109 children with UTIs or dysfunctional voiding without UTI and found that one-third of girls with VUR had dysfunctional voiding, and 21% of girls with dysfunctional voiding had VUR, suggesting an association between these two conditions, but not a cause-and-effect relationship.[42]

In 1998, in a landmark retrospective study, Koff et al. reported that bowel disorders also contribute to VUR morbidity, and coined the term *dysfunctional elimination syndrome* (DES).[43] In a retrospective study of 143 children with primary VUR, DES was present in 43% of children thought to have primary VUR. Of these, 82% had breakthrough UTIs and underwent ureteral reimplantation, compared with 18% with VUR without DES. Following the disappearance of VUR, UTI developed in 18 children, including 14 (78%) with DES. Unsuccessful surgical outcomes involving persistent, recurrent, and contralateral VUR occurred only in children with DES. Unfortunately, this study was published the year after the initial AUA VUR guidelines, and its importance was not recognized until the second AUA VUR guidelines report.

Snodgrass reported a series of 128 children with VUR, 66 of whom had dysfunctional voiding and underwent treatment with anticholinergic therapy and antibiotic prophylaxis.[44] Although the VUR resolution rate was similar among those with and without dysfunctional voiding, 43% of those with BBD had a breakthrough UTI, whereas only 5% of patients without BBD had a breakthrough UTI. This report supported the findings of the study by Koff et al.[43] In another report, Chen et al. evaluated a database of 2759 children with UTI, VUR, or both, and found that 36% of girls with VUR had BBD and 21% of boys with VUR had BBD.[45]

The potential risk of BBD in a child with VUR is exemplified in a clinical case in Figure 43.2.

BBD in Infants

BBD in >2-year-old children is characterized by a combination of the following symptoms: urgency, urge incontinence, frequency, infrequent voiding, and constipation. In infants, however, parents typically are unaware of their child's toileting habits, unless they have significant constipation.

Sillén et al. evaluated the voiding pattern in 41 infants with grades III–V VUR using a noninvasive 4-hourly voiding record.[46,47] They found that 36% of boys voided frequently in small volumes, often with an uninterrupted stream, compared with 15% of the control group. Girls with moderate- and high-grade VUR typically were infrequent voiders. In addition, residual urine volume was significantly elevated in both boys and girls. The same group performed urodynamic studies in infants admitted to the hospital with clinical pyelonephritis.[48] Bladder instability was found in two-thirds of male and female infants. Compared with older children, male infants had a high voiding detrusor pressure and low bladder capacity. Female infants also had increased voiding pressure levels, but they were significantly lower than those in male infants. The voiding detrusor pressure was even higher in both sexes when evaluation was delayed after the UTI.

In a subsequent study, 89 males and 25 females with grades III–V dilating VUR underwent three videocystometric studies at mean ages of 6, 20, and 40 months.[49] They found that the voiding pattern at 6 months was similar in infants with VUR and controls. However, at 20 months, bladder dysfunction was seen in 48 children (42%), of whom 34 primarily had high bladder capacity with incomplete emptying ("dilated bladder dysfunction") and 14 had an overactive bladder. Predictors for development of dilated bladder dysfunction were high residual urine at 6 months and recurrent UTIs. Recurrent UTIs were significantly correlated to high residual urine at all investigations and to detrusor overactivity at the 20-month examination.

In summary, nearly half of infants with dilating VUR have dysfunctional voiding, including enlarged bladder capacity, overactive bladder, and incomplete bladder emptying; bowel dysfunction has not been systematically assessed in this patient population. Breakthrough UTIs occur most commonly in affected infants.

Medical Risks in Children with VUR and BBD

Few prospective trials have been conducted in children with VUR and BBD. However, children with VUR need to be assessed for BBD because the association of these conditions increases the risk for VUR-related complications. In addition, BBD in children with VUR requires directed therapy.

In the Swedish Reflux Trial, 203 children age 1–2 years with grades III and IV VUR were randomly assigned to receive antibiotic prophylaxis, subureteral injection therapy, or observation and were monitored for a period of 2 years.[50] At study entry, 20% of patients had lower urinary tract dysfunction characterized by high bladder capacity and increased postvoid residual urine volume.[51] After 2 years of follow-up, BBD was evident in 34% of all patients. Overall, 9% had an overactive bladder and 24% had voiding phase dysfunction. Those with voiding phase dysfunction at 2 years were significantly less likely to have VUR resolution. Renal damage at study entry and at 2-year follow-up was significantly more common in patients with lower urinary tract dysfunction. Recurrent UTIs occurred in 33% of children with and 20% of those without BBD, but these differences did not reach statistical significance.[51] These results were similar to previous reports that indicated BBD increases the risk of breakthrough UTI in children with VUR.

The 2010 AUA Reflux Guidelines Committee performed the most comprehensive analysis of the association between BBD and VUR through to 2008.[29] The reports that were analyzed included 2039 children with VUR, 75% of whom were female and 32% of whom had a concurrent diagnosis of BBD. In children receiving CAP, spontaneous resolution rates were 31% for those with BBD and 61% for those without BBD (Figure 43.3). The incidence of UTI managed with CAP was 44% in children with BBD and 13% in those without BBD (Figure 43.4), indicating that BBD is a significant risk factor for UTI in children with VUR receiving CAP. In children with VUR treated

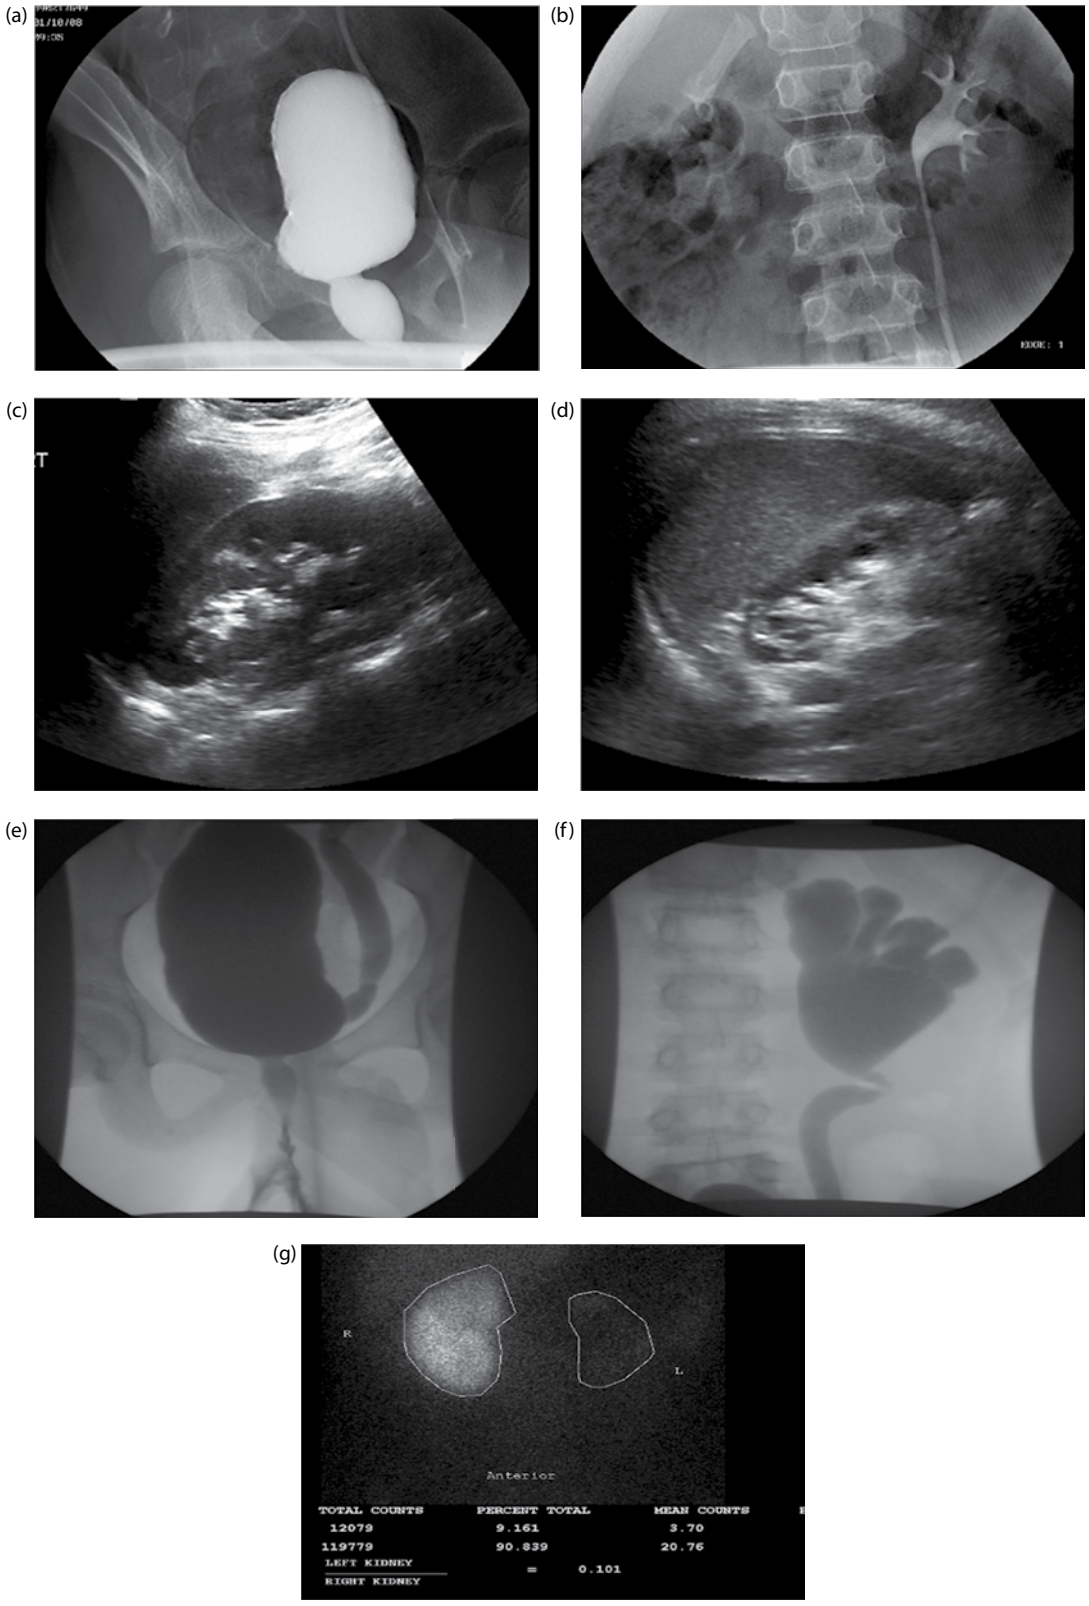

FIGURE 43.2 Six-year-old girl with BBD, with day and night incontinence and febrile UTIs. (a and b) A VCUG shows detrusor hypertrophy, "spinning top" deformity of urethra, and bilateral grade II or III VUR. Patient treated with antibiotic prophylaxis, bladder training, and anticholinergic therapy. Patient did not return for follow-up after age 7 years. At age 12 years, the child returned with recurrent febrile UTI and diurnal incontinence. (c and d) A renal sonogram shows a normal right kidney (c) and small irregular left kidney (d). (e and f) A VCUG shows detrusor hypertrophy and grade V left VUR with calyceal clubbing. (g) A DMSA renal scan shows a normal right kidney and minimal function in the left kidney.

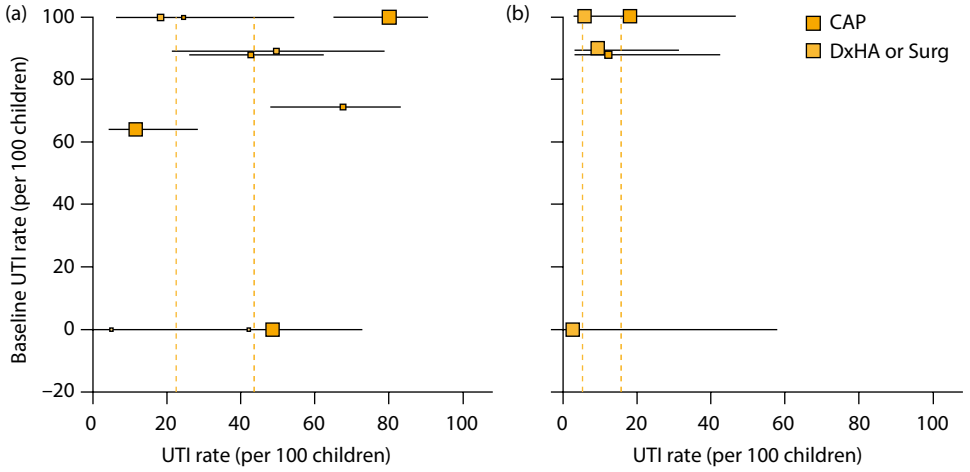

FIGURE 43.4 Forest plots comparing rates of UTI in children with (a) and without (b) BBD. DxHA = subureteral injection with dextranomer–hyaluronic acid copolymer; Surg = open surgery. Figures were drawn from data available from the AUA VUR guidelines. (Adapted from Peters CA et al. *J Urol* 2010;184:1134–44.)

surgically with subureteral injection therapy, resolution rates at 3–12 months were 50% for those with BBD and 89% for those without BBD (Figure 43.3). For children treated with open surgery, the presence of BBD did not alter the surgical resolution rate, which was 97% in both groups.[29] In each of these groups, the specific treatment method of BBD could not be assessed. Finally, the meta-analysis showed that the incidence of UTI was 22.6% for children with BBD and 4.8% for children without BBD following open or endoscopic surgical treatment, representing a statistically insignificant difference ($P = 0.08$); however, BBD outcomes were not stratified by sex, grade, or laterality for the BBD and non-BBD groups. More recent studies also have demonstrated that the rate of UTI following endoscopic injection therapy is higher in children with a history of BBD than in children without BBD (Table 43.3).

Based on these data, the 2010 AUA VUR guidelines recommend as a *standard* that symptoms indicative of BBD should be sought in the child's initial evaluation.

Evaluation for BBD in Children with VUR

Symptoms of BBD include urinary frequency and urgency, prolonged voiding intervals, daytime wetting, perineal or penile pain, holding maneuvers (posturing to prevent wetting), and constipation or encopresis (Table 43.4). Important points in the history include the pattern of incontinence, including the frequency, the volume of urine lost during incontinent episodes, whether the incontinence is associated with urgency or giggling, whether it occurs after voiding, and whether it is continuous. The frequency of voiding and whether there is nocturnal enuresis; a strong, continuous urinary stream; or sensation of incomplete bladder emptying should be assessed. Bowel habits also should be evaluated, because incontinence is common in children with constipation and/or encopresis. Physical examination is directed at identifying signs of organic causes of incontinence: short stature, hypertension, enlarged kidneys and/or bladder, constipation, labial adhesion, ureteral ectopy, back or sacral anomalies, and neurologic abnormalities.

TABLE 43.3 Studies of VUR in patients with or without VUR, 2008–2014

Study	VUR intervention	BBD intervention	Duration of treatment	Incidence of UTI in patients	
				With BBD	Without BBD
Chi et al.[52]	Dextranomer–hyaluronic acid injection therapy	Anticholinergic, bladder training, stool softeners	Median 32 months	17/39 (44%)	12/58 (21%)
Dwyer et al.[53]	Dextranomer–hyaluronic acid injection therapy	Anticholinergic, bladder training, stool softeners	Median 28 months	12/48 (24%)	5/58 (9%)

TABLE 43.4 Evaluation and management of bladder–bowel dysfunction

Clinical aspects	Urinary	Bowel
Signs and symptoms	Increased or decreased urinary frequency Daytime incontinence Urgency Nocturia Hesitancy Straining Weak stream Intermittent stream Holding maneuvers Sensation of incomplete voiding Postvoid dribbling	Two or fewer defecations per week ≥1 episode per week of stool incontinence Excessive stool retention Painful or hard bowel movements Large fecal mass in the rectum Large-diameter stool that blocks the toilet
Evaluation	Physical examination Bladder diary Pediatric Symptom Checklist Uroflow[a] Invasive urodynamics 4-hour voiding observation (infants) 24-hour fluid consumption and urine volume Voiding cystourethrogram	Abdominal x-ray Pelvic ultrasonography Spinal MRI
Management	Behavioral modification (e.g., timed voiding, bladder diary) Alarm therapy Biofeedback Sacral neuromodulation Pharmacologic (e.g., anticholinergic, alpha-blocker) Intermittent catheterization Antimicrobial prophylaxis (if recurrent UTI)	Education and behavioral modification Disimpaction Dietary intervention Oral laxatives Enemas Behavioral therapy and biofeedback

[a] Postvoid residual urine volume, flow rate, and flow curve shape.

Assessment tools should include urinalysis, with culture if indicated. In addition, a bladder diary, post-void residual urine volume (generally obtained by bladder scan), Dysfunctional Voiding Symptom Score (Figure 43.5), Bristol Stool Form Score (Figure 43.6), and uroflow with or without Electromyography (EMG) (patch electrodes) (patch electrodes) may be useful.

To help assess whether voiding dysfunction (BBD) is present, Farhat et al. reported a validated Dysfunctional Voiding Scoring System (DVSS), which consists of 10 questions pertaining to urinary and bowel habits.[57] Subsequently, this group applied the DVSS to children with reflux in a retrospective study. In children with a high symptom score managed with behavioral modification, those with a significant reduction in symptom score were most likely to show reflux resolution or improvement, whereas those with only a minor reduction in symptom score tended to have persistent reflux.[58] Prospective trials of this type of scoring system are necessary.

Bladder Diary

A record or diary of when the child voids and whether the child was wet or dry before voiding can also be helpful. Indeed, the 14-day bladder diary is useful in children of >5 years of age and in children who have achieved bladder control.[37] Important information recorded in the diary includes frequency of diurnal incontinence, frequency of daytime voiding, frequency of nocturia, severity of nocturnal enuresis, fluid intake volume and time, when the child goes to sleep and wakes up, frequency of defecation, and severity of encopresis.

Assessment of Bowel Function

Until recently, assessment of stool habits was based on the Bristol Stool Scale, in conjunction with stool frequency. The definition and diagnosis of functional constipation have evolved recently, following an international consensus (Rome III) for assessing this disorder.[59] Some urologists use the Rome III diagnostic criteria, which classify

Appendix 1 – *Original dysfunctional voiding symptom score.*

Over the Last Month	Almost Never	Less than Half the Time	About Half the Time	Almost Every Time	Not Available
1 - I have had wet clothes or wet underwear during the day.	0	1	2	3	NA
2 - When I wet myself, underwear is soaked.	0	1	2	3	NA

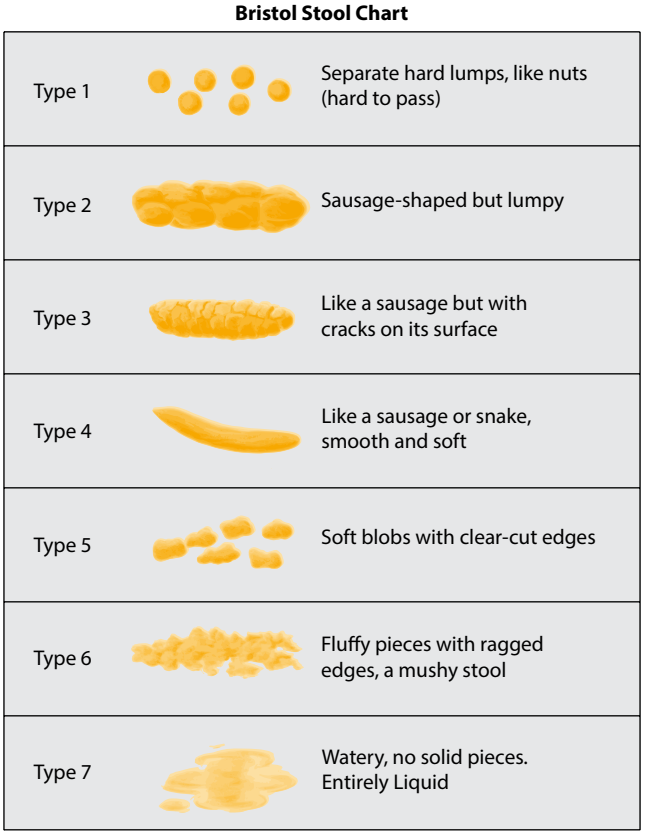

FIGURE 43.6 Bristol Stool Scale.

functional gastrointestinal disorders that do not have underlying structural or tissue-based causes.[60] Children of ≥4 years of age are diagnosed as being constipated if they fulfill two or more of the following criteria over a period of 2 months: two or fewer defecations in the toilet per week, at least one episode of fecal incontinence per week, a history of retentive posturing or excessive volitional stool retention, a history of painful or hard bowel movements, the presence of a large fecal mass in the rectum, and a history of large-diameter stools that obstruct the toilet.[59,61] In 2013, the ICCS published a report on the evaluation and management of functional constipation in children with lower urinary tract symptoms.[62] They recommended a complete history (including assessment of lower urinary tract symptoms and constipation) and physical, a urinalysis, a 7-day bowel diary, and measurement of postvoid residual urine volume, rectal diameter, and bladder wall thickness. For complex cases, they recommended evaluation by a pediatric gastroenterologist (colonic transit measurement, spinal MRI, defecography, and anorectal manometry). Encopresis was not addressed in this document, but is presumably a severe form of functional constipation.

Pediatric Symptom Checklist

The Pediatric Symptom Checklist (PSC) consists of 35 questions pertaining to cognitive, emotional, and behavioral problems experienced by the child; it may also be helpful in assessing external factors contributing to BBD. The questionnaire can be filled out by the parent or by both parent and child.[63,64] Those with a high overall PSC score may be referred to a pediatric clinical psychologist for evaluation and treatment, particularly if they are not already under the care of a neurologist. In addition, the Parenting Stress Index/Short Form (PSI/SF) may be useful in children who are refractory to conventional treatment. In addition, there is evidence that bullying might contribute to pediatric BBD.[65,66]

Urodynamic Tests

Noninvasive Urodynamic Tests

Uroflow

Measurement of urine flow and residual urine volume is an important diagnostic study, and consideration should be given to repeating these measurements once or twice to be certain that the results are consistent. Furthermore, pelvic floor electromyography is quite useful during uroflow to demonstrate sphincter relaxation during micturition (normal) or sphincteric contraction during micturition (indicative of detrusor sphincter discoordination).

The maximum flow rate is the most relevant variable and should be based on peak flow rates that have a duration of at least 2 seconds.[37] In healthy children and adults, a linear correlation between maximum flow and the square root of voided volume has been reported.[67] For example, if the square of the maximum flow is equal to or exceeds the voided volume in milliliters, the recorded maximum flow is probably within the normal range. Furthermore, the normal voiding curve is smooth and bell shaped, but in children with bladder outlet obstruction, a plateau curve of low amplitude can be recorded. If the patient has sphincter overactivity during voiding, a staccato flow curve is recorded, termed a continuous but fluctuating flow curve. In a staccato flow curve, the fluctuations should be larger than the square root of the maximum flow rate.[37]

In children, the postvoid urine volume might not consistently be <10% of bladder capacity, as it is in healthy adults, but the bladder should empty to this level at least once during a 4-hour observational period.[68] A volume of >20 mL on repetitive occasions suggests incomplete emptying, assuming the child has not waited too long before voiding. A persistent elevated postvoid residual urine volume is suggestive of BBD, but is also observed in boys with a urethral stricture.

An important urodynamic measurement to evaluate detrusor function in infancy is the 4-hourly voiding observation. This assessment involves continuous observation of a freely moving infant with frequent ultrasonography measurements of bladder filling and measurement of residual urine after each micturition. Voided volume can be measured by weighing the infant's diaper.[46]

Invasive Urodynamic Tests

Urodynamic assessment (or videourodynamics) should be performed if the child has symptoms of detrusor sphincter discoordination (such as intermittent stream, slow stream, or incomplete bladder emptying), and if he or she does not respond to empirical treatment (European Association

of Urology [EAU] recommendation).[69] The voiding cystourethrogram (VCUG) should be inspected carefully for evidence of detrusor sphincter discoordination, with the presence of a dilated urethra proximal to the sphincter (the so-called spinning top deformity) in both girls and boys (Figure 43.2a).[70] If the patient has VUR of grade III or higher, a DMSA renal scan is indicated to determine whether the child has renal scarring.

An appropriate filling rate is 5% of the expected bladder capacity per minute.[71] The expected bladder capacity (mL) is approximately (Age [in years] + 2) × 30. With regard to bladder sensation, decreased bladder sensation during bladder filling is suggestive of detrusor underactivity.[37] However, unlike older children and adolescents, children of <5 years are only able to express a strong desire to void. Instead, nonverbal signs of bladder sensation must be interpreted, which include holding maneuvers such as toe curling and leg movements.

In a normal urodynamic study, little or no change in pressure is evident during bladder filling and no involuntary bladder contractions occur. In contrast, detrusor overactivity is characterized by involuntary contractions involving an increase of >15 cmH_2O in detrusor pressure above baseline. In normal children, a detrusor pressure of 10 cmH_2O at expected bladder capacity is appropriate, and when bladder capacity is reached, the child experiences considerable suprapubic discomfort. Bladder compliance is an indication of detrusor hypertrophy and is calculated by dividing the volume change by the change in detrusor pressure, and is expressed in milliliters per cmH_2O. However, no reliable reference values for bladder compliance in infancy and childhood are available; in general, detrusor pressure should be 10 cmH_2O at expected bladder capacity for age. The elevated bladder compliance typically is observed in children with neuropathic bladder, valve bladder syndrome, and Hinman syndrome.

To investigate the role of urodynamic assessments in children with VUR and suspected BBD, Ramamurthy and Kanitkar prospectively analyzed the results of history, physical examination, voiding diary, urinalysis, sonography, and renal function tests, and compared these with invasive urodynamics in 41 children.[72] They reported a sensitivity of 88% and specificity of 73% with the noninvasive approach, suggesting that the invasive tests should be reserved for children with complex voiding disorders or those who are resistant to conventional therapy.

MANAGING PATIENTS WITH BBD AND VUR (TABLE 43.4)

The management of children with VUR and BBD should be individualized. Currently, no randomized trials have compared children with VUR and BBD receiving treatment with those not receiving specific treatment for BBD. Despite this fact, both the 2010 AUA and 2015 EAU/ESPU (European Society for Paediatric Urology) guidelines agree that BBD should be treated in children with VUR.[29,69] For these reasons, comparison of medical treatment options is difficult.

Urotherapy (Bladder Training)

Bladder training refers to regular, volitional, complete emptying of the bladder through behavioral conditioning to achieve balanced, low-pressure voiding with coordinated relaxation of the external sphincter and pelvic floor during voiding. The goal of bladder training is to reduce the likelihood of developing UTI and reduce voiding pressure. Measures include a voiding schedule every 2–3 hours, complete bladder emptying during micturition, reeducation in proper voiding dynamics if voiding dysfunction is present, and elimination of constipation. The practice also includes genital and perineal hygiene. Although these recommendations are practical, no firm evidence exists that a specific regimen is beneficial.

Bowel Management

Aggressive treatment of constipation is the first step in dealing with BBD. Typically, in these children, maintenance treatment with polyethylene glycol powder dissolved in water or juice is prescribed once daily, to stimulate a soft bowel movement each day. Compliance with this regimen is inconsistent because of side effects, and concern by the parents that the child might experience encopresis at school. Alternatives include other osmotic oral laxatives (lactulose and magnesium hydroxide), a lubricant laxative (mineral oil), or stimulants (orally or rectally administered bisacodyl or senna). Some have questioned the effectiveness of polyethylene glycol treatment. For example, Bush et al. reported that in a series of 138 children with urinary urge symptoms randomly assigned to empiric polyethylene glycol or placebo, 50% showed improvement in urge symptoms after 1 month of treatment in both groups.[73] In addition, they observed that the plain abdominal film used to assess stool retention did not correlate with baseline or follow-up bowel or urinary symptoms. On the other hand, Champeau and Baskin suggested that all children with lower urinary tract symptoms are constipated and should be treated accordingly.[74] This recommendation was based on the fact that five of the six Rome III criteria are based on patient history, and emphasize that patient history provided by parents is often inaccurate.

Biofeedback

In children with BBD, typically there is inconsistent relaxation of the external sphincter during voiding. This pattern may occur because of repeated unstable bladder contractions that cause the child to tighten his or her sphincter, as opposed to the normal pattern, in which the sphincter is relaxed during a detrusor contraction. Many of these children demonstrate a staccato voiding pattern on a uroflow study. Biofeedback may be useful, not only to establish a normal pattern of sphincteric relaxation during voiding, but also to eliminate or reduce the need for anticholinergic medication for the overactive bladder. A typical treatment session might include a uroflow study, sonographic evaluation of postvoid residual urine volume, and a 1-hour session with perineal patch electrodes for EMG. The child watches the sphincter activity on a television screen and learns to contract and relax his or her external sphincter,

essentially Kegel exercises. In addition to this simple office setup, video games have been developed that help the child coordinate his or her sphincter tone.[75] An alternative is to simply teach the child pelvic floor exercises without using sophisticated urodynamic equipment.[76]

The concept of biofeedback is that children may have difficulty isolating their external sphincter, and biofeedback sessions allow them to learn sphincteric relaxation, which is necessary as a prerequisite to normal bladder emptying. In addition, pelvic floor exercises may also ameliorate unstable bladder contractions. Children should perform these exercises daily, although no formal regimen is used. Several weekly or monthly sessions are necessary to reinforce the importance of the treatment, as well as determine whether voiding patterns are improving and whether residual urine volumes are decreasing. Subsequently, the sessions can be spaced farther apart.

Most reports of biofeedback for the management of voiding dysfunction have been favorable. Some utilize biofeedback in children with symptoms of an overactive bladder that do not respond to anticholinergic therapy and timed voiding, while others use it as an alternative to anticholinergic medication. However, it is uncertain how often anticholinergic therapy can be reduced or eliminated in children with an overactive bladder. Some centers have reported that the need for antireflux surgery was eliminated in many cases,[75] and that the rate of reflux resolution was higher in children submitted to biofeedback.[77] Furthermore, animated biofeedback with video games has been reported to be more effective than nonanimated biofeedback.[78]

Although reports of biofeedback have demonstrated success, many patients undergoing treatment have also been receiving pharmacologic therapy, making it difficult to accurately assess the benefit of biofeedback. One problem when comparing these studies is that inclusion criteria for clinical trials regarding BBD and treatments are inconsistent. The preferences and situations of the families can also influence the kinds of treatments that can feasibly be offered to the patients. For example, some families live far away from biofeedback centers and are unable to make the multiple appointments. In addition, some families prefer to avoid medications, or if medications are prescribed, compliance or adherence might be inconsistent. These issues often occur in families where the child stays in two different homes and the parents have disagreed on the need for treatment.

DeSantis et al. performed a systematic review of reports on biofeedback in patients with BBD with or without VUR.[79] Of the 27 studies included in the review, only one was a randomized controlled trial. Overall, the reduction in UTI was 83% and the improvement in diurnal incontinence 80%. More recently, Fazeli et al. performed a meta-analysis of five randomized controlled trials and was unable to demonstrate any benefit from biofeedback.[80] In their analysis, the rate of resolved incontinence, maximum urinary flow, and UTI was similar in both treatment groups and controls. The authors pointed out that the clinical responses were often short-lived, 6 or 12 months, with little or no mention of longer-term successes. The main issue is that this therapy is recommended as a cookbook approach that is not tailored to specific sets of symptoms. Children with incomplete emptying from infrequent urination often have an abnormal flow pattern that increases the risk of UTI, and they may need a different form of therapy compared with children with diurnal incontinence secondary to a small bladder capacity or overactive bladder. The former require instruction in pelvic floor (external urethral sphincter) relaxation, while the latter need to learn tightening techniques when they have the urge to void in response to detrusor overactivity.

Pharmacologic Therapy

Anticholinergic Therapy

Children with an overactive bladder typically have urgency, frequency, and/or urge incontinence. When girls with this condition sense a sudden bladder contraction, they often cross their legs or squat down on their foot to try to prevent incontinence. In these children, a combination of anticholinergic therapy and timed voiding may be beneficial.[81] The anticholinergic is administered according to the incontinence pattern of the specific child. Most children with an overactive bladder experience incontinence throughout the day and night, and these children should receive the medication so that the effect lasts 24 hours. Other children may be incontinent only during the day, and these children do not need nighttime medication. Typically, 2.5–5 mg of oxybutynin chloride tid is prescribed initially, as it is the only antimuscarinic medication approved for use in children. The medication is available as a tablet or suspension. Typical side effects include xerostomia (dry mouth), facial flushing, reduced sweating, and constipation, and less commonly blurred vision and drowsiness. Side effects are dose related and may be eliminated with dose reduction, or with the extended-release or transdermal patch. Other antimuscarinics include hyoscyamine, which is available as a sublingual tablet, 0.125–0.25 mg qid, or as a capsule taken twice daily; tolterodine 1–2 mg bid; trospium 10–25 mg daily in two doses; darifenacin; solifenacin;[82,83] and propiverine (not available in the United States).[84,85] In children with an overactive bladder who fail urotherapy, anticholinergics can result in diurnal dryness in as many as 80%.[86] These medications have the same potential for side effects as oxybutynin, but their incidence and severity are less. Oxybutynin and tolterodine may affect attention span and short-term memory in elderly patients, but these side effects have not been observed in children.[87] Although these medications are not specifically approved for use in children, they are utilized in many centers, but their dosage and timing of administration need to be individualized and closely monitored. In children receiving an anticholinergic with persistent diurnal incontinence, combining two different medications ("double anticholinergic") has a significant likelihood of achieving dryness.[88] The beneficial effect attributed to anticholinergic medications may be due in part to a placebo effect, as in phase 3 clinical trials many patients achieve dryness on the placebo arm. On the other hand, anticholinergic therapy should be considered a therapeutic modality in children with VUR and an overactive bladder, in that there is an increased likelihood of spontaneous reflux resolution in children

treated with anticholinergics, in addition to its reduction in diurnal incontinence.[39,42]

Alpha-Blocker Therapy

Some children with BBD have pelvic floor overactivity and have significant postvoid residual urine volumes. These children may benefit from alpha-blocker therapy. In a prospective randomized double-blind trial of 38 children, Kramer et al. found that 0.5 mg of doxazosin resulted in a dramatic reduction in incontinence episodes, compared with no change in the placebo group.[89] The differences were not statistically significant, because of small patient numbers. There was significant subjective improvement, however, in the children receiving doxazosin. In a more recent trial of 62 children with VUR and bladder neck dysfunction treated with prazosin or placebo, there was a significant reduction in VUR grade, postvoid residual urine volume, and average flow rate.[90]

CHAPTER
44

Surgery for Vesicoureteral Reflux

John W. Brock III and Douglass B. Clayton

INTRODUCTION

Multiple techniques for the open surgical repair of vesicoureteral reflux (VUR) have been described since Hutch first reported the successful correction of VUR in 1952.[1] Although many methods have been proposed, most of these techniques have become footnotes in the evolution of the surgical management of VUR. Today, most surgeons employ only a handful of the previously described repairs.

The surgical correction of VUR has as its goal the restoration of the flap valve mechanism absent in children with reflux. Success using any of the described open techniques requires adherence to the general surgical principles of proper tissue handling and preservation of tissue vascularity. Specific surgical tenets of ureteral reimplantation surgery include the establishment of an adequate submucosal tunnel, a smooth course for the intravesical ureter, and an adequate posterior bladder wall for submucosal tunnel backing. Despite the emergence of less invasive alternatives to antireflux surgery, open surgical repair of VUR continues to be the "gold standard" against which all other methods are measured.

HISTORICAL BACKGROUND

The earliest descriptions of ureteral reimplantation surgery appeared in the medical literature near the turn of the twentieth century. The first reported ureteroneocystostomy is credited to Tauffer in 1877 by Bovee in a review article on ureteral surgery in 1900.[2] Bovee described 80 cases of ureteral reimplant surgeries, the vast majority performed following accidental division of the ureter at the time of laparotomy for ureteral fistulae resulting from prolonged labor or forceps delivery. Subsequently, other innovative procedures for reimplanting the ureter were described in the early part of the twentieth century unrelated to the treatment of VUR.[3–9]

In 1952, Hutch reported the successful correction of VUR in seven out of nine paraplegic patients with a combined extravesical and intravesical dissection.[1] Hodson followed with his findings that VUR was more common in children with urinary tract infections (UTIs), and that there was a high correlation between VUR and chronic pyelonephritis, as seen on intravenous pyelography (IVP).[10] These landmark papers led to further investigation into the treatment of VUR and played a pivotal role in the development of pediatric urology as a separate subspecialty.

Following Hutch's seminal paper, many surgical techniques were described. Landmark refinements of Hutch's operation included Politano and Leadbetter's technique of intravesical mobilization of the terminal ureter with subsequent reimplantation through a new vesical hiatus and submucosal tunnel.[11] Paquin's method summarized several fundamental requirements of successful VUR surgery, including the creation of a tension-free ureteral anastomosis and a submucosal tunnel length five times longer than the diameter of the ureter.[12] An extravesical approach soon followed, with almost simultaneously reported techniques described by Lich and colleagues in the United States and Gregoir and Van Regemorter in France in the early 1960s.[13,14] Glenn and Anderson reported success using their modified ureteral advancement technique without creating a new muscular hiatus in the mid-1960s.[15] Cohen subsequently modified the ureteral advancement procedure and achieved adequate submucosal tunnel length by using the posterior aspect of the bladder for cross-trigonal tunneling.[16] These descriptions, in addition to contributions by other surgeons over the last 50 years, have made open surgical correction of VUR an effective and durable surgical treatment.

INDICATIONS

The surgical indications for VUR should be tailored to the individual patient. However, standard indications for antireflux surgery have been generally accepted. Absolute indications for surgery include breakthrough UTIs despite prophylactic antibiotics or because of medical noncompliance. Relative indications for reimplant surgery include the following: persistent grade IV or V reflux, VUR associated with congenital abnormalities at the ureterovesical junction, renal growth retardation or the presence of new renal scars, and dilating reflux persisting in girls who have reached full somatic growth potential.

At Vanderbilt Children's Hospital (VCH), detailed counseling is initiated at the first clinic visit in patients referred to our office with concomitant diagnoses of UTI and VUR. Such counseling includes the importance of maintaining good voiding mechanics, adhering to daily antibiotic suppression, and avoiding bladder–bowel dysfunction. These issues are repeatedly stressed to both the patient and the parents. If indications for surgical

intervention are present, other factors to consider include the nature of the infections while on medical therapy, possible neurologic or nonneurologic bladder dysfunction, and the presence of bladder–bowel dysfunction. Informed operative consent and expectations following surgery are explained in detail to both the parents and the child.

The evaluation and management of pediatric patients with UTI and VUR has changed dramatically over the last decade, as will be discussed at length in Chapter 43. Undoubtedly, restricting the use of voiding cystourethrography (VCUG) in younger children with febrile UTI, as recommended by the American Academy of Pediatrics in 2011, will impact the specialty of pediatric urology.[17] As fewer children undergo VCUG for febrile UTI following the release of these guidelines, the impact on subsequent surgical management remains unclear. Likely, the practice patterns for treating VUR both medically and surgically will change and surgical intervention may decline over time. At VCH, our practice patterns have remained stable in that we continue to primarily perform open ureteral reimplantation for antireflux surgery compared with endoscopic procedures. The release of new guidelines is unlikely to change this fact. Despite the evolving nature of VUR screening, evaluation, and management, open surgery for VUR remains a safe and effective procedure for children in whom it is indicated.

SURGICAL TECHNIQUES

Cystoscopy

Cystoscopy may be performed prior to open ureteral reimplantation surgery following induction of general anesthesia. Cystoscopy should take only a few minutes from positioning to completion. It alerts the surgeon to unexpected anatomical findings not found on preoperative imaging studies. Duplication anomalies, the presence of small ureteroceles, or evidence of posterior urethral valves or other urethral abnormalities may be found. Bladder trabeculae are seen well during cystoscopy and may be related to voiding dysfunction. Additionally, acute cystitis, if found during endoscopy, delays open surgery until an appropriate course of antibiotic therapy has been completed.

However, cystoscopy is not mandatory in all patients and, with the improvement in diagnostic imaging techniques, typically adds little information. Male patients, those with unclear radiographic findings, or patients with anatomic abnormalities found on preoperative imaging studies are a few of the select group of patients who may benefit from endoscopy.

Positioning

If cystoscopy is performed, the bladder is left moderately distended. The child is then positioned supine and either a rolled towel is placed at the level of the upper sacrum, or a slight break in the table is used to raise the lower pelvis and hips (Figure 44.1a and b). All pressure points are appropriately padded, and a wide surgical prep is performed with the perineum draped and exposed within the surgical field (Figure 44.1c).

INTRAVESICAL TECHNIQUES

Exposure and Initial Dissection

Exposure for all methods of intravesical repair involves a series of similar steps before the individual techniques diverge during ureteral reimplantation. A Pfannenstiel skin incision is made along an appropriate skin crease about one fingerbreadth above the pubic symphysis (Figure 44.2a and b). The subcutaneous tissue and Scarpa's fascia are incised the length of the skin incision (Figure 44.2c). The anterior rectus sheath is then opened in a horizontal fashion (Figure 44.3a) with the creation of superior and inferior rectus flaps (Figure 44.3b). The rectus muscle bellies are then incised in the midline through the linea alba, separating the rectus and the pyramidalis muscle (Figure 44.3c). Alternatively, the anterior rectus fascia can be opened in a vertical fashion, extending the incision posteriorly through the linea alba.

Following the fascial incision, the space of Retzius is entered bluntly. The peritoneal reflection is displaced superiorly, the bladder is visualized, and full-thickness bladder wall stay sutures, or Allis clamps, are placed on either side of the midline of the bladder. The Denis Browne retractor is a helpful aid in allowing for sustained exposure and is used extensively at VCH. The anterior bladder wall is then incised longitudinally, and the inferior edges of the bladder wall are sewn to the lower

abdominal skin edges, immobilizing the inferior aspect of the bladder (Figure 44.4a). Moist sponges are packed in the dome of the bladder behind the cephalad blade retractor to flatten the posterior bladder wall and elevate the entire bladder in the pelvis, bringing the ureteral orifices into the middle of the operative field. Lateral blades are secured to the Denis Browne to obtain further exposure (Figure 44.4b). Optimal exposure involves the immobilization of the inferior aspect of the bladder, flattening of the posterior bladder wall, and elevation of the bladder into the pelvis, bringing the ureteral orifices into the middle of the operating field. Care must be taken during positioning of the Denis Browne blades to prevent tearing of the bladder incision through the bladder neck region. Also, excessive touching, suctioning, or rubbing of the bladder mucosa is avoided to prevent edema or inflammation of the mucosa, which can lead to bleeding and difficult mucosal dissection.

Ureteral dissection begins with intubation of the ureter with either a 5 or 3 French feeding tube, depending on the size of the ureteral orifice (Figure 44.5a and b). The tube is secured to the ureter with a 4-0 silk suture placed in a transverse fashion just inferior to the ureteral orifice, and then through the feeding tube, which maintains orientation of the ureter throughout mobilization (Figure 44.5c). The mucosa is then circumferentially incised around the ureteral orifice with the electrocautery in the cutting mode, leaving a several-millimeter cuff of bladder mucosa (Figure 44.6a). The muscular attachments of the ureter to the bladder are then carefully divided with the electrocautery device using the coagulation mode. This dissection involves gentle countertraction of the ureter away from the periureteral tissue using the feeding tube, in concert with judicious use of the cautery device (Figure 44.6b). Care is taken to avoid both devascularization and injury to the continuity of the ureter. The appropriate plane of dissection is achieved if the shiny, reflective ureteral wall in Waldeyer's sheath is seen. As the dissection proceeds proximally, division of the ureteral attachments is taken down further from the ureter to avoid devascularization. Ureteral dissection ends after an adequate distance of the ureter has been freed. A good measure of this distance is for the ureter to have enough length to reach the contralateral bladder wall. An additional clue is the subtle feeling of ureteral release the experienced surgeon is alert to, which allows the redundant ureter to easily slide back and forth in the muscular hiatus (Figure 44.6c).

Politano–Leadbetter Repair

The original Politano–Leadbetter technique described in 1958 involved the blind creation of a new suprahiatal muscular location for the ureter.[11] Following adequate ureteral mobilization as described above, the peritoneum is reflected superiorly away from the posterior aspect of the bladder using the original muscular hiatus as a window in which to work through (Figure 44.7a). If the muscular opening is not adequate for exposure, the posterior bladder wall may be incised superiorly to allow for better visualization. Perivesical crossing vessels, when encountered during division of the bladder wall, are fulgurated. The posterior bladder wall dissection is done under direct

visualization. Blind passage of instruments behind the bladder is forbidden because of the risk of unrecognized entry into the peritoneum or injury to the bowel, vagina, or vas deferens.

Once the posterior bladder wall is freed from the peritoneal reflection, a right-angle clamp is passed through the original hiatus superiorly under direct vision, hugging the posterior wall and indenting the bladder wall superiorly, marking the new muscular entrance for the ureter (Figure 44.7b). The location of the new hiatus is slightly medial and cephalad, typically 2–3 cm above the original hiatus. Excessive lateral placement allows for potential kinking and "J-hooking" of the ureter during bladder filling. The mucosa and muscle are incised directly on the right-angle clamp with the electrocautery device, and the right-angle tip is delivered into the bladder, dilating the opening carefully (Figure 44.7c). A second right-angle clamp is passed through the newly made hiatus inferiorly, and the ureter is then transferred to its new muscular hiatus, using the amputated feeding tube as a handle (Figure 44.7d–f). Careful relocation of the ureter involves ensuring a relatively smooth entrance of the ureter without acute angulations or kinks. The original muscular opening is then closed with 3-0 interrupted chromic sutures in a buried fashion. Adequate room for the ureter to emerge through the new hiatus is measured by the gentle insertion of the tip of a Schnidt clamp (Figure 44.7g).

A submucosal tunnel or mucosal flaps are created from the new entrance of the ureter toward a spot distally near the bladder neck, which is marked with the electrocautery. A modification of Politano and Leadbetter's original description involves increasing the submucosal tunnel length by extending the tunnel past the native ureteral orifice toward the bladder neck. Submucosal dissection is performed carefully with tenotomy scissors or the cautery device, and should proceed with ease through a bloodless field if in the correct plane (Figure 44.7f). Once an adequate submucosal tunnel has been made, the ureter is transferred through the tunnel (Figure 44.7h). The feeding tube is then removed, and the ureter is spatulated if needed. If excessive ureteral redundancy is present, the distal tip of the ureter may be excised. Three 6-0 vicryl sutures are placed through the posterior apex of the distal ureter and through both bladder mucosa and muscle to secure the ureter distally and prevent it from springing back into the tunnel. Then 6-0 vicryl mucosal sutures are placed circumferentially around the ureteral orifice, completing the mucosal anastomosis. The original mucosal opening is closed with fine absorbable suture, and if mucosal flaps were created, they are approximated with a running fine absorbable suture (Figure 44.7i). The bladder is then closed in two layers with a 3-0 chromic suture in a running fashion.

Cohen Cross-Trigonal Repair

Arguably, today's most popular open technique for ureteral reimplantation is the cross-trigonal repair described by Cohen in 1975.[16] Ureteral dissection is performed as described above; however, this method typically requires less ureteral mobilization than the Politano–Leadbetter

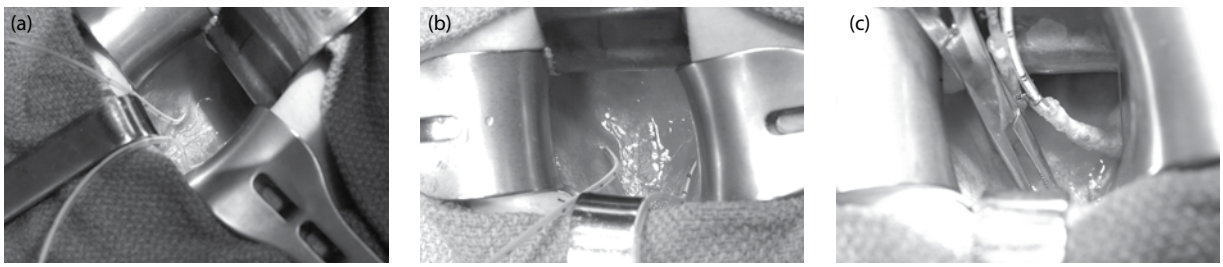

FIGURE 44.5 (a and b) With the Denis Browne retractor in place, 5 French feeding tubes are placed into the ureteral orifices to allow ureteral dissection to begin. (c) A 4-0 silk suture is used to secure the feeding tube at the orifice. The feeding tube is then used as a handle during dissection. (Photos courtesy of Anne Raynor, Vanderbilt University Medical Center, Nashville, Tennessee.)

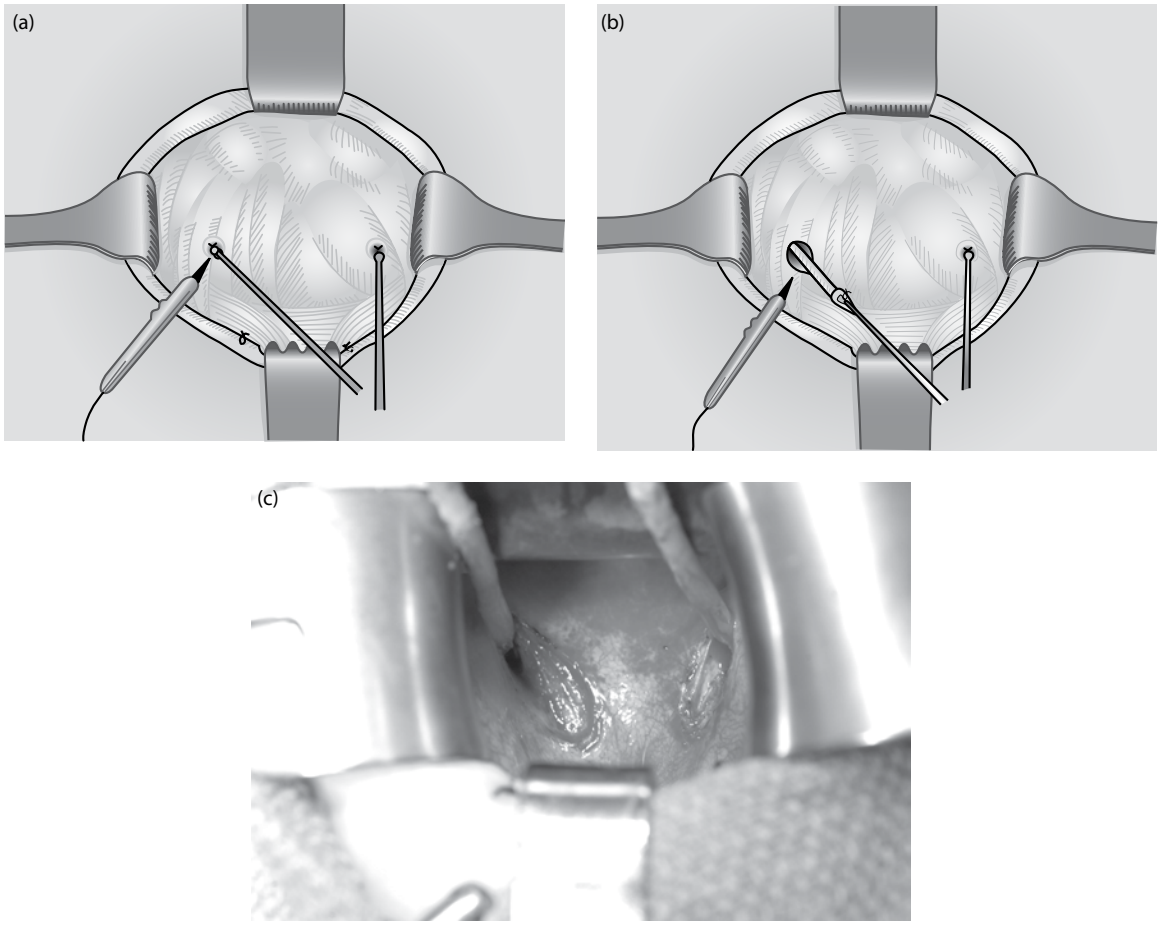

FIGURE 44.6 (a) The mucosa is incised circumferentially around the ureteral orifice with an electrocautery device. (b) The ureteral attachments are carefully divided, and an adequate ureteral length for reimplant is obtained. (c) Ureteral dissection has been completed bilaterally. Each ureter has been dissected well into the retroperitoneum, allowing sufficient redundancy of length. (Photo courtesy of Anne Raynor, Vanderbilt University Medical Center, Nashville, Tennessee.)

technique. The submucosal tunnel is created along the posterior bladder wall without transferring the ureter to a new muscular hiatus, virtually eliminating kinking of the distal ureter. The major drawback to this operation is the subsequent difficult intubation of the ureteral orifices related to their transtrigonal location. Despite this drawback, a number of authors have published techniques for facilitating endoscopic retrograde ureteral access after cross-trigonal reimplantation. Proposed techniques include the use of angle-tipped ureteral catheters, angled guidewires with torque devices, super stiff guidewires, and lateral percutaneous bladder puncture.[18–20]

Following ureteral mobilization, the muscular hiatus may need approximation if a patulous opening is present. Cinching of the hiatus with a 3-0 chromic suture should bring the muscle together tightly but allow for the tip of a Schnidt clamp to pass between the bladder and ureter. Aggressive closure of the muscular hiatus can cause kinking with angulation of the ureter and possible distal ureteral obstruction. In contrast, too lax of a muscular approximation may lead to diverticulum formation.

During unilateral ureteral reimplantation, a submucosal tunnel is developed across the posterior bladder wall in a cross-trigonal fashion. The new mucosal hiatus is created above the contralateral ureteral orifice. This ureteral position allows for an adequate submucosal tunnel. Once the submucosal tunnel is created, the ureter is transferred through the tunnel using the shortened feeding tube and stay suture as a handle. The feeding tube is then removed from the ureter. The ureter is spatulated, as indicated, and three fine absorbable sutures are placed through the lateral, posterior apex of the ureter and the bladder mucosa and muscle. Placement of these tacking sutures in the correct position creates an appropriate lateral vector force on the ureter, preventing medial regression of the ureter and loss of the effective submucosal tunnel. The newly created ureteral orifice is then matured with circumferential fine absorbable sutures. The mucosal defect from the old ureteral orifice is then closed with interrupted fine absorbable sutures (Figure 44.8a and b). Prior to closing the bladder, the free, smooth passage of a small feeding tube rules out excessive ureteral kinking.

When both ureters are reimplanted, the submucosal tunnel for the most superior ureter is made with the mucosal hiatus located just above the contralateral ureter. Subsequently, the other ureter is brought across the posterior bladder wall, with the new ureteral orifice positioned close to the inferior portion of the old contralateral

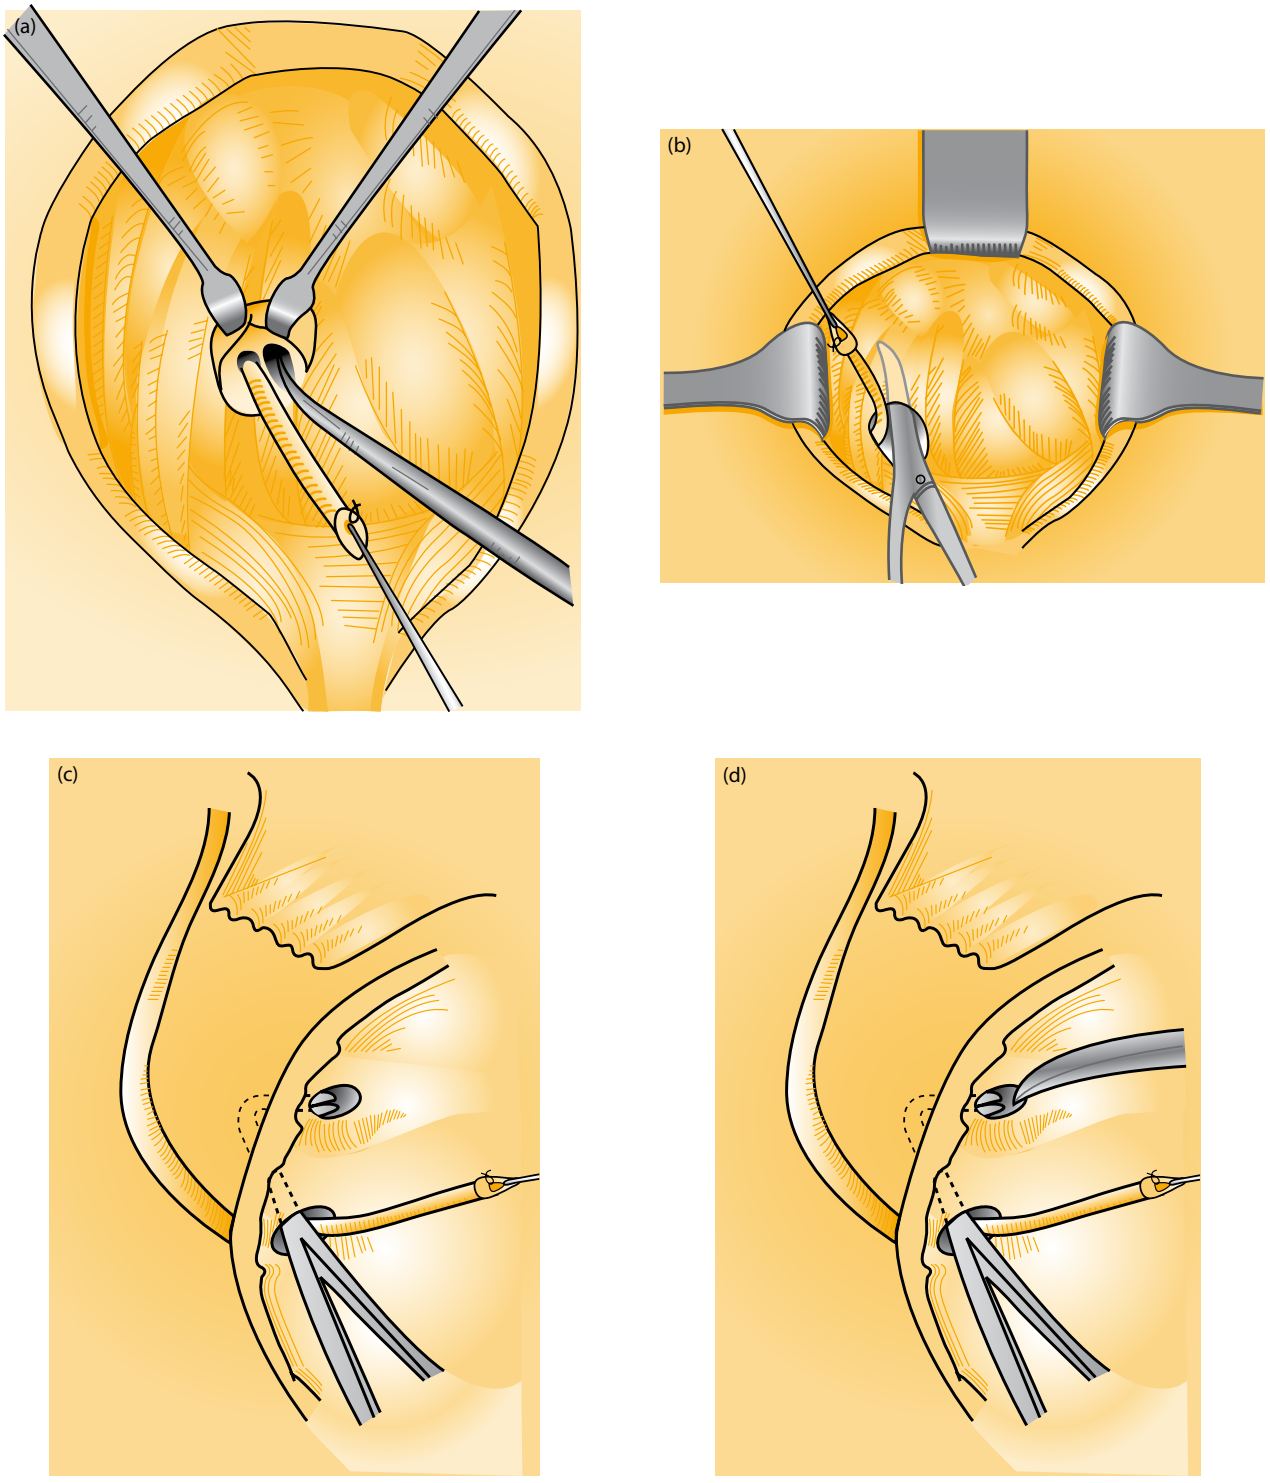

FIGURE 44.7 (a) Following adequate ureteral mobilization, the peritoneum and other structures (vas deferens or vagina) are displaced under direct vision. The posterior aspect of the bladder may be opened to allow for better visualization during this dissection. (b) Once the peritoneum is swept away, a right angle clamp is passed from the original hiatus, indenting a region superior and medial to the native hiatus. The electrocautery device incises the bladder tissue indented by the clamp. (c) The new hiatus is opened widely with the tip of the right angle clamp to allow for accommodation of the ureter. (d) A second right angle clamp is passed from the new hiatus down through the original hiatus. (*Continued*)

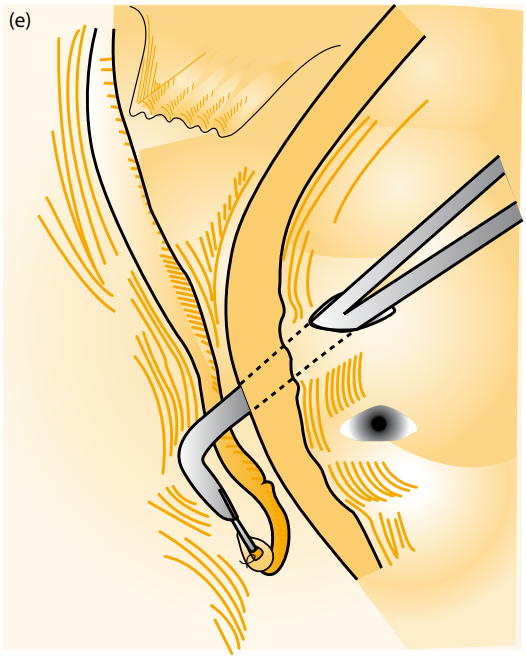

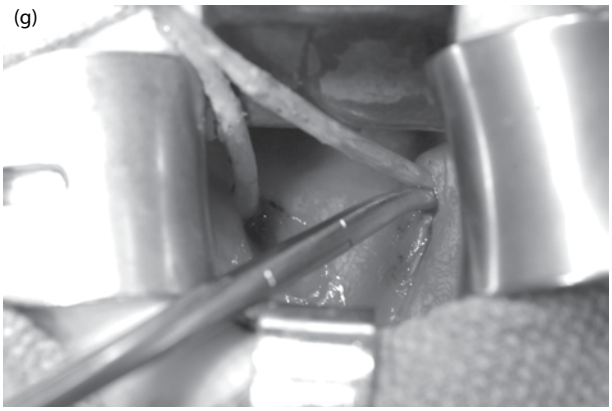

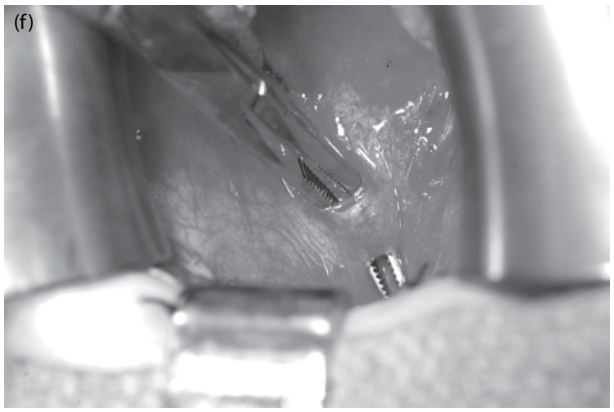

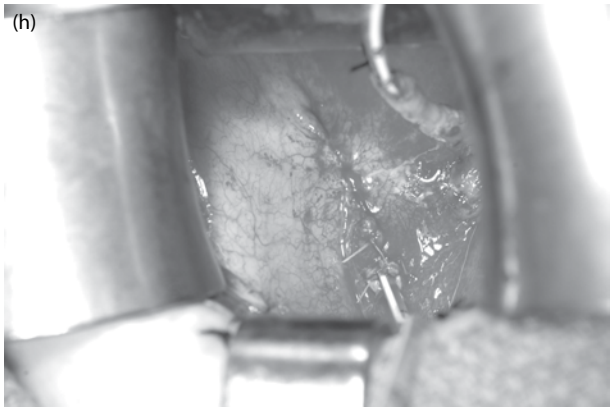

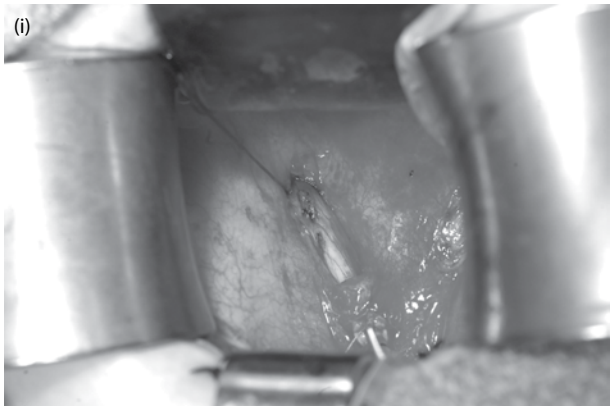

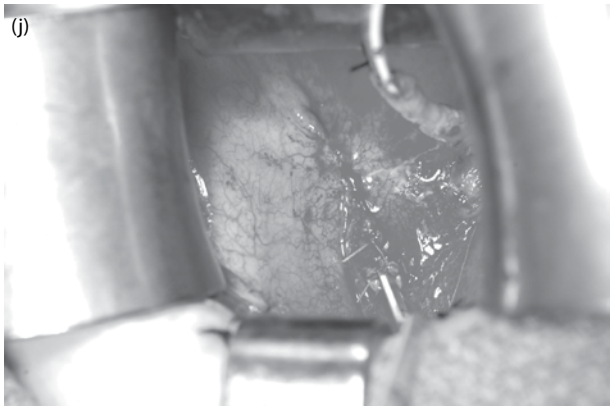

FIGURE 44.7 (Continued) (e) The ureter is then grasped by the second clamp after amputating the distal aspect of the feeding tube. (f) A new submucosal tunnel has been created distally, as illustrated by the right-angle clamp. (g) The detrusor muscle has now been closed with fine absorbable suture and will serve as a muscular backing for the ureter. The tip of a Schnidt clamp has been placed next to the ureter to ensure the new muscular hiatus is not overly tight. (h) The right ureter is laid down into the new submucosal tunnel. (i) The ureter is anastomosed to the bladder using an interrupted vicryl suture. (j) The mucosal defect has been closed over the right ureter using a fine absorbable suture in a running fashion. (Photos in panels f–j courtesy of Anne Raynor, Vanderbilt University Medical Center, Nashville, Tennessee.)

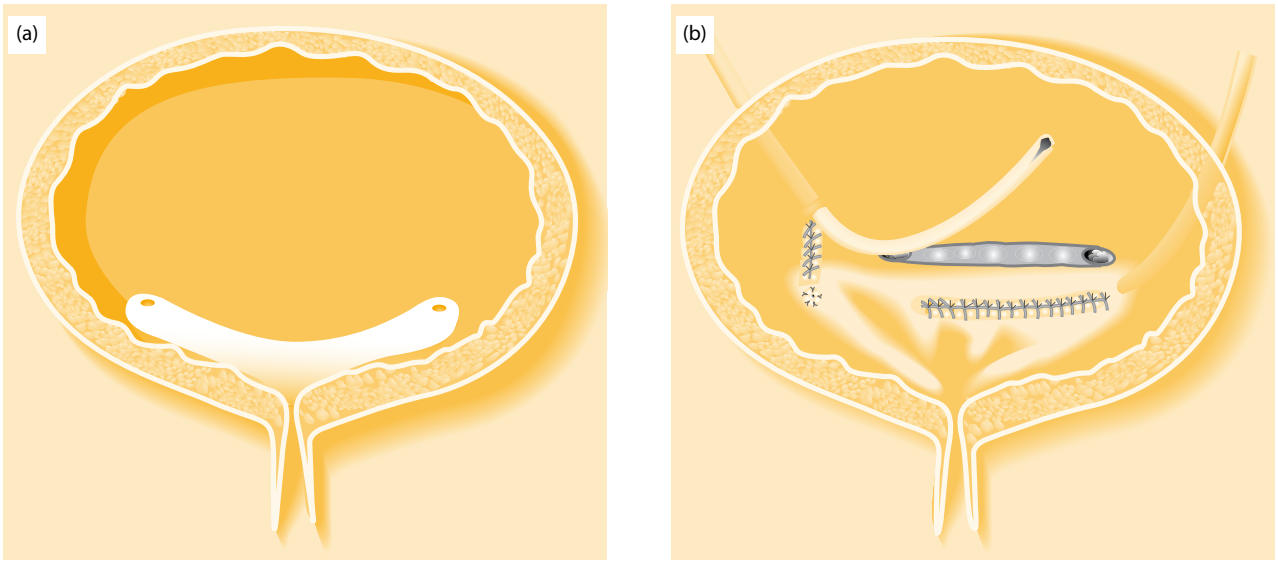

FIGURE 44.8 (a) Laterally displaced, refluxing ureteral orifices with an adequate posterior bladder wall for cross-trigonal reimplantation. (b) The left ureter was reimplanted using this technique. The native right ureteral orifice becomes the new left orifice after reimplant. The right ureteral muscular hiatus is incised superiorly to shift the ureter in a cephalad fashion, allowing a smooth tunnel for cross-trigonal reimplantation.

hiatus. Visual inspection of the anatomy of the trigone and posterior bladder wall aids the surgeon in deciding how to orient the ureters in regards to superior and inferior location. At times, proper positioning of the submucosal tunnels dictates carefully incising the posterior bladder wall following peritoneal displacement in a superolateral fashion (Figure 44.8b). This leads to a cephalad shift of the ureter at the muscular hiatus, and allows for a smoother course across the posterior bladder wall for the superiormost ureter. Additionally, a lateral, muscular incision may be performed to recess the ureter laterally and can be used to increase the tunnel length in small bladders. Following ureteral reimplantation, the bladder is closed in two layers using a 3-0 chromic suture.

Glenn–Anderson Repair

In 1967, Glenn and Anderson refined and popularized the intravesical ureteral advancement procedure that had been reported by several other authors.[15,21,22] Patients in whom this technique is used are selected based on the location of their refluxing ureteral orifices (Figure 44.9a). Those patients with laterally displaced ureters and a sufficient posterior bladder wall are good candidates for this procedure.

Ureteral dissection is performed in a fashion as described previously. If the muscular hiatus is gaping, the muscle edges are approximated with a buried 3-0 chromic suture, allowing for an adequate, smooth entrance for the ureter. Following ureteral mobilization, a mucosal tunnel or mucosal flaps are developed from the original mucosal hiatus and extended in a caudal fashion to a point marked superior to the bladder neck. Once the tunnel or flaps are created, the ureter is either transferred through the tunnel or placed in the mucosal trough. The ureter is then secured distally to the newly created mucosal hiatus in a manner similar to that of the Politano–Leadbetter technique. The mucosal hiatus is then matured circumferentially with interrupted absorbable sutures, or the mucosal trough is closed with a running fine absorbable suture (Figure 44.9b). The bladder is then closed in a fashion similar to that of the other repairs.

Gil-Vernet Repair

A simple advancement technique for those patients with lateral ectopia and a widened "megatrigone" was described by Gil-Vernet in 1984.[23] Exposure of the ureters is similar to that in other open procedures; however, minimal ureteral dissection is needed. A traction suture is placed at the medial aspect of the ureteral orifice, and adequate mobility of the distal ureter and intrinsic muscular fibers of the terminal ureter is demonstrated by the ability of the ureter to be pulled toward the midline (Figure 44.10a and b).

If mobility of the distal ureter is found to be adequate, a transverse incision is made through the mucosa across the superior aspect of the trigone between the ureteral orifices. The mucosa is then elevated off the bladder wall muscle. The classic description by Gil-Vernet uses a single 3-0 nylon or proline suture placed in a mattress fashion at the base of each ureter, encompassing the periureteral sheath and muscle. This suture advances the ureters toward the midline, increasing their intramural length. The permanent suture is then buried by approximating the bladder muscle with 3-0 chromic sutures. The mucosa is then closed vertically with interrupted, fine absorbable sutures (Figure 44.10c). A modification of this technique using absorbable suture for the medial advancement has been described, and that is our practice at VCH.[24] The bladder and the overlying incision are then closed in a routine fashion.

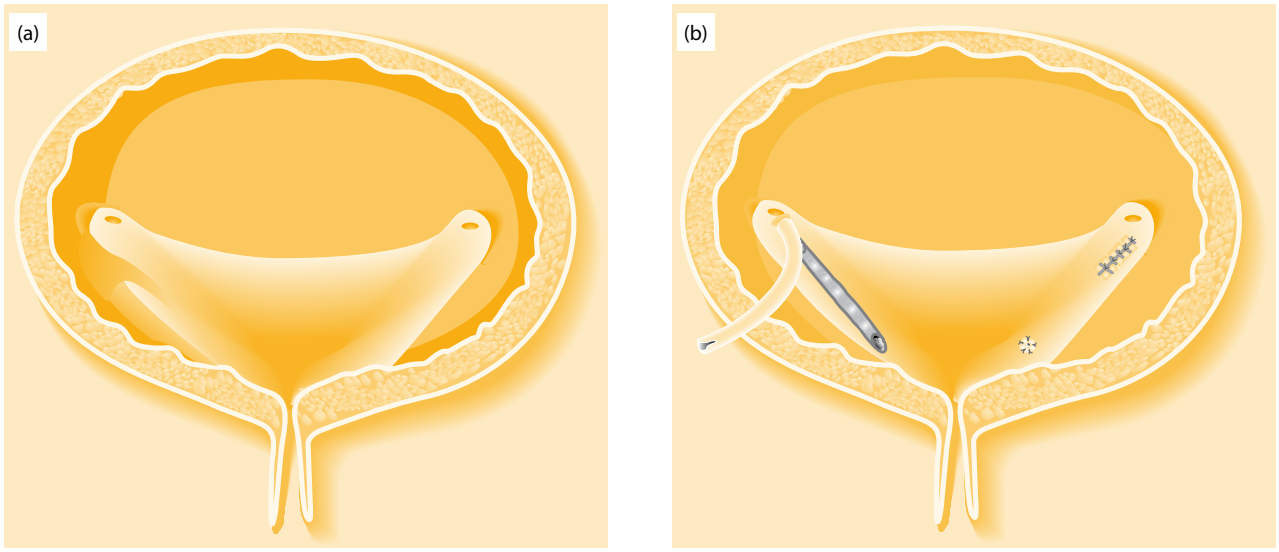

FIGURE 44.9 (a) Lateral and cephalad ureteral orifices that are ideal for the Glenn–Anderson advancement technique. (b) The ureters are advanced to an area superior to the bladder neck with an adequate submucosal tunnel.

EXTRAVESICAL TECHNIQUES

Lich–Gregoir Repair

An extravesical approach to the correction of VUR was almost simultaneously described in the United States and in Europe by Lich and colleagues and Gregoir and Van Regemorter in the early 1960s.[13,14] This technique, commonly referred to as Lich–Gregoir, is similar to previous methods published by others around the turn of the twentieth century.[4,25] Despite its popularity in Europe, American surgeons were less enthused following Hendren's disappointing initial results using a modification of this repair.[26] Subsequent studies with minor modifications have found this technique to be both durable and reliable.[27,28]

Because the bladder is not opened during the repair, cystoscopy is performed prior to opening to rule out any bladder abnormalities. Once cystoscopy is complete, a Foley catheter is placed and clamped, and the bladder is left moderately full. Bladder exposure is obtained in a fashion similar to that for the intravesical repairs. The bladder volume is then emptied, and the bladder is retracted medially to expose the refluxing ureter. The peritoneum is reflected superiorly away from the posterior bladder wall, and the obliterated hypogastric artery is identified and ligated. The ureter is then found, mobilized, and freed of attachments distally to the posterior aspect of the bladder (Figure 44.11a). A network of small vessels typically congregates near the ureterovesical junction, and they need to be divided carefully with the electrocautery.

Following ureteral mobilization, the serosal and muscular layers of the detrusor are incised superiorly 4–5 cm to create a trough for the ureter. The bulging bladder mucosa is seen following muscular division and ensures adequate mucosal exposure. Distension of the bladder during this

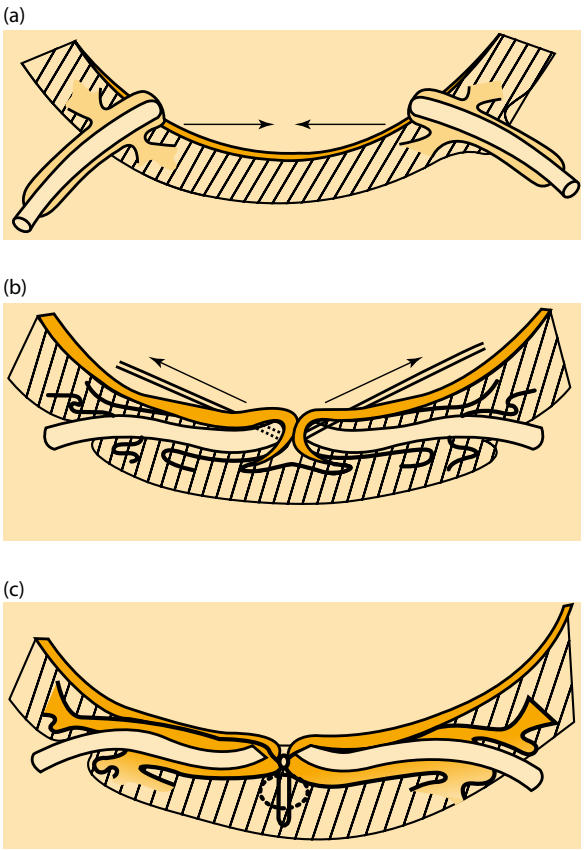

FIGURE 44.10 (a) The Gil-Vernet technique of advancing mobile ureters across the trigone. (b) Traction sutures are placed at the medial aspect of the ureteral orifices to test mobility. (c) Mattress sutures advance the ureters towards the midline, increasing their submucosal tunnel length. (Modified from Gil-Vernet *JM. J Urol* 1984;131:456–8.)

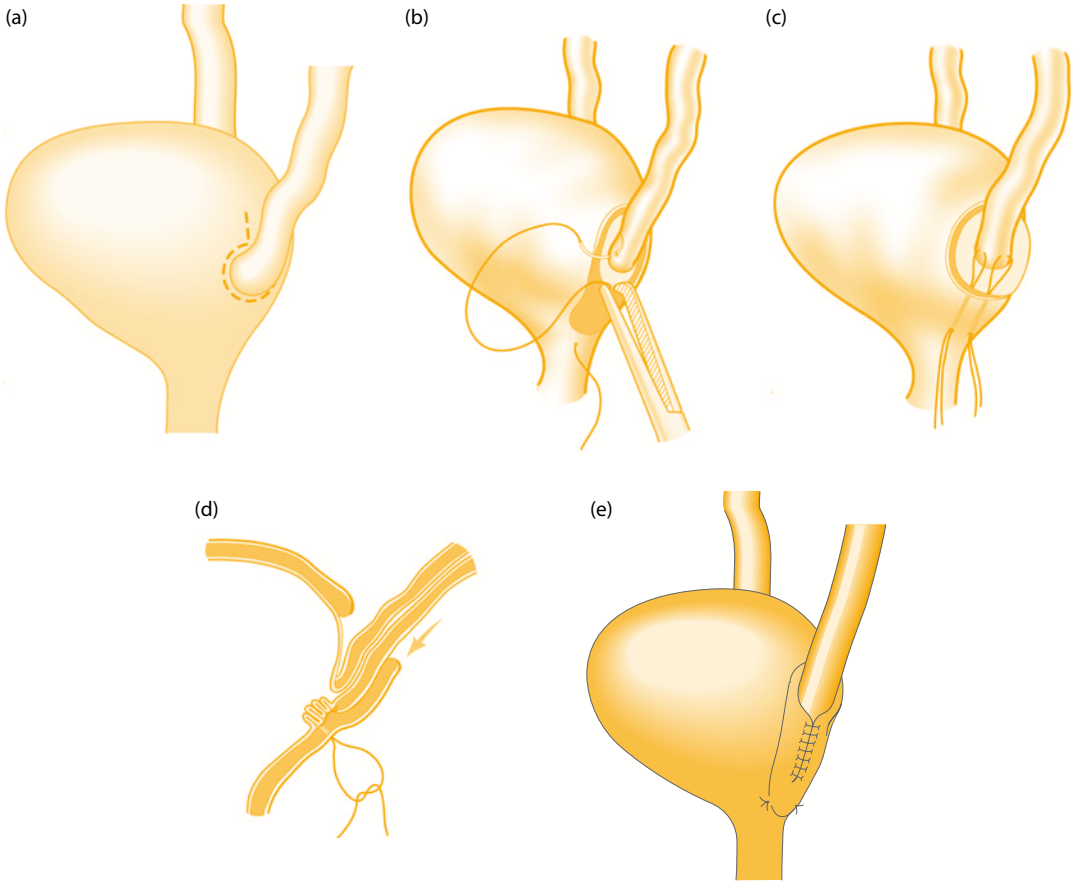

FIGURE 44.11 (a) The extravesical approach begins with ureteral mobilization followed by detrusorrhaphy. (b) After mobilization of the mucosa off the bladder muscle, two or three vest sutures are placed in an appropriate fashion. (c) Tying of the sutures advances the ureter down toward the inferior aspect of the trough. (d) A sagittal view following ureteral advancement. (e) The detrusor is loosely closed over the ureter once secured in the trough.

step makes this dissection easier. Mucosal rents made during this step are closed with fine absorbable suture. The muscular division continues in a caudal direction 1–2 cm past the ureterovesical junction. The ureterovesical junction is freed circumferentially. Mobility of the ureterovesical junction is needed for ureteral advancement. Two to three 4-0 chromic "vest-type" sutures are placed through the bladder wall and ureter to advance and anchor the ureter to the distal aspect of the trough (Figure 44.11b–d). The ureter is then placed in the trough, and the detrusor is closed over it with interrupted 3-0 chromic sutures (Figure 44.11e). Approximation of the muscle edges proximally should be loose, allowing for the tip of a Schnidt clamp at the muscular hiatus. While no perivesical drain is typically used, an indwelling Foley is left overnight and removed on postoperative day 1. If bilateral extravesical reimplants are performed, a voiding trial is initiated prior to discharge because of the risk of transient postoperative bladder retention. Additionally, several centers have reported successful results using the Lich–Gregoir technique for unilateral reimplantation, but approached via a small, 2 cm hernia-type inguinal incision instead of the traditional Pfannenstiel incision.[29–31]

POSTOPERATIVE EVALUATION

The majority of children following simple ureteroneocystostomy are managed without indwelling urethral catheterization or perivesical drainage at VCH. Surgical repair of VUR via a catheterless ureteroneocystostomy at our institution was found to reduce hospital stay when compared with those patients undergoing ureteral reimplantation with a urethral catheter, without increasing complication rates.[32] Most patients are discharged on postoperative day 1, once the child demonstrates adequate po intake.

Standard postsurgical management includes a renal ultrasound at the first postoperative visit at 1 month to assess for the presence of hydronephrosis. Mild, transient hydronephrosis is commonly seen and resolves within the first several postoperative months. Management of persistent severe hydronephrosis will be discussed later in the chapter.

At our institution, voiding and stooling habits are verbally reviewed during all postoperative clinic visits and validated voiding dysfunction questionnaires are administered at every visit.[33] Postoperative bladder–bowel dysfunction is identified and treated aggressively with

educational reinforcement and medications, including laxatives and anticholinergics, when needed. Suppressive antibiotic therapy is continued for 3–6 months following surgery. The child's preventative antibiotics are discontinued on an individual basis. Factors considered in the cessation of antimicrobial therapy include the demonstration of good elimination habits, a consistent UTI-free state, and evidence of resolved hydronephrosis. Routine VCUG in patients undergoing simple ureteroneocystostomy is not performed at our institution, and this approach has been supported by others.[34,35] Following the early postoperative clinic visits, annual or semiannual appointments are made to follow the child's voiding history and check the patient's blood pressure, urine (with a urinalysis), and kidneys with ultrasonography. Later in adult life, periodic evaluation should continue as indicated.

RESULTS

The open surgical treatment of VUR has a long record of impressive correction rates following surgery. Initial and follow-up series of accepted surgical methods have success rates of 94%–99%. The 2010 American Urologic Association (AUA) Guidelines for the Management and Screening of Primary VUR in children found a resolution rate of 98.1 per 100 children undergoing open ureteral reimplantation.[36] In the 1997 AUA guidelines on this topic, reimplanted ureters with grade I–IV VUR had surgical correction rates of 98%–99% independent of technique, and these findings hold true at VCH.[37] However, patients with grade V VUR were found to have a persistent but lower grade of VUR 19% of the time following surgery.[38] Rates of febrile UTI are low following open ureteral reimplantation as well. In the 2010 guidelines, the rate of febrile UTI after surgical therapy, either open reimplant or endoscopic injection, was reported to be 4.9 per 100 children treated. Additionally, the number of postoperative UTIs correlated with the number of preoperative UTIs.[36] Some authors have suggested that patients undergoing open ureteral reimplantation may be at increased risk of febrile UTI following surgery compared with endoscopic injection.[39] At our institution, febrile UTI occurred in 4.6% of patients following open surgery.[40] With improvements in instrumentation and suture material, modifications of techniques, proper performance, and appropriate selection of patients, success nears 99% in those patients undergoing simple ureteral reimplantation with low- to moderate-grade reflux.

COMPLICATIONS

Ureteral Obstruction

Postoperative complications are rare following ureteroneocystostomy. Hydronephrosis is not unusual in the early recovery period and often correlates with the degree of hydronephrosis present prior to surgery. Recent data report the incidence of de novo postoperative hydronephrosis to be 12%. Hydronephrosis resolved in 71% of these patients over a period of 1.3 years.[41] Similarly, in our series of patients who underwent ureteral reimplantation surgery, 8% of patients had grade I hydronephrosis, which resolved over a period of several months.[34] Severe, persistent hydronephrosis is uncommon and likely is related to ureteral obstruction. Fortunately, ureteral obstruction is rare, with an occurrence rate between 0.1% and 1%.[34,35,41,42] In 28 articles reviewed for the 2010 AUA guidelines, ureteral obstruction occurred at a rate of 0.4 per 100 children.[36] Fortunately, the few patients with ureteral obstruction typically present with clinical signs and symptoms that distinguish them from patients with nonobstructive hydronephrosis.[41,43,44] In cases of ureteral obstruction, initial management includes the placement of a percutaneous nephrostomy tube or indwelling stent in hopes that the obstruction is transient and will resolve over time. In patients with persistent ureteral obstruction, a repeat ureteral reimplant is required. This procedure may necessitate significantly more ureteral mobilization than the initial surgery, requiring both an intravesical and extravesical approach. A viable ureter is then found and the distal fibrotic ureter is discarded. A psoas hitch or Boari flap may be needed if a significant length of distal ureter is lost. In rare instances, a transureteroureterostomy or ileal ureter is required for reconstruction.

Persistent Reflux

Persistent reflux following ureteroneocystostomy is rare. The success rate as noted previously exceeds 98% in those with nondilating VUR. Poor selection of patients for specific operative techniques may have led to early reports of persistent reflux following surgery using specific methods.[26] The creation of an adequate submucosal tunnel in children with severe, dilating VUR is challenging. Ureteral tapering is often required, which increases the complexity of the surgery and risk for postoperative morbidity and is discussed in detail in Chapter 36. Fortunately, in most patients with persistent VUR, their reflux is downgraded substantially following surgery and may resolve with growth and good voiding mechanics. One unusual cause of persistent VUR is the development of a ureterovesical fistula postoperatively. This complication does not typically resolve with expectant management. If problematic, surgical correction is indicated.

New Contralateral Reflux

The development of new contralateral VUR following unilateral ureteral reimplantation is uncommon. Occurrence rates vary from 1% to 18% and were reported to be 9.6 per 100 children in the 2010 AUA guidelines.[36,45,46] Possible factors associated with de novo contralateral VUR include a prior history of resolved contralateral reflux, correction of grade V VUR, or VUR into a duplicated system.[45,47] Contralateral VUR is usually low grade, causes no sequelae, and resolves within 1–2 years if the child adheres to a good voiding regimen. The need for surgical correction of new-onset, contralateral VUR following surgery is a rare event.

CONCLUSIONS

The paradigm of treatment for VUR continues to develop as the aggressiveness of evaluating children with UTI evolves. Irrespective of the manner in which children are ultimately found to harbor VUR, the open surgical repair for the correction of VUR remains both a safe and effective management option. Classically described methods, such as the Politano–Leadbetter technique, are successful, durable repairs and continue to be used today. Whereas laparoscopic and endourologic techniques are being performed in greater numbers, the ease and success of the open surgical repair is the standard by which all other repairs continue to be judged.

CHAPTER 45

Minimally Invasive Approaches to Correct Primary Vesicoureteral Reflux

Molly E. Fuchs, Ahmad Z. Mohammed, Daniel G. Dajusta, and Venkata R. Jayanthi

INTRODUCTION

There are many controversies among physicians regarding the management and indications for surgical repair of vesicoureteral reflux. However, currently, and probably for many years to come, good medical practice still has a place for antireflux surgeries. As in many other surgical approaches, minimally invasive modalities are gradually being introduced to decrease morbidity and pain, shorten hospitalization, speed up recovery, and provide improved cosmetic results. As the indications for surgical interventions are discussed elsewhere in this book, our aim in this chapter is simply to shed a light on the available minimally invasive options and their history, techniques, and results.

Generally speaking, a new minimally invasive technique must achieve the main surgical principles of traditional surgery. In the case of antireflux surgery, the aim should be to achieve adequate detrusor muscle backing for the intramural ureter, as achieved by open surgery, while elongating the submucosal tunnel, and providing sufficient ureteral mobilization while preserving adequate blood supply.

Unlike minimally invasive options for other urological surgeries, laparoscopic reimplantation techniques have not gained popularity for several possible reasons:

- The high success rate of traditional surgeries, about 95%–98%,[1] and relative ease and familiarity of open procedure, as opposed to the demanding learning curve required for minimally invasive techniques.
- Open techniques can be done through a small incision, usually a Pfannenstiel, with already fast recovery and cosmetic results. Additionally, the hospital length of stay for open surgery is already very short, on average less than 24 hours.
- There exists another minimal intervention, in the form of endoscopic bulking material injection, which is an alternative option, the indications and results of which are discussed elsewhere in this book.
- Compared with ablative surgery, reconstructive laparoscopic surgery is more technically demanding, especially in children, as the working space available for dissection and suturing is smaller.

This chapter discusses five options, namely, percutaneous transvesical trigonoplasty, extravesical (laparoscopic and robot-assisted) ureteral reimplantation, and intravesical (laparoscopic and robot-assisted) ureteral reimplantation.

PERCUTANEOUS TRANSVESICAL TRIGONOPLASTY

This technique was first described simultaneously in 1996 by Okamura and Cartwright and is included mostly for historical perspective, as it was among the first attempts at performing a reconstructive procedure for vesicoureteral reflux using endoscopic techniques.[2,3] This procedure is an attempt at reflux correction using the principles of the Gil-Vernet technique, a method by which the ureters are advanced into the bladder, thus increasing the length of the intravesical portion of the ureters without formally mobilizing them. Although Okamura reported 100% success in the initial 6 cases,[2] a larger series by Cartwright involving attempted procedures on 22 children (32 ureters) had a success rate of 62.5%.[3] Gatti reported on the long-term outcomes of this procedure and showed that the reflux often recurred and that the long-term success rate was 47%.[4] There is at present no role for endoscopic trigonoplasty in the correction of reflux, but these authors are to be commended for their attempts at innovation.

LAPAROSCOPIC EXTRAVESICAL REIMPLANT

The first reported cases of laparoscopic vesicoureteroplasty in humans were performed by Ehrlich et al. in 1993 and Janetschek in 1995.[5,6] Interestingly, the latter, in his conclusion, described it as a complicated procedure offering no advantage over conventional surgery. However, since then, several groups have adopted the technique and reported very good results, comparable to, if not equal to, open surgery.[7,8]

Surgical Technique

- As initially described: Cystoscopy is performed first to assess the bladder wall, the ureteric orifice, and the available posterior wall length for creation of the tunnel. An open-ended 3 or 5 Fr catheter may be inserted in the ureter at this stage, to help identify and protect the ureter during its dissection. This catheter is tied to a Foley outside the urethral meatus, and both should be accessible within the operative field. Later reports found the ureteral stenting unnecessary,[7,8] but either way, a Foley catheter should be placed in the operative field. The catheter should be accessible to control the bladder filling and emptying, which plays a crucial role during dissection of the ureter and creation of the extravesical tunnel.
- The patient is placed in the Trendelenburg position, with legs spread apart and arms tucked to the side. The monitors are placed at the foot of the bed. The surgeon and assistant stand on the contralateral side of the ureter they are reimplanting.
- Port placement: In the original description of the procedure by Ehrlich et al., the umbilical trocar (11.5 mm) is inserted first and used for the camera. Two 10 mm working trocars are inserted in each lower quadrant in the midclavicular line, and an additional 5 mm port is inserted on the contralateral side, 1 inch above the other trocar. More recently, there has been an inclination toward using smaller and fewer trocars. A common practice is to place the three lower ports along the line of a Pfannenstiel incision (Figure 45.1).[7,8] Tsai et al. reported using three 3.5 mm ports, one at the umbilicus for the 3 mm camera, and the other two for 3 mm instruments.[9]
- The next step is exposure of the ureter. It may be identified at the pelvic brim and the peritoneum incised transversely over it, or alternatively, the peritoneum is incised adjacent to the bladder. That incision is just caudal to the vas in males, reflecting it cephalad, or between the broad ligament and the bladder base in females. A vessel loop can be passed through the midline lower port, passed under the ureter, and used for traction. The bladder should be half full at this stage. The ureter is dissected cranially and caudally, freeing it from surrounding structures using blunt dissection and minimal cauterization. Care must be taken not to skeletonize the ureter to preserve its blood supply. There is usually no need to dissect distal to the ureterovesical junction (Figure 45.2).
- A line is demarcated starting at the site of the original ureterovesical junction and directed cephalad, marking the site of the tunnel. A traction suture is placed distally using a Keith needle, or alternatively, two suspension sutures are placed percutaneously with the aid of a fascial closure device, on either side of the apex of the proposed tunnel. Another holding suture may be passed through the anterior abdominal wall and then through the proximal end of the tunnel site to provide more traction if needed.
- The seromuscular layer is then incised carefully, using electrocautery and sharp scissors, without injuring the bladder mucosa, to create a trough (Figure 45.3). The degree of bladder filling and the bulge of mucosa can be adjusted at this point using the urethral catheter in the field. If the mucosa is accidentally punctured, it should be repaired with a figure eight stitch of fine absorbable suture. There is no need to undermine the mucosal edges of the tunnel. An advancing suture, which is taken at this point in open surgery from the distal end of the ureterovesical junction, fixing it to the most distal point of the trough, is not applicable in most laparoscopic cases, as the distal attachment of the ureter to the bladder wall is left intact. An inverted-Y detrusorotomy is not routinely performed, and required only if closure of the distal tunnel is under tension.
- The distal ureter is laid in that tunnel and the edges closed over it with interrupted absorbable sutures, taking care to avoid suturing and obstructing the ureter.
- After closure of the tunnel, the traction sutures are released and the bladder is filled and cycled to exclude leaks and ureteral kinks.

Results

The importance of proper surgical techniques cannot be overemphasized for this procedure. One of the concerns when performing extravesical ureteral reimplantation is the denervation of the bladder, which can lead to transient

or prolonged urinary retention at the time of catheter removal, especially in bilateral cases. However, according to the more recent literature, this may no longer be as common as it was previously thought to be,[8,9] but if it occurs, it is certainly distressing to the patient, the family, and the surgeon. An important factor to consider while performing this surgery is to minimize dissection and handling of the distal ureter and the lateral bladder wall, aiming for a "nerve-sparing" technique.

Many authors have described the technique with different variations. The results are overall comparable to those of open surgery. In 2000, Lakshmanan and Fung reported on 71 ureters in 47 patients,[7] with resolution of VUR in 100%. However, they reported three complications in the form of distal ureteral necrosis, and that was attributed to prolonged traction on the ureter using a Babcock. In 2006, Riquelme et al. reported their results on 19 patients, of which 18 (95%) were cured and 1 was downgraded.[10] They also reported that they had three mucosal perforations but no significant postoperative leakage. Worth mentioning is that their series included double ureters. In 2008, Capolicchio described his experience with 20 patients over 5 years. As he discussed his results and complications, he showed that their complications, including two cases that were converted to open surgery, were among the first few cases.[8] In the same year, Tsai et al. reported their experience with mini-laparoscopy, and they had excellent results with 11/14 cured and 2 downgraded.[9]

With the improved experience and techniques, urologists have become more willing to apply laparoscopy for more complicated cases, as in megaureters,[11] double ureters, ureteroceles, and even diverticulae.[10,12]

ROBOTIC EXTRAVESICAL REIMPLANT

Robotic surgical techniques have been increasingly accepted and adopted in pediatric urology. The da Vinci® system (Intuitive Surgical, Sunnyvale, California) offers advantages over conventional laparoscopy, including three-dimensional vision and articulating instruments. Additionally, as robotic surgery has become a mainstay in adult urologic surgery, the younger generation of urologists has adopted the robotic technique for reconstructive surgery in favor of standard laparoscopy. One of the main reasons for this shift is the more manageable learning curve with robotics than with traditional laparoscopic surgery. The first reports of robotic ureteral reimplantation were by Peters in 2004,[13] and since that time, there have been multiple additional contributions describing the technique.

Technique

- The steps for robotic reimplantation are similar to those for the transperitoneal extravesical laparoscopic technique, as detailed above. The primary difference is port and camera placement, as the instruments and camera are larger.
- A 12 mm camera port is placed in the umbilicus using the Hasson or Veress needle technique, depending on

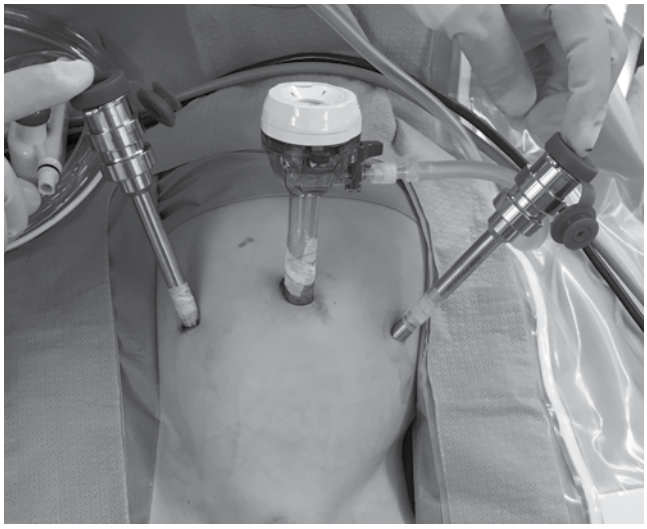

FIGURE 45.4 Port placement for robotic extravesical ureteral reimplant.

surgeon preference. Two 8 mm robotic ports are then placed lateral and slightly inferior to the umbilical port. It is important to ensure adequate distance between the working ports and the camera port as to minimize clashing of the instruments during the procedure. Typically, 8–10 cm (or a hand's width) is adequate (Figure 45.4). Conversely, one could use the 8 mm robotic camera and the 5 mm robotic arms, but this would limit the available robotic instrumentation.

- An assistant port may be utilized if the surgeon desires. This is typically a 10 mm port, although a 5 mm port could be used as well, to accommodate passage of needles or other instruments necessary for the operation. The assistant port is placed on the ipsilateral side of the reimplant and placed midway between the camera and the working port and slightly cephalad, so that the assistant can easily access the port while the robot is docked.
- The position of the robot while docking depends on laterality, patient size, and which da Vinci system is being used. The new da Vinci Xi robot can be docked from a more versatile position. Here we describe positioning for the da Vinci Si robot. All patients are positioned in the supine position. For small children, the robot can be docked directly from the foot of the bed with the patient positioned as far to the foot of the bed as possible. In larger patients, for whom the robot will not reach the ports from the foot of the bed, the robot is docked at a 45° angle from the ipsilateral side of the bed. The robot base should straddle the ipsilateral corner of the base of the operating table to provide optimal positioning. Prior to docking, the patient should be placed in a small degree of Trendelenburg in order to allow for more space in the pelvis, as the bowel will move to the upper abdomen.
- Cystoscopy for evaluation of the bladder wall, ureteral orifice position, or placement of a ureteral catheter is optional, but the technique is the same for nonrobotic laparoscopic extravesical ureteral reimplant. In these authors' experience, ureteral catheter or stent placement during cystoscopy prior to robotic laparoscopic dissection adds rigidity or immobility to the ureter, which makes manipulation of the ureter and placement into the new detrusor tunnel more difficult. Although the presence of a ureteral catheter can be helpful in initial ureteral identification, its advantage is far outweighed by this unwanted technical disadvantage.
- An orogastric or nasogastric tube is placed by anesthesia, and a Foley catheter for intraoperative bladder filling is placed prior to prepping the patient.
- The dissection of the ureter is the same as in the laparoscopic technique described above. Again, a vessel loop or umbilical tape can be used for retraction purposes, and it is critical to ensure that the ureter has been dissected distally to the ureterovesical junction. However, the authors prefer not to use it, given the possibility of ureteral necrosis, associated with aggressive retraction. The extravesical tunnel is then created with electrocautery, and the bladder mucosa is easily seen bulging out in the created tunnel.
- Care should be taken not to violate the bladder mucosa. However, if a hole is created, it can be closed with an absorbable suture, if necessary, to complete the dissection.
- These authors do recommend dissecting the detrusor off of the bladder mucosa laterally on each side of the tunnel when doing this operation robotically, although this is based on surgeon preference.
- A small ruler is passed through the assistant port to measure the tunnel length. Typically, 3–4 cm is an adequate length.
- The ureter is then laid into the tunnel, and absorbable sutures are used to close the detrusor over the ureter. Suture selection is variable, but these authors use 4-0 vicryl sutures.
- The interrupted horizontal mattress technique is used to close the tunnel. A small bite of the ureteral serosa should be taken in the first few stitches to anchor the ureter in place. After the tunnel is completely closed, the traction sutures are removed and the bladder cycled as described above.

Results

Robotic-assisted surgery offers better visualization and articulating instruments, which give it an advantage over pure laparoscopy. Early on in its adoption, robotic extravesical ureteral reimplantation offered promising results for both unilateral and bilateral procedures. Smith et al. reported on 25 cases (33 renal units), with a success rate of 97% and a transient postoperative voiding dysfunction in 3 out of 8 bilateral cases (37.5% of bilateral cases).[14] This did not coincide with the reported results by Casale et al. in 2008 that showed no episodes of urine retention after 41 cases and a success rate of 97.6%.[15] In 2012, the same group (Kasturi et al.) presented their experience with 150 bilateral robotically assisted transperitoneal extravesical ureteral reimplants. They had a 99.3% success rate, and none of their patients developed de novo voiding dysfunction on prolonged follow-up.[16] More recently, however, studies have shown lower success rates and increased complication rates. In 2015, a large multi-institutional study of 61 patients (93 ureters) had only a 72% success rate at mean follow-up of 11.7 months.

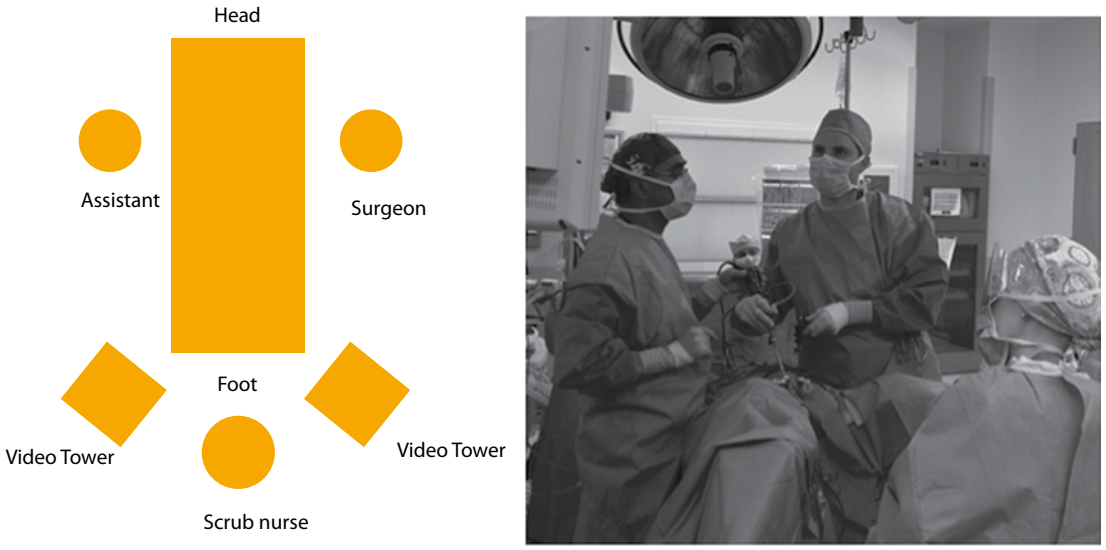

FIGURE 45.5 Position of the surgeon, assistant, nurse, and monitors for vesicoscopic intravesical reimplant. Patient is in the lithotomy position.

In addition to this lower success rate, complications were quite high, with 23% having persistent vesicoureteral reflux, 10% with complications, and 11% requiring reoperation.[17] Subsequently, a large single-institutional study reported similar inferior success rates and found that when stratifying for unilateral and bilateral procedures, there was a significant difference. Unilateral robotic reimplantation had a success rate of 91.5%, while bilateral was only 77.8% successful. This study also found that bilateral procedures had higher complication and reoperation rates than unilateral ureteral reimplantation.[18] Not only has the success and complication rate of robotic reimplant been called into question, but also the cost of the procedure has been criticized, with one study finding that in addition to a higher complication rate of robotic ureteral reimplantation, the median hospital cost was also significantly higher ($p = 0.049$).[19] The emerging literature that critically evaluates the efficacy, safety, and cost of robotic ureteral reimplantation is leading most to implement this technology with caution, particularly when compared with the traditional open surgical alternative.

VESICOSCOPIC INTRAVESICAL REIMPLANT

For open surgery, many centers prefer the Cohen cross-trigonal ureteral reimplantation over the extravesical technique, especially in bilateral cases. That is why the feasibility of this technique laparoscopically was investigated and proven possible in animals,[20] and then by Gill et al. in 2001. He used glycerine to distend the bladder.[21] Yeung et al., in 2005, reported a series of 23 ureteral reimplants in 16 children, using an endoscopic cross-trigonal technique under CO_2 insufflation.[22] Several others have reported their experience and modifications to the technique.[23–26]

Technique

- *Positioning*: The procedure is performed with the child in the low dorsal lithotomy position. Areas prone for pressure sores and neuropraxia, including the back, popliteal fossae, and heels, are adequately padded. The abdomen and perineum are included in a single sterile field, since urethral access is needed for initial cystoscopy, port placement, splinting, and catheterization. The surgeon typically stands on the patient's left side, with the assistant, scrub nurse, and monitors positioned over the patient's legs (Figure 45.5).
- *Cystoscopy and marking the port sites*: After the patient is positioned, CO_2 cystourethroscopy is performed using a 30° lens and a rigid cystoscope. Any urine in the bladder is emptied by suctioning through the irrigation port of the cystoscope. When the bladder is distended adequately with CO_2, the sites for port placement are decided. It is desirable to place the ports as cranially as possible with a distended bladder, without traversing the peritoneum. Apart from the potential for bowel injury, if the port traverses the peritoneum, the subsequent pneumoperitoneum may result in poor visibility and distortion of the bladder. Being overcautious and placing the ports too cephalad may make the dissection extremely challenging, since the working instruments will be perpendicular to the ureteral orifices. If pneumoperitoneum is encountered, it may be decompressed by placing a Veress needle through the umbilicus to vent the carbon dioxide.
- *Anchoring sutures*: The first step is to anchor the bladder to the anterior abdominal wall under cystoscopic guidance. Fixation of the bladder provides adequate resistance to allow ports to be more easily introduced into the otherwise freely mobile bladder. Second, in case of inadvertent extrusion of the port during the procedure, having the bladder fixed to the abdominal wall will prevent distortion of the track due to escape of the CO_2 into the prevesical space and collapse of the bladder. Briefly, a 2-0 PDS

suture, after cutting off the needle, is passed through an 18-gauge spinal needle, well past the needle tip, so that the thread goes through and through and both ends of the suture are outside the needle. The abdominal wall and the bladder are then traversed with the needle, at a site immediately cephalad to the site chosen for port placement. Under cystoscopic guidance, the spinal needle is advanced into the bladder. When the needle is advanced, the suture advances into the bladder along with it. After the tip of the spinal needle enters the bladder, the suture within the needle is further advanced to form a loop, called the pulling loop. This loop is retained in the bladder, and the needle is carefully removed. Through an adjacent puncture, the spinal needle is inserted into the bladder again, and the tip is advanced through the pulling loop. Another 2-0 PDS that will ultimately be anchoring the bladder to the abdominal wall is then inserted through the needle, thus placing it through the loop. Retracting both tails of the pulling loop together out of the bladder pulls the anchoring suture, creating a through-and-through suture that can be tied fixing the bladder to the abdominal wall. Fixation sutures are placed in the midline, as well as the lateral walls of the bladder. Alternately, we have noted that applying traction on the anchoring sutures and securing them to the drapes without tying over the abdominal wall serves the same purpose. Removing this is easy, and there is no suture impression on the abdominal wall.

- *Port placement*: A 5 mm port is placed in the midline for the camera. Two 3 mm working ports are then placed. They must be sufficiently lateral and minimally caudal to the telescopic port to give a comfortable working angle at the depth of the bladder base, for the reconstruction. These ports are placed immediately distal to the fixation sutures in the direction of the bladder neck. For most children, 3 mm laparoscopic instruments that are 20 cm in length are ideal (Figure 45.6).

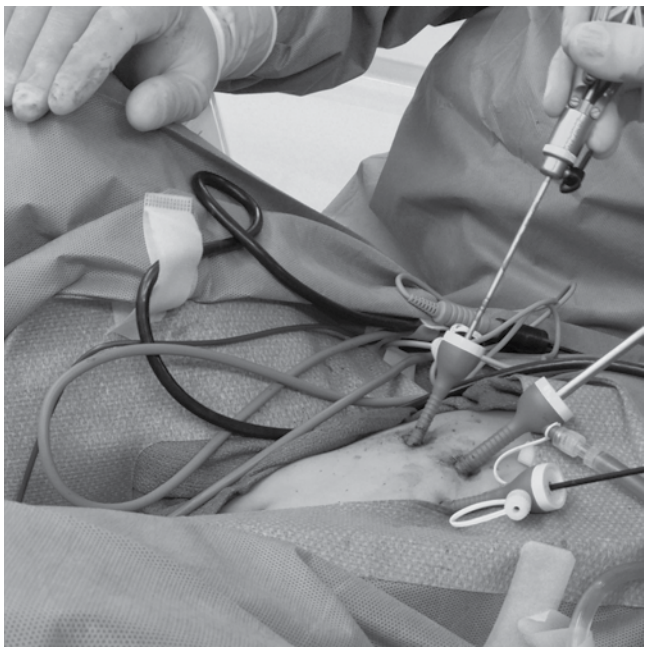

FIGURE 45.6 Suggested port sites for vesicoscopic intravesical reimplant.

- *Ureteral dissection*: Vesicoscopy is performed using a 5 mm 30° lens. The orientation is such that the bladder neck will be located at the twelve o'clock position. Feeding tubes (3.5 Fr) are placed per urethra, passed up each ureter, and fixed with fine suture. Placement of the fixation suture through the tube prior to introducing it transurethrally makes this step easier. Using a hook electrode at a low-power setting begins dissection. Applying gentle traction on the fixation suture away from the line of incision enables precise dissection, retaining a rim of the bladder mucosa with the ureter. Using a combination of sharp and blunt dissection in a manner analogous to open transvesical surgery, the surgeon dissects the ureter off the surrounding detrusor muscle. Extreme care must be used when transecting investing bands of detrusor, and it may be safer to divide these bands sharply as opposed to using cautery. This dissection is rather easy and rapid in children with thin-walled bladders, but it can be quite difficult if a child has a markedly thickened bladder wall. Dissection is continued until enough length is gained to bring the ureter to the contralateral side. The posterior detrusor opening is then closed with an interrupted 4-0 PDS suture. For bilateral repairs, the contralateral ureter may then be mobilized. During the procedure, a suction device is needed to remove not only blood but also urine that may accumulate at the bladder base. Some authors have left a small urethral catheter indwelling to assist with suction, but our preference is to simply use a 3 mm suction–irrigation device through one of the working ports as needed.
- *Tunnel creation*: The tunnel is usually created from the initial hiatus across the contralateral hiatus. Whenever the hiati are located close by and a longer tunnel is required, the mucosa lateral to the contralateral hiatus may be dissected off from the detrusor to increase the tunnel length. With a combination of blunt and sharp dissection, a submucosal tunnel is created. Maryland graspers are used to elevate the mucosa, and fine scissors are used to initiate and develop the plane. The positive pressure within the bladder along with the optics of the 30° lens can assist with visualizing the appropriate plane. After creation of the tunnels, the ureters may be placed in the tunnels and passed to the other side. The feeding tube splint anchored to the ureter often helps in guiding the ureter through the tunnel. The ureters are then fixed in place with an interrupted 5-0 polydioxanone suture. The remaining mucosal openings are then closed with absorbable sutures and the feeding tubes removed.
- *Port closure*: To maintain the pathway through the incision into the bladder, a feeding tube is placed through each port prior to its removal. Under cystoscopic guidance, the sutures to close the port are placed in a manner analogous to that for the initial fixation sutures. After placing the bladder port closure sutures, a Foley catheter is inserted to decompress the bladder and the fixation sutures are removed. This allows the bladder to fall away from the abdominal wall. The bladder port sutures are then carefully tied and the skin incisions subsequently closed. The Foley catheter is typically removed in 36 hours.

Results

Published success rates approach, but are not yet equal to, those of open repair, ranging from 92% to 96%.[22–27] Most of the failures were early in the series, as the surgeon was learning and refining the technique. To date, in these authors' series, 180 children have undergone vesicoscopy, with a mean age of 79 months (16–226 months). Of these, 164 were female and 16 were male. One hundred thirty-four underwent bilateral reimplantation and 46 were unilateral. There were four open conversions. Observed complications early in the series were persistence of reflux, urine leak, ureteral stricture, and port dislodgement with surgical emphysema, although there have been no complications or adverse effects in the last 50 patients treated. The operative time was significantly more than that for open surgery, especially in early cases. It is a technically challenging procedure, but may be justified given the demonstrable reduction in analgesic requirements compared with open surgery.[22,28]

ROBOTIC INTRAVESICAL CROSS-TRIGONAL REIMPLANT

Peters and Woo, in 2005, presented their initial experience trying to combine the benefits of the transvesical approach with the minimal invasiveness of robotic surgery.[29] The drawback at that time was the need for a 12 mm camera port and two 8 mm robotic cannulas. This may be less of an issue with the current and future smaller robotic cameras, ports, and instruments.

The steps after port placement are the same as described above for laparoscopic vesicoscopic cross-trigonal reimplants. The difference lies in the technique of port insertion and port site closure at the end, as the ports are much larger. These authors also noted that the metal of the robotic trocars tends to be very slippery, and it is difficult to keep their position in the skin, even with traction stitches. One technique to help combat this problem is to advance them through a VersaStep™ sheath, which tends to reduce the amount of displacement of the trocar during the procedure.

Results

In their report, Peters et al. tried this technique on six patients, and mild reflux persisted in one of them (83% success rate).[29] In 2011, Marchini et al.[30] published a comparative study in which they had two groups of children that underwent robotic-assisted reimplantation; one group was intravesical (19 patients) and the second extravesical (20 patients). They were compared with a matched cohort of patients that underwent open surgery, 22 intravesically and 17 extravesically. They showed similar success rates in all groups. The robotic-assisted intravesical approach had shorter operative stay, shorter postoperative catheterization, and fewer bladder spasms than the open intravesical group. The difference in bladder spasms was not as pronounced in the extravesical groups. However, both robotic-assisted groups had a significantly longer operative time than the open ones.

CONCLUSION

As surgeons gain experience in laparoscopy and robotic-assisted surgery, we predict that there will be an expanding role for minimally invasive techniques in the correction of reflux. As we have shown, several minimally invasive techniques have been employed, including pure laparoscopy and robotic-assisted laparoscopy, through extravesical and transvesical approaches, which provide valid options with comparable success rates to open surgery.

CHAPTER 46

Injection Therapy for Vesicoureteral Reflux

Anthony A. Caldamone

INTRODUCTION

Vesicoureteral reflux (VUR), one of the most common urologic abnormalities in children, occurs in 0.4%–1% of the general population and in 30%–50% of those children who present with urinary tract infections (UTIs).[1] When correction of VUR is determined to be necessary, historically ureteral reimplantation by a variety of techniques has been the mainstay of treatment. This approach is justified because surgical correction affords a very high success rate, approaching 99% in experienced hands, and a low complication rate.[2]

The search for a less invasive approach to the correction of reflux, however, dates back to 1981, when Matouschek[3] first described the injection of polytetrafluoroethylene (PTFE) at the ureteral orifice to correct VUR. Reports then followed by McDonald and McDonald.[4] After using PTFE for incontinence, Politano then reported on its use in VUR.[5–8] Puri and O'Donnell brought this clinical concept to the laboratory and demonstrated the successful correction of experimentally produced VUR in a piglet model by the intravesical injection of PTFE.[9] In their classic article in 1986, they reported on the successful endoscopic correction of primary VUR in 103 ureters, achieving a success rate of 75% after a single injection.[10]

This approach earned widespread international acceptance but only sporadic usage in the United States because of the lack of Food and Drug Administration (FDA) approval. It was quite apparent, however, that the potential for revolutionizing the management of children with VUR was real. Although the procedure requires general anesthesia and possible repeat injections, the ease of treatment, lack of open surgery, and minimal hospitalization were extremely attractive in the pediatric population. However, the lack of demonstrated long-term safety and concerns raised in experimental and clinical settings on the potential migration of PTFE particles prohibited its widespread acceptance in the United States. It was quite clear, however, that while the material had its drawbacks, the technique itself was reproducible and reliable. The search was on, therefore, for a substance that would fulfill the following characteristics: ease of injection, maintenance of injected volume, minimal host response, no evidence of distant migration of material particles, maintenance of the injected mound without shifting, and no significant volume loss, longevity of effect, and biocompatibility. The mechanism for the endoscopic correction of VUR involves one or more of the following effects: (1) improved backing of the intramural ureter, (2) fixation of the ureterovesical junction (UVJ) to the trigone by spot welding, or (3) decreased caliber of the distal ureter.

In this chapter, we review the substances that have been used both experimentally and clinically for the endoscopic correction of reflux. In addition to the use of this technique for primary VUR, the applicability of the endoscopic correction technique to other reflux variations is also discussed. Finally, as with any new technology, one must address the issue of whether this new technology changes the indications for surgical correction of VUR.

TECHNIQUE OF ENDOSCOPIC INJECTION

The technique of endoscopic injection for correction of VUR has changed little since it was first described by O'Donnell and Puri.[11] The technique is relatively independent of the material used, although variations in material properties may result in minor modifications in technique. The technique is often referred to as STING, an acronym for subtrigonal injection (Figure 46.1).

Under cystoscopic control, the orifices and bladder mucosa are inspected. Whereas the type of cystoscope is not critical, an offset lens system allows for a straight route for the needle through the scope, which is especially helpful if using a metal needle (Figure 46.2). The degree of bladder filling is critical, as a full bladder may make it more difficult to accurately place the material behind the ureter and still be in the wall of the bladder. Either a rigid metal needle or a malleable needle (most commonly 3.7–4 Fr in size) may be used. A syringe of material is fixed to the needle, and for viscous material like PTFE and silicone, a ratcheted metal syringe holder may be needed. The needle is introduced through a cystoscope using a 0° or 30° lens. Under direct vision, the needle is advanced bevel up and introduced submucosally at the six o'clock position of the UNJ (Figure 46.3). Puri and O'Donnell originally reported piercing the mucosa 2–3 mm distal to the UVJ and advancing the needle 4–5 mm into the lamina propria of the submucosal portion of the ureter. Alternatively, for more gaping orifices, the needle can be placed directly through the mucosa at the UVJ. This can be facilitated by hydrodistention of the ureter, by having irrigation flowing through the cystoscope at the time of the injection, thus dilating the ureteral orifice.[13] The critical step

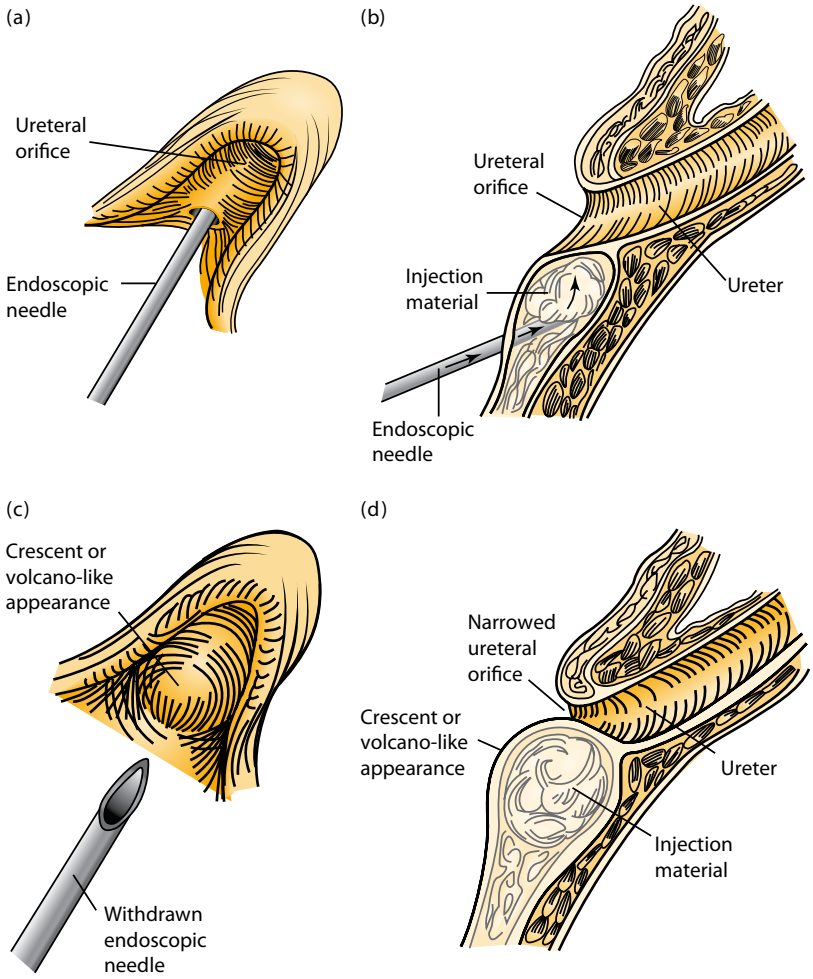

FIGURE 46.1 Standard subureteric injection technique: (a) Needle placed at six o'clock position, bevel upward. (b) Slow injection in subureteric space. (c) Postinjection appearance. (d) Appropriate position of injected material. (Reproduced from Russinko PJ, Tackett LD. *Atlas Urol Clin* 2004;12:55–63. With permission.)

of the procedure is observing the effect from injection of 0.1–0.2 mL. One should carefully assess the positioning of the mound with this minimal initial injection. A "volcanic" bulge should be observed, raising the ureteral meatus onto the dome of the mound. Minor adjustments in the direction of the bevel or the depth of the needle can be made based on the initial 0.1–0.2 mL injection volume. Once the appropriate effect is obtained, more material can be injected to achieve a volcanic mound with a crescent-shaped orifice at the dome (Figure 46.4).

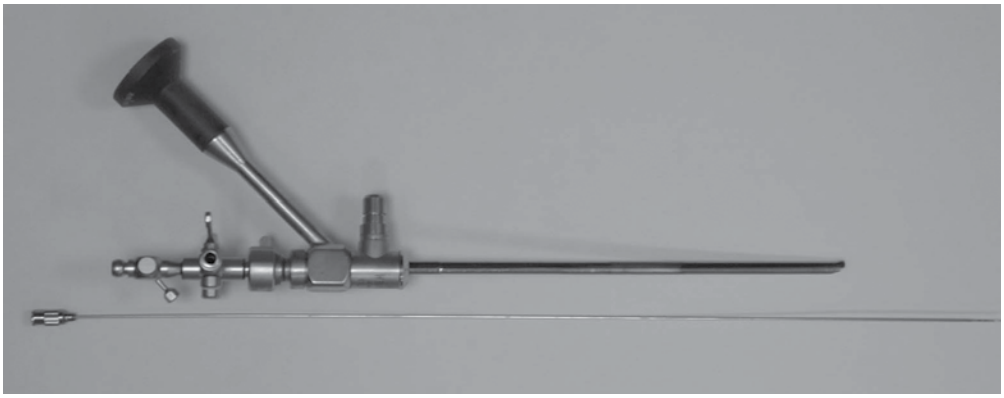

FIGURE 46.2 Offset lens "STINGER" scope, allowing for a straight 4 Fr channel to pass a rigid or flexible needle for injection of material.

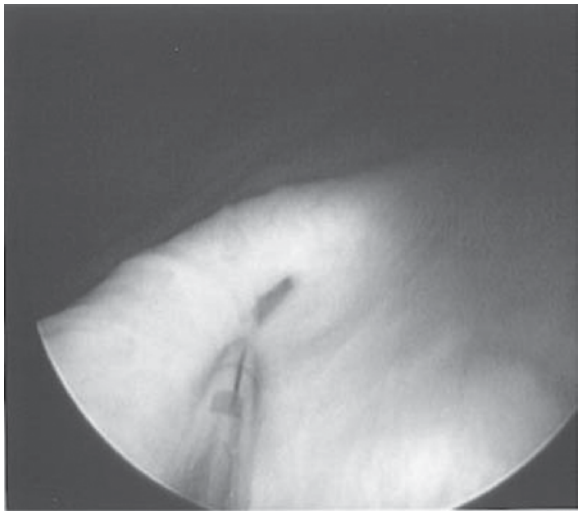

FIGURE 46.3 Needle in six o'clock position at left ureteral orifice subureteric injection.

Depending on the material injected, there is a variable degree of leakage from around the needle or through the needle track once the needle is removed. For PTFE or silicone, the needle should be left in place for 30–60 seconds prior to removal to avoid extrusion. At the conclusion of the injections, the bladder is then drained; viscous 2% lidocaine can be injected into the bladder if desired, prior to cystoscope removal. The patient is discharged from the recovery room on a therapeutic dosage of antibiotics for 3 days, followed by prophylaxis, if indicated, until a postoperative ultrasound and voiding cystourethrogram (VCUG) are done at 3 months. The presence of a well-positioned mound on ultrasound, while reassuring, does not predict successful correction of VUR (Figure 46.5). If reflux is resolved, antibiotic prophylaxis is discontinued and a follow-up ultrasound is done at 1 year.

Postinjection catheter drainage is generally not necessary. Most clinicians recommend antibiotic prophylaxis for 3 months until a follow-up ultrasound and VCUG are performed. If there is persistent VUR, a second endoscopic

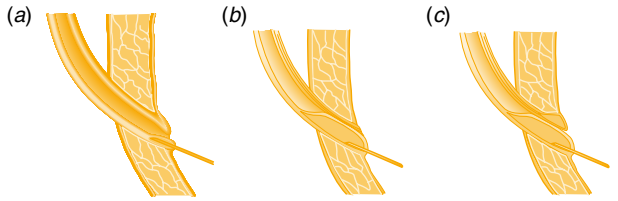

FIGURE 46.5 HIT: Modification of the STING procedure places implant material along the entire subureteral tunnel and leads to greater ureteral wall coaptation. (a) The needle is placed within the ureteral submucosal to the level of the midureteral tunnel. (b) Initial injection causes the floor of the ureteral tunnel to rise up to meet the ceiling of the tunnel. (c) Further injection leads to tracking of implant circumferentially within the ureteral tunnel, resulting in complete coaptation. (From Kirsch AJ et al. *J Urol* 2004;171:2413–16.)

injection can be performed, especially if improvement has been demonstrated after the initial treatment. If failure occurs again, most clinicians would recommend ureteral reimplantation. All studies to date have demonstrated the same high success rate of ureteral reimplantation following endoscopic injection, regardless of the agent used, compared with a primary ureteral reimplantation.[14] It is apparent to most surgeons who have performed endoscopic injection procedures for VUR that, whereas the procedure is relatively straightforward, there are subtle aspects of the technique that are learned over time. Kirsch et al. demonstrated a learning curve over their first 180 cases. The success rate after a single injection for their first 20 patients was 60%, compared with 80% for the last 20 patients in this series.[15]

Kirsch et al. reported on a variation of the classic STING technique in which material is implanted submucosally within the intramural ureter.[13] They referred to this as the hydrodistension technique (HIT). This is accomplished by hydrodistension of the ureteral orifice to allow for injection of the material within the ureteral lumen, rather than injecting in a subureteric position. In a comparative study, they found the success rate with the modified technique to be significantly greater than that with the standard technique, overall 97% versus 79% (Figure 46.5).

Cerwinka et al. have advocated a double HIT for endoscopic injection consisting of two tandem intraluminal ureteric injections (Figure 46.6), one at six o'clock in the midtunnel, which coaps the tunnel. A second injection is made at the more distal aspect of the tunnel close to the ureteral orifice to allow for coaptation of the ureteral meatus. They suggested a classic STING if after the double HIT injection ureteral hydrodistention persists.[16] In a 1-year follow-up of patients in which the double HIT was used, Kalisvaart et al. reported a 93% clinical and radiographic success rate, and raised the question as to the necessity of the postinjection VCUG.[17]

MATERIALS

Many materials have been used over the past 25 years of endoscopic treatment for VUR. Whereas success rates vary little from material to material, other properties—such as ease of injection, particle size and migration, inflammation response, longevity, and biocompatibility—vary greatly (Table 46.1). Materials may be divided into nonautologous and autologous.

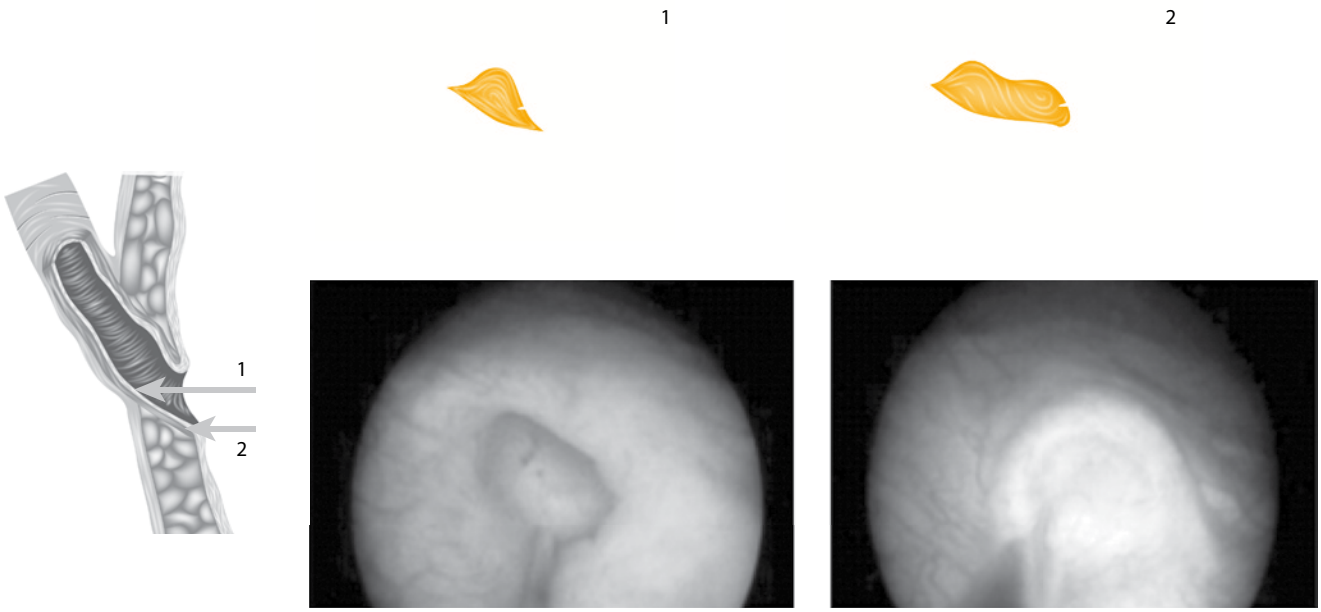

FIGURE 46.6 New double HIT as described by Cerwinka et al. (Courtesy of A. Kirsch.)

TABLE 46.1 Characteristics of available injection materials

Product	Material composition	Particle size (μm)
Teflon, polytef	PTFE particles, which are inert and suspended in glycerin 50% by weight	4–100
Deflux	Dextranomer microspheres cross-linked in 1% sodium hyaluronan solution	80–120
Zyderm, Zyplast, Contigen	Derived from bovine dermis, cross-linked to glutaraldehyde: GAX 35, 35 mg/mL collagen; GAX 65, 65 mg/mL collagen suspended in pH neutral saline	—
Macroplastique	Polydimethylsiloxane (PDMS), a biphasic copolymer polymerized and vulcanized PDMS in polyvinylpyrrolidone hydrogel	35–540; mean maximal diameter, 209 μm
Coaptite	Calcium hydroxylapatite spheres suspended in water and glycerin mixture with cellulose gel former	75–125
Urocol	50% microporous hydroxyapatite ceramic suspended in gel with 4% collagen in glycerin	100–400
Chondrocytes	Auricular chondrocytes suspended in an alginate solution with calcium salt	20×10^6
Fat	Suprapubic adipose tissue obtained by microliposuction	—
Autologous collagen	Extracted from dermis	—Autologous blood
Autologous blood	Extracted from patient	—
Autologous bladder muscle	Extracted from animal	—
Polyacryl polyalcohol copolymer	Synthetic acryl particles	300

Nonautologous Materials

Polytetrafluoroethylene

In 1973, Berg reported a method for the correction of urinary incontinence using an injectable form of PTFE paste.[18] In 1981, Matouschek injected PTFE at the UVJ for the correction of VUR.[3] This was then first studied in an animal model by Puri and O'Donnell,[9] and then in human subjects.[11,19] PTFE, a polymer composed of large molecules formed by chemical combinations of smaller ones into chains, has been used in the manufacture of plastic materials for medical devices for many years, including vascular grafts, cardiac valves and implants, stents, cartilage or bone replacement, sutures, and patches. The paste form of PTFE is a suspension of inert PTFE particles in a glycerin carrier. The glycerin, which represents 50% of the weight, is absorbed by the tissues after injection. The size of the particles ranges from 4 to 100 μm, with approximately 90% <40 μm. Because of its high viscosity, PTFE requires a ratcheted syringe mechanism for injection. Upon injection, a foreign body giant cell reaction occurs with the infiltration of histiocytes, which is followed by a fibrous encapsulation.[10,20–22] The material is not biodegradable, and therefore should persist throughout a lifetime. Results of endoscopic correction of VUR with PTFE approach 90% after a single injection in some series and 94% after subsequent injections.[23,24] Long-term follow-up in a multicentered report indicate a sustained effect for up to 10 years.[25,26] In this multicentered study, the overall success rate in 6216 ureters and 4166 children treated at 18 European centers demonstrated a cure rate of 86% after one to four injections, with an obstruction rate of 0.0003%. In a 17-year follow-up of 247 patients treated with PTFE, Chertin et al. demonstrated a sustained 95% success rate after one to four injections and a 5% recurrence rate, with 1.8% requiring open surgery.[27] In the meta-analysis review by Elder et al. of 33 studies reporting on the results of PTFE, the overall success rate after a single injection for all grades combined was 67%.[28]

Experimental studies done shortly after the introduction of PTFE in clinical reports demonstrated the migratory property of PTFE as a result of a significant percentage of particles being <80 μm.[29,30] These particles become phagocytized and carried to regional lymph nodes or enter into capillaries directly upon injection. Malizia et al. had found particles in lymph nodes and distant organs in an experimental model.[31,32] Particle migration has also been reported in humans,[30,33–35] including, in a speculative report, to a child's cerebral microcirculation and associated with an ischemic stroke.[36] Some clinicians have argued that particle migration is at least partially related to the volume of injection; however, clinical reports indicate that particle migration has occurred with volumes as small as 0.5 mL of PTFE.[37,38]

The potential of carcinogenesis with PTFE and other nonautologous substances has been of concern. Although there has not been direct evidence of carcinogenesis with PTFE in an experimental model,[39] there has been experimental evidence linking injected foreign substances of large particulate size to potential carcinogenesis.[40]

Cross-Linked Bovine Collagen

Cross-linked bovine collagen has been used for multiple medical purposes, such as cardiac valves, hemostatic

agents, sutures, and a soft tissue substitute. It is harvested from bovine hide and treated with pepsin to reduce its antigenicity associated with the telopeptides of the collagen helix. It is composed of 95% type I collagen and 5% type III collagen. It is cross-linked with glutaraldehyde to reduce breakdown after implantation by human collagenases. For human implantation, several products have become available (Contigen, Zyplast, Zyderm, GAX 35, and GAX 65).

Upon injection, collagen causes very little local tissue reaction and no granuloma formation. To variable degrees, there is an ingrowth of fibroblasts and eventual replacement with native collagen.[41–43] The degree to which native collagen ingrowth occurs is thought to determine the potential for long-term cure.

Collagen is injected easily with finger pressure, with no special device required. However, as a result of this relatively low viscosity, precise injection may be more difficult. Preinjection skin testing is necessary, as 3% of patients have a hypersensitivity reaction to collagen, although a negative reaction does not completely eliminate the risk of an allergic reaction.[44] As noted in Table 46.2, the initial success with the endoscopic injection of collagen is similar to that of other materials. However, several reports indicate poor sustained results. Haferkamp et al. reported an initial success of 92% after a single injection in 36 children, with a recurrence of reflux in 91% after 37 months.[50] In a similar study, the recurrence rate was 63%.[51] The use of a more concentrated mixture of 65 mg collagen/mL (GAX 65) has shown promise of a more sustained cure in a report by Frey et al., where a 6-month evaluation postinjection demonstrated more retained volume, 26.9% versus 0.1% for GAX 35.[55] Reunanen reported on 197 ureters treated with endoscopically implanted collagen in which 84% remained without reflux at 4 years follow-up.[46] De Grazia and Cimador reported a 16.8% recurrence rate in 129 refluxing ureters injected, with higher rates of recurrence in the higher initial grades of VUR.[52]

TABLE 46.2 Results of endoscopic treatment of vesicoureteral reflux with collagen

Authors	No. of ureters treated	Percent success, after one injection

Polydimethylsiloxane

This bulking agent is composed of particulate silicone in an injectable mixture of fully vulcanized polydimethylsiloxane (40%) suspended in a water-soluble polyvinylpyrrolidone (60%). The particulate size ranges from 35 to 540 μm (average 209 μm) with 28% <80 μm and 7% <50 μm.[56] It is not surprising, therefore, that studies by Buckley et al.[57,58] and Henly et al.[59] found particle migration to the lungs, kidneys, brain, and lymph nodes after injection in animal models. It has been shown that a particulate size of <80 μm facilitates particle migrations.[31] Shedding of silicone particles with migration has been reported from implanted medical devices.[60] The advantage of particulate silicone is that there appears to be less inflammatory response and granuloma formation, although those findings have not been consistent. Silicone is nonbiodegradable and therefore should be permanent once injected at the UVJ. Similar to PTFE, a ratcheted mechanism is required for injection. The injection of silicone induces an inflammatory response with macrophages and fibroblasts and later ingrowth of collagen.[61]

Silicone has been implicated in autoimmune reactions[29,59] and associated with a possible risk of malignancy,[40,62–64] although the data for the latter have been inconsistent.[65] Multiple studies have demonstrated the reproduced effectiveness of injected particulate silicone to correct reflux.[56] Herz et al. demonstrated a success rate of 81% after a single injection and 90% of ureters after repeated injection with a 12-month follow-up.[66] In a 1-year follow-up study from two centers, van Capelle et al. reported success with the endoscopic implantation of silicone in 155/195 children treated, representing 82.3% of ureters injected one or more times.[67] Aboutaleb et al. compared particulate silicone injection versus extravesical ureteral reimplantation for primary low-grade reflux (grades I–III) in 180 patients, 74 silicone injections, and 106 extravesical reimplantations.[68] Of the injected group, 81% were cured at 3 months and 92% at last follow-up compared with 96% at 3 months and 99% at 1 year in the reimplantation group. There were no complications in the injected population, whereas 7% of the reimplanted group had postoperative complications, including 3.3% (two patients) with transient urinary retention. In summary, silicone appears to be an effective agent for the treatment of VUR. Concerns remain regarding its particle size, and therefore its migratory potential, as noted in experimental studies.

Dextranomer/Hyaluronic Acid Copolymer

Dextranomer microspheres were first introduced by Stenberg and Läckgren in experimental models in which 1 mL was placed into the abdominal wall of rats and into the bladder wall of piglets.[69] At 3 months, the implants became encapsulated, with a 23% reduction of the injected volume. Repeat studies performed with radiolabeled dextranomer spheres demonstrated no evidence of distant migration, lymphadenopathy, mutagenic effect, DNA changes, or tumor development.[70] The larger particulate size of the dextranomer/hyaluronic acid (Dx/HA) copolymer compared with PTFE and silicone is thought to account for the fact that it is not phagocytized, and therefore its lack of particulate migration to distant organs.

Puri et al.[76]	2341	87.1
Kaye et al.[77]	521	90

[a] Reported only after multiple injections.

The Dx/HA copolymer is a solution of cross-linked dextranomer microspheres (80–250 μm in diameter) suspended in a carrier gel of stabilized sodium hyaluronate.[54] Dextranomers have found previous uses in medicine for wound healing, and sodium hyaluronate has been used for eye surgery and joint injection. The Dx/HA copolymer differs from other nonautologous materials, such as PTFE and silicone, in that it is biodegradable. Its volume stability over time results from fibroblast migration and collagen ingrowth between the dextranomer microspheres (Figure 46.7), as the hyaluronate dissipates 12 weeks after implantation.[70] It is injected with a standard syringe mounted on an endoscopic needle with finger pressure. In animal studies, carried out for 3 years, the durability of the spheres has been demonstrated without granuloma formation or calcification.[69,72]

The overall results with the Dx/HA copolymer compare favorably with those of PTFE and silicone, as noted in Table 46.3, which lists the results after a single injection. In a long-term follow-up study by Läckgren et al. of 221 children followed for a mean of 5 years, 68% of patients (75% ureters) maintained grade I VUR or less and 81% (85% ureters) grade II VUR or less at the last VCUG done. Of 49 patients who had a VCUG at 3–12 months, reflux recurred in 13%, 4% of which were grade III or greater.[14] No long-term adverse effects were noted, with 2% developing postoperative UTIs, and early mild postoperative hydronephrosis occurring in four patients, none of whom developed signs of ureteral obstruction. In the largest reported series to date, Puri et al. reported an overall success rate of 87.1% after a single injection in 2341 ureters of 1384 children.[76] No patients developed obstruction and 4.6% had postinjection febrile UTIs. The success rate per grade after a single injection was grade II 100%, grade III 95%, grade IV 75.2%, and grade V 62.4%. While some series, such as that by Kaye et al., have reported such high success rates after single injection to be able to recommend avoiding the postinjection VCUG, most surgeons recommend an ultrasound and VCUG at 3 months postinjection with Dx/HX, and then again should there be a subsequent febrile UTI.[77] In a study comparing the Dx/HA copolymer and silicone, Oswald et al. reported a slightly higher success rate with silicone, but the difference was not statistically significant.[74]

Coaptite

Calcium hydroxylapatite is composed of calcium hydroxylapatite spheres suspended in a water and glycerin mixture with 3% methylcellulose gel. Calcium hydroxylapatite particles are synthetic, and therefore a uniform spherical shape with a narrow range of 75–125 μm. This material represents synthetic bone, and therefore, as a subureteric bulking agent, theoretically should have a limited local reaction and a very durable long-term effect. A clinical trial by Mevorach et al. on 98 patients and 155 ureters with grade II–IV reflux demonstrated reflux resolution in 67% of patients and 75% of ureters, and improvement was noted in 77% of patients and 84% of ureters.[78] Interestingly, five patients in this particular subgroup demonstrated progressive improvement in reflux grade postinjection at 1 year to reflux resolution when evaluated with a VCUG at 2 years. The procedure was tolerated well by all patients, and there were no significant safety issues disclosed. Calcium hydroxylapatite is therefore determined to be a safe, durable, and effective material for the endoscopic treatment of reflux, although at this time clinical trials are still being evaluated by the FDA.

Polyacryl Polyalcohol Copolymer

Experience with a nonbiodegradable material, polyacrylate polyalcohol bulking copolymer, has been reported by some centers.[79,80,81] This substance is synthetic with an average diameter of 300 μm, which should prevent distal migration. Success rates for uncomplicated VUR have ranged from 83% to 92.1%, with a low rate of obstruction

(1%–2%). Long-term data with late follow-up VCUG have not been reported to date. The anticipated long-term success comes from its nonbiodegradable property and the formation of a pseudocapsule.

Autologous Materials

Autologous materials have the appeal of not having the concern of a foreign body reaction to the injected mound. The disadvantage, however, is the need for a harvesting step, which, with all materials tried to date in the pediatric population, requires an additional anesthetic. These autologous materials must behave as free grafts, and therefore are subject to the physiology of graft survival. To date, the autologous materials that have been tried are collagen, fat, and chondrocytes.

Chondrocytes

Following demonstration that the harvesting and subsequent implantation of autologous chondrocytes resulted in viable chondrocytes, first in the mouse model and later in the pig model by Atala et al.,[82,83] Diamond and Caldamone used harvested chondrocytes in the human model.[84,85] Chondrocytes were harvested from the posterior auricular cartilage, grown in culture for 6 weeks, suspended in an aqueous mixture of alginate and calcium salts, and subsequently injected at the UVJ. Long-term results of 47 ureters with grade II–IV VUR demonstrated an 80% cure rate at 3 months and an 86% cure rate at 1 year following one or more implantations. In those children requiring a subsequent open ureteral reimplantation, no viable chondrocytes were identified, however. It was unclear whether the failure to correct the reflux was attributed to a failure of chondrocyte survival, or whether this was a more universal effect. In those children who underwent a second injection or open reimplantation after a failed injection, the most common findings were shifting of the materials and a loss of material volume.[85]

Fat

Autologous fat has been used as an implant for correction of reflux. It was initially reported in an experimental model by Matthews in 1994, followed by clinical reports by Palma and Chancellor.[86–88] In follow-up studies at 3 months postimplantation, reflux persisted in 70% of Chancellor's study group and 83% of Palma's group. Viability appears to rely on vascular ingrowth to the injected cells, and therefore small volumes injected appear to be more effective in survival. In the rabbit model by Matthews, there was a 25%–100% loss of volume postinjection in 47% of sites injected.[86]

Collagen

Cendron et al. reported on the use of autologous collagen as an injectable material for correction of VUR.[89] The rationale for the use of autologous collagen is to improve the longevity of bovine collagen preparations, as well as to avoid the hypersensitivity potential. Collagen fibers were isolated by centrifuge from the dermis. In an experimental study, collagen integrity was demonstrated at 50 days.

Muscle

Autologous bladder muscle cells have been used in an experimental study to correct reflux.[90] Muscle cells were harvested from the bladder, coupled with an alginate mixture, and reinjected through a 21-gauge needle. Cell survival was demonstrated in a short-duration study.

Cumulative Results

Endoscopic treatment for VUR in children has a high success rate (Table 46.4). The success rate is universally proportional to the grade of reflux treated (Table 46.5). Multiple injections are advantageous in increasing the success rate, and prior endoscopic material implantation does not appear to significantly alter the open surgical success rate.

Special Considerations

Neurogenic Bladder

A significant number of patients, upwards of 50%, with spina bifida have associated VUR. This can be a cause of significant morbidity and renal damage in this population. The mainstay of management of VUR in association with a neurogenic bladder has been modulation of bladder pressures and frequent complete emptying. This is usually

TABLE 46.4 Overall resolution rate after single injection for all reflux grades based on ureter and material

Agent	Number in studies	Sample	Percent resolution

accomplished by a combination of intermittent catheterization with or without the addition of anticholinergic therapy and/or suppressive antibiotics. When children fail this regimen, treatment has been bladder augmentation with or without ureteral reimplantation. Some have advocated the addition of endoscopic correction of reflux to the armamentarium for management of VUR in the setting of the neurogenic bladder (Table 46.6). Technically, this can be more difficult to perform because of the trabeculation of the bladder, and a ureteral catheter in the orifice at the time may facilitate injection. However, in spite of these difficulties, success has been reported in up to 90% of cases after multiple injections.[93,98,100,101] Engel et al. reported success in 57% of reflux in ureters after a single injection of PTFE and 62% after a second injection.[92] They compared this with their open surgical population, in which they were able to achieve an 84% success rate in 30 patients undergoing ureteral reimplantation. Haferkamp et al. found that the long-term success rate using collagen (GAX 35) was only 15% of treated units after 24 months.[51] Part of that falloff in success rate could be a result of the degeneration of collagen, but it also may result from the inherent neurogenic disorder. It is imperative that once these children are treated endoscopically or with open surgery, continued bladder management is carried out in order to prevent long-term complications, such as the recurrence of reflux or functional UVJ obstruction. Similarly, Dewan and Guiney reported that 4 of 23 successfully treated ureters recurred.[97] Granata et al. reported a comparative study on surgical and endoscopic correction of reflux in children with a neurogenic bladder.[91] They found an overall success rate of 72.5% using PTFE, compared with 95.5% when a Cohen cross-trigonal ureteroneocystostomy was performed. They found that 2 of their 29 ureters that were cured with the endoscopic approach recurred with VUR; however, both were treated successfully by a repeat endoscopic procedure. There were no recurrences observed in the patients cured by open reimplantation. In a meta-analysis recorded by Elder et al. of 10 articles, there was a significantly lower rate of success of the endoscopic approach in the neurogenic bladder (53.5%) versus the nonneurogenic bladder (74.2%).[28] However, more recently, on both univariate and multivariate analyses, Routh et al. found that neurogenic bladder was not a predictor of failure.[102] It is likely that surgical experience with endoscopic injection for VUR in the neurogenic bladder is a major variable in success rates.

Dysfunctional Voiding

Studies by Frey et al.,[41] Trsinar et al.,[103] and Capozza et al.[47,104] have implicated undisclosed dysfunctional voiding as a cause of failure of endoscopic correction of VUR. In each of these cases, the authors found displacement of the mound to be a common occurrence using either collagen or dextranomer microspheres. In each of these studies, however, the diagnosis of dysfunctional voiding was based on clinical history and not urodynamic findings, representing some limitation to their conclusion. The implication from these studies, therefore, would be to control or at least stabilize the dysfunctional voiding prior to the endoscopic correction of the reflux. Other studies have not found a higher failure rate or recurrence rate following endoscopic correction for VUR in dysfunctional voiders.[102,105] Several studies have pointed out that management of dysfunctional voiding improves the spontaneous resolution of reflux and decreases the need for ureteral reimplantation.[106,107] Läckgren and Stenberg noted, however, that when the endoscopic correction of reflux in children with dysfunctional elimination syndrome was undertaken, they found an overall cure rate of 65% across all grades of reflux, indicating no particular difference as to whether preinjection bladder retraining had been undertaken.[108] Of 35 patients that were cured of their reflux on a single injection, 8 continued to have evidence of minor bladder dysfunction, whereas 27 appeared to have completely resolved their symptoms of bladder dysfunction. This may indicate a potential role of the reflux in either the causation or the promotion of bladder dysfunction in this particular population.

Duplicated Systems

More experience is being gained in the use of injectable materials for duplicated systems. At one time, a duplicated

system was considered to be a relative contraindication to the use of injectable material;[109] however, several reports have now indicated that with experience, the success rate for the endoscopic correction of reflux in the duplicated system approaches that of a single system. Miyakita et al.[110] reported on their results with the use of PTFE in both partial and complete duplication. Their success rates were 87% in partial duplication and 59% in complete duplication. Similarly, Steinbrecher et al. reported a cure rate of 68% in completely duplicated systems using PTFE.[111] Dewan and O'Donnell reported on 32 children with duplex systems and VUR treated endoscopically with PTFE.[112] They were able to cure VUR in 21/32 patients. In the meta-analysis by Elder et al., the success rate of endoscopic correction for duplicated systems was 50% compared with 73% for nonduplicated systems.[28] Perez-Brayfield et al. reported a 73% success rate in using dextranomer microspheres for the endoscopic correction of reflux and completely duplicated systems.[99] Läckgren et al. reported on the use of the Dx/HA copolymer and duplicated systems, and found a 63% success rate, defined by improvement to grade 0 or I.[113] In a study of Dx/HA injection for VUR in the setting of bladder and ureteral anomalies, Routh et al. demonstrated on univariate analysis that ureteral duplication was a predictor of injection failure. However, in a multivariate analysis controlling for VUR grade, subureteric injection technique, and surgeon experience, there was no difference in the failure rate for duplicated systems compared with single systems.[102]

It should be pointed out, however, that the technique of the injection varies with the anatomy. For those completely duplicated systems in which there is wide separation of the ureteral orifices, and therefore more likelihood to reflux just to the lower pole, separate injections under each orifice are recommended. However, for those duplicated systems where the orifices are closely approximated, a single injection may suffice (Figure 46.7).

Aboutaleb et al. compared the results with polydimethylsiloxane injection versus open surgery for the treatment of VUR in duplex systems.[114] The open surgical approach for reflux in this study was extravesical common sheath ureteral reimplantation. The endoscopic injection of polydimethylsiloxane was performed in 15 patients with 22 refluxing units. The success rate for the endoscopic correction was 68% at 3 months and 82% at 12 months, with one patient developing contralateral VUR. There were no cases of de novo hydronephrosis or UTIs postoperatively. This compared with the success rate of extravesical common sheath ureteral reimplantation of 96% at 3 months and 97% at 15 months. The authors concluded that whereas injection therapy was highly successful in patients with low-grade VUR in duplex systems, it still fell short of the open surgical cure rate.

Paraureteric Diverticulum with VUR

Bladder diverticulum can be found in association with VUR. Whereas those diverticulae that are small have a spontaneous resolution rate similar to that of primary VUR, moderate to large diverticulae, which usually lie lateral and cephalad to the ureteric orifice, will often drag the orifice into the diverticula on filling or voiding. This relationship portends a poor spontaneous resolution rate. The presence of a paraureteric diverticulum that is associated with reflux presents a significant challenge to the accurate placement of material at the UVJ endoscopically. Perez-Brayfield et al.[99] report on six such cases, with a success rate of 67% using the Dx/HA copolymer. It appears that with experience, the presence of a paraureteric diverticulum represents only a relative contraindication to endoscopic treatment. Puri and Läckgren (personal communication) have stated that a modified technique to this anatomy is needed, in which the material is injected beneath the ureteric orifice for a longer length into the diverticulum.

Refluxing Ureteral Stump

There have been isolated reports of success using the endoscopic approach for the refluxing ectopic ureter, refluxing ureteral stump, and reflux after transurethral ureterocele incision.[99,115,116] The results in the ectopic ureter, however, have been very disappointing to date.[99] This may also be true for the refluxing stump, which is often ectopic at or below the bladder neck, although there have only been a few reported cases.[115,116]

Failed Ureteral Reimplantation

From the 1997 report of the American Urological Association Pediatric Vesicoureteral Reflux Guidelines Panel, the success rate for correction of reflux by open ureteral reimplantation ranges from 80% to 99%, based on the grade of reflux.[117] Overall, the incidence of persistent reflux is generally 2% and the incidence of ureteral obstruction is 2%. Reoperation for the failed ureteral reimplantation can be a difficult procedure, with a significant complication rate.[118] There have been reports on the use of the endoscopic approach to reflux correction for the failed ureteral reimplantation.[99,119–121]

Kumar and Puri reported on 31 children with persistent reflux with 40 persistently refluxing units after failed ureteral reimplantation.[119] These patients represented a diverse group that includes primary reflux, duplicated systems, reflux secondary to neuropathic bladder, posterior urethral valves, ureterocele, bladder exstrophy, and UVJ obstruction. Twenty-seven of 40 persistently refluxing units were cured after a single injection of PTFE, 7 refluxing units required two injections, and 4 required three injections for correction of the reflux. Failure to correct reflux by endoscopic correction was noted in two ureters of one patient with bladder exstrophy. In the report by Gaschignard et al., 1 of 12 patients developed a late meatal stricture, occurring 2 years after endoscopic correction following a failed ureteral reimplantation.[121] Perez-Brayfield et al. reported on 17 patients who had failed open surgical correction of reflux. The success rate with endoscopic correction in this group was 88%.[99] Capozza et al. reported success in 12 of 18 ureters with endoscopic treatment after failed ureteral reimplantation.[47] In a review of 9 studies and 80 ureters, Elder et al. reported a cumulative success rate of 65% for endoscopic injection after failed ureteral reimplantation, compared with 74% in the nonreimplanted ureter.[28]

Complications

The risk–benefit ratio for endoscopic correction of reflux remains very low. Specific complications related to inherent material properties have been mentioned, such as particle migration with PTFE and with polydimethylsiloxane. Other specific concerns have been raised, such as malignant degeneration with PTFE or the development of connective tissue disorders with polydimethylsiloxane.[64,122–125]

More generic complications, such as ureteric obstruction, have been reported infrequently. Engel et al. reported obstruction in a single ureter after the endoscopic implantation of PTFE in their series of 60 injected ureters.[92] In the reported series by Capozza et al. of 1244 patients injected with a variety of materials, 8 (0.5%) developed temporary obstruction, 2 requiring a double-J stent.[47] In their meta-analysis, Elder et al. noted a very low incidence of de novo injection hydronephrosis (Table 46.7).[28] In a report by Mazzone et al. of a series of Dx/HA injections in 87 ureters (45 patients), 5 ureters (5.7%) in 5 patients developed significant obstruction requiring intervention, 4/5 were transient but symptomatic (2 requiring percutaneous nephrostomy and 2 ureteral stenting), and 1 required ureteral reimplantation.[126] Other outcomes, such as UTIs, febrile or not, do not appear to occur with an increased frequency over that seen with open ureteral reimplantations: 6.4% in a meta-analysis of 11 studies, 0.7% for febrile UTI, and 6% for cystitis.[28]

The development of contralateral de novo VUR following reflux correction may be troublesome.[127] Studies by Ross et al. indicate a 35% risk of contralateral VUR after unilateral open correction if there has been a remote history of contralateral VUR.[128] Hoenig et al. reported an incidence of contralateral VUR occurring in 17% of cases after unilateral open correction similar to that reported by other surgeons.[127,129–131] Following the endoscopic correction of reflux with PTFE, Kumar and Puri reported the contralateral de novo VUR rate to be much lower, at 7%.[132] Similarly, Kirsch et al. reported its occurrence in 4.5% with the Dx/HA copolymer.[15] This lends credence to the theory of trigonal distortion during open reimplantation rather than a pop-off mechanism theory as the etiology for de novo postoperative VUR.[133]

Controversy still exists as to whether injection of the contralateral nonrefluxing orifice is warranted in unilateral VUR. As other studies have shown for ureteral reimplantation, Chertin et al. demonstrated recurrence of previously resolved VUR in the contralateral ureter after unilateral injection in 14 of 15 children.[134] Approximately half of the children with contralateral reflux recurrence became symptomatic with breakthrough UTIs. However, de novo contralateral VUR (in the setting of no history of prior VUR) is of relatively low incidence, of low severity when it occurs, and generally asymptomatic. In a study by Menezes et al., 10% of 662 patients developed contralateral de novo VUR after unilateral injection, ranging in grade from I to IV, with 90% grade III or less.[135] Routh et al. reported on a series of patients with unilateral VUR in which an assessment was made of the morphologic cystoscopic appearance of the contralateral nonrefluxing orifice.[136] If subjectively the contralateral orifice appeared abnormal, prophylactic injection with Dx/HA was done. Of those contralateral orifices injected, 9% developed de novo VUR compared with 13% of those that were not injected, suggesting that the subjective assessment of the cystoscopic appearance of the nonrefluxing contralateral orifice as a determinant of prophylactic injection is of little benefit. Therefore, considering cost, it would seem unnecessary to prophylactically inject a nonrefluxing contralateral ureter.

TABLE 46.7 De novo postinjection hydronephrosis based on material used: A meta-analysis

Material	Denovo hydronephrosis/ total number[a]	No. requiring intervention[a]
Polytetrafluoroethylene	34/3616	19
Collagen	2/947	0
Polydimethylsiloxane	4/347	3
Dextranomer	2/385	2

[a] Data from Elder JS et al. *J Urol* 2006;175:716–22.

Recurrence of Vesicoureteral Reflux

Recurrence after proven correction of reflux remains an issue with certain materials. The difficulty is determining a firm and reliable figure for this, as only selected series have performed a VCUG beyond the initial negative study. In addition, one must distinguish between a maintained clinical cure (i.e., no febrile UTIs) and a proven long-term cure by a negative VCUG. Chertin et al. reported on 247 patients who were treated for VUR with PTFE and followed for 17 years.[27] They reported a recurrence rate of 5%, with 1.8% requiring open ureteral reimplantation. Capozza et al. reported on their long-term experience with bulking agents—specifically PTFE, collagen, and dextranomer—in 1244 patients, all of whom had a VCUG at 3 and 12 months postinjection. They found that a significant percentage of those patients who relapsed had evidence of voiding dysfunction by micturation questionnaire.[47] Läckgren et al. reported their long-term results with the use of the Dx/HA copolymer in 221 children who had a VCUG at 3 and 12 months postinjection.[14] In addition, a later VCUG was performed in 49 patients 2–5 years after initial treatment. Reflux on the late VCUG occurred in 13% of those previously cured. It is unclear how many of those late recurrences were symptomatic.[14]

Several series have reported on the recurrence rate of VUR in children with postinjection febrile UTIs. In a series by Chi et al. of 15 patients post–Dx/HA injection with a febrile UTI, VCUG revealed recurrent VUR in 7.[137] Sedberry-Ross et al. reported that 27% of their patients treated successfully endoscopically with Dx/HA had a febrile UTI (12/45).[138] Ninety-two percent (10/12) were found to have recurrent reflux when evaluated with a cystogram after their infection. In analyzing the 12 patients who had postinjection febrile UTIs, most of them had multiple predictive factors of UTIs, including preoperative febrile UTIs, dysfunctional elimination, and existing renal cortical defects on dimercaptosuccinic acid (DMSA)

scanning. It seems clear, therefore, that those patients who are likely to have a febrile UTI after successful endoscopic treatment for VUR are predictive from analyzing preinjection risk factors. In the Swedish Reflux Trial, Holmdahl et al. demonstrated a 20% recurrence rate of dilating VUR in asymptomatic children studied 2 years after injection.[139] Similarly, Lee et al. performed a follow-up VCUG on 150 asymptomatic children 1 year after a successful endoscopic treatment with Dx/HA and found recurrence of reflux in 26%.[140]

Haferkamp et al. reported on the use of a second collagen injection in 16 children with 21 ureters with a failed first injection.[51] They found that the reflux was cured after a second injection in 17/21 ureters. Of those cured with a second injection, a repeat VCUG was performed every 6 months, with a mean follow-up of 11 months. Of these patients, eight ureters remained reflux-free, whereas in nine units the reflux recurred. The authors noted that the interval to recurrence of reflux was longer after the second injection than with the first injection. In a similar report, Haferkamp et al. found that of 55 renal units successfully treated with collagen, only 5 (9%) remained reflux-free after 37 months of follow-up.[51] Other studies have shown a more modest recurrence rate of 11%–16%.[52] In a report of 132 children, Frey et al. reported late reflux recurrence in 11.3% of 204 renal units treated with GAX 35 collagen.[45] In the meta-analysis study by Elder et al., the probability of recurrence for all agents used was 8%.[28] In a review of contemporary series of multiple bulking agents for VUR correction with at least a 1-year follow-up VCUG, including their own experience, Chertin and Kocherov determined that Dx/HA has the highest recurrence rate (3.9%–26%).[141]

The lowest recurrence rate was with PTFE. Overall, it appears that collagen carries a higher recurrence rate than other bulking agents that have been followed with a VCUG beyond 1 year postinjection, with the lowest recurrence rate from PTFE.

Reasons for Failure of Endoscopic Treatment

Whereas most series have demonstrated a high success rate for the endoscopic subureteric injection for the treatment of VUR, very few have discussed the reasons for failure. The mechanism of failure of endoscopic correction of reflux can be divided into three categories:

- Technical factors
- Bladder dynamics issues
- Individual physical properties of the particular material used

Technical factors include anatomic abnormalities of the UVJ or bladder, including duplicated systems; paraureteric diverticulum; a trabeculated bladder, from either neuropathic origin or obstructive origin, be it functional or anatomic; or a previously reimplanted ureter. In addition, the position of the orifice can certainly be influenced by the degree of fullness of the bladder, making the injection zone for the material larger or smaller. It is also theoretically possible that—with the bladder relatively empty at the time of the injection, as is the standard recommendation—when the bladder fills, the mound and orifice may not have the same relationship to each other.

Elevated bladder pressure that is seen in the neurogenic bladder, the previously obstructed bladder, or dysfunctional voiding may affect outcomes after injection therapy. Capozza et al. implied that voiding dysfunction could contribute to endoscopic injection failure.[47] They theorized that elevated intravesical pressures could displace or shift the injection mound or cause migration from the original site of implantation. They found, in retrospect, that a high percentage of those patients who had failed initial endoscopic treatment had evidence of voiding dysfunction on clinical evaluation. Therefore, they advocated that voiding dysfunction be addressed prior to undertaking the endoscopic treatment for reflux. Trsinar et al. also observed displacement of failed injection mounds and theorized that this was due to voiding dysfunction, although there were no urodynamic studies or voiding diaries presented.[103]

Specific material properties may also play a role in the failure of endoscopic correction of reflux. Materials that have been utilized have a variable degree of longevity. Loss of material can occur by absorption of the carrier substance that is used for the specific material, as seen with glycerol for PTFE, hyaluronic acid with dextranomer particles, alginate solution with chondrocytes, or aqueous gel with calcium hydroxylapatite. These materials will be absorbed in a variable amount of time from the implant site, decrease the site of the injection mound, and therefore possibly hinder the mechanism for ureteral closure or insufficient support of the intramural ureter. In addition, there is an intrinsic material biodegradability that plays a role with certain substances. Collagen is known to have a significant loss of volume over time, and its long-term success is thought to be due to the development of natural collagen to replace the resorbed injected collagen. Haferkamp et al.[51] demonstrated a low rate of long-term success with collagen in that after 37 months, only 5 out of 57 ureters previously corrected with a single injection remained cured. Similarly, dextranomer microspheres have some degree of biodegradability, which eventually should be replaced by the ingrowth of native fibroblasts. McMann et al. performed sonographic volumetric analyses on injected Dx/HA mounds and found a 20% volume loss, most of which occurred within the first 2 weeks postinjection.[142]

The ability of a particular material to weld at the injection site may be a factor in the long-term success as well. Materials that tend to create an inflammatory response may be more likely to stick to the site of the injection. The viscosity of the material may also be a factor that may or may not allow it to easily leak through the needle track of the injection site. When dealing with autologous materials, as previously mentioned, free graft issues come into play. The ability of fat, collagen, muscle, or chondrocytes to grow in their new location may require some of the same principles of imbibition and inosculation that one sees with larger tissue graft physiology. This was shown in the report by Diamond et al. on autologous chondrocytes, in which those mounds that were explanted at the time of ureteral reimplantation failed to demonstrate viable chondrocytes.[143]

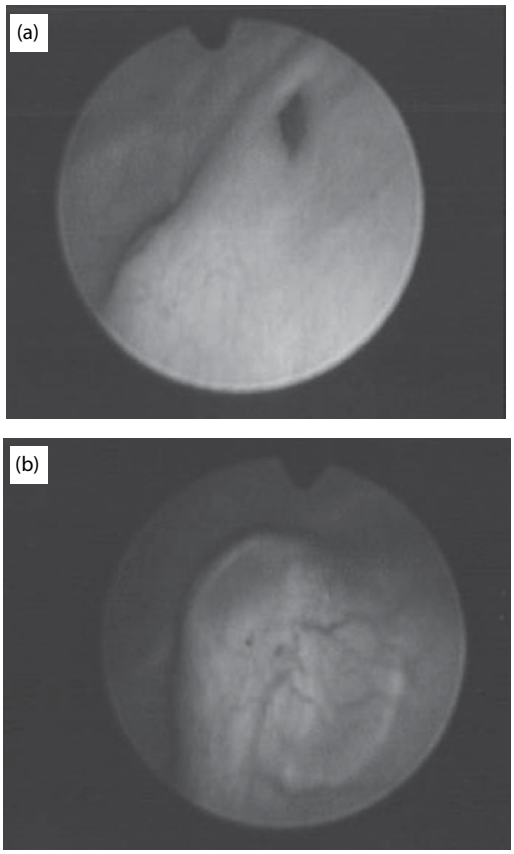

FIGURE 46.8 (a) Duplicated left ureters with lower-pole reflux. (b) Mound under lower-pole refluxing orifice.

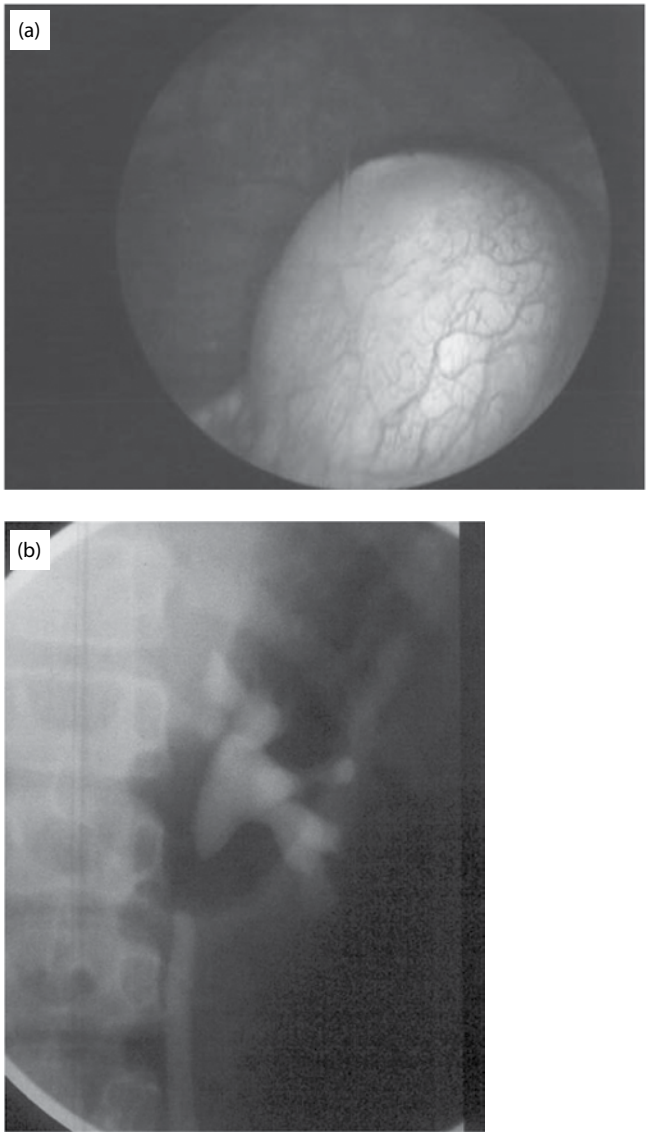

FIGURE 46.9 Mound shifting or displacement. (a) Appearance of mound and left ureteral orifice at time of initial injection. (b) Appearance at time of reinspection for persistent VUR on a VCUG.

Several studies have documented that in those cases where observation of the injection site was possible after a failed implantation, displacement appeared to occur quite frequently (Figure 46.8). In a series reported by Diamond et al. on cystoscopic examination of patients who had failed subureteric injection with autologous chondrocytes, it was noted that 35% had mound shifting, 25% had shifting and volume loss, and 13% had isolated volume loss. It appeared that the most frequent direction of mound shifting was distally and medially toward the bladder neck from the original injection site.[143] Eleven percent of their population, however, were classified as indeterminate; i.e., there was failure on postoperative VCUG to resolve the reflux, but the appearance of the mound on cystoscopic or intraoperative inspection was perfectly normal (Figure 46.9). Other studies also found that either mound displacement or absence of a mound was the most common cause of failure on reinspection either cystoscopically or by open surgery of failed primary injections.[66,144,145]

Fewer studies have focused on failures from the injection of the dextranomer microspheres. Capozza et al. reported on 45 failures with the Dx/HA copolymer, and found 60% had mound displacement and 33% had absence of the mound on reinspection.[146] They reported a high percentage of their cases with failed dextranomer microspheres and suspected high intravesical pressures noted by voiding diaries. In two cases, however, there was a unilateral cure and contralateral mound displacement. It is uncertain as to whether this represented a technical failure or an anatomic failure. However, it is unlikely that they represented abnormal bladder physiology. Kirsch et al.[15] reported on 18 patients who underwent reinjection for primary failures and found that 61% had shifting of the mound away from the injection site. In the remainder of patients, the mound was either absent or present, and therefore indeterminate.

Higham-Kessler et al. reported a multi-institutional review of failures after Dx/HA injections for VUR.[147] Eighty patients (97 ureters) who failed a single injection underwent mound observation prior to a second injection or at the time of open surgery. They found that in those who had a mound abnormality, in 49% the mound had shifted, in 22% the mound was absent, and in 10% there

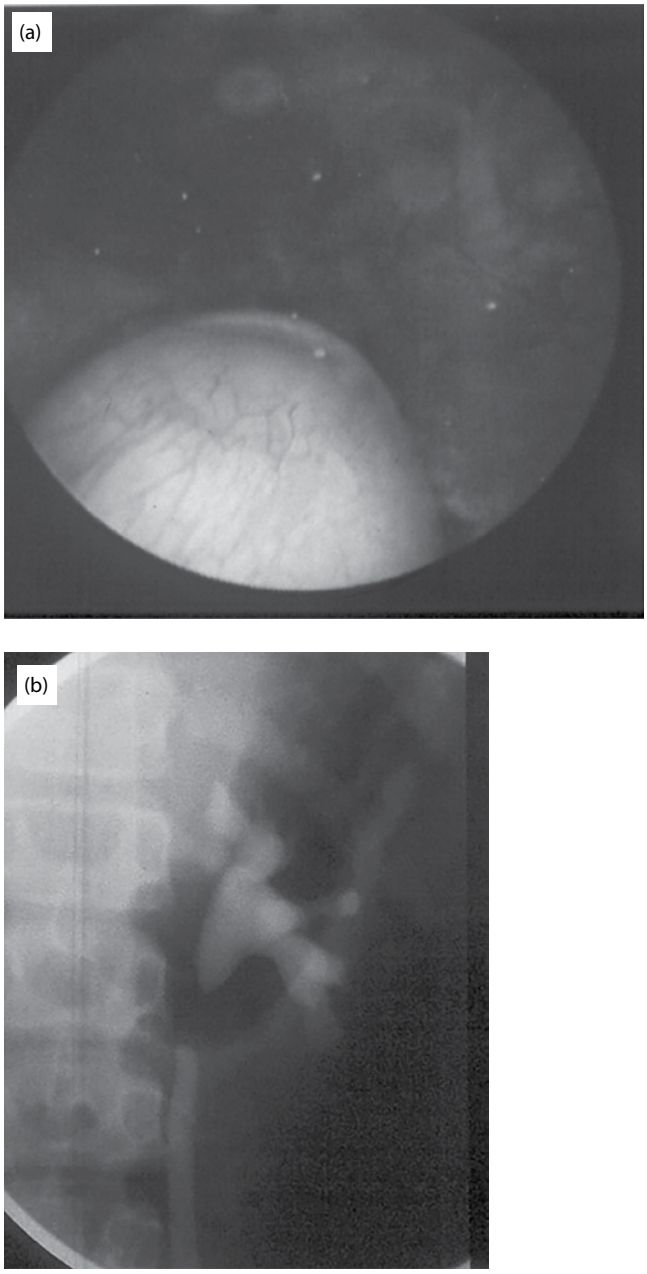

FIGURE 46.10 Perfectly injected mound with persistent VUR on a VCUG classified as an indeterminate failure. (a) Mound on recystoscopy. (b) VCUG demonstrating left VUR.

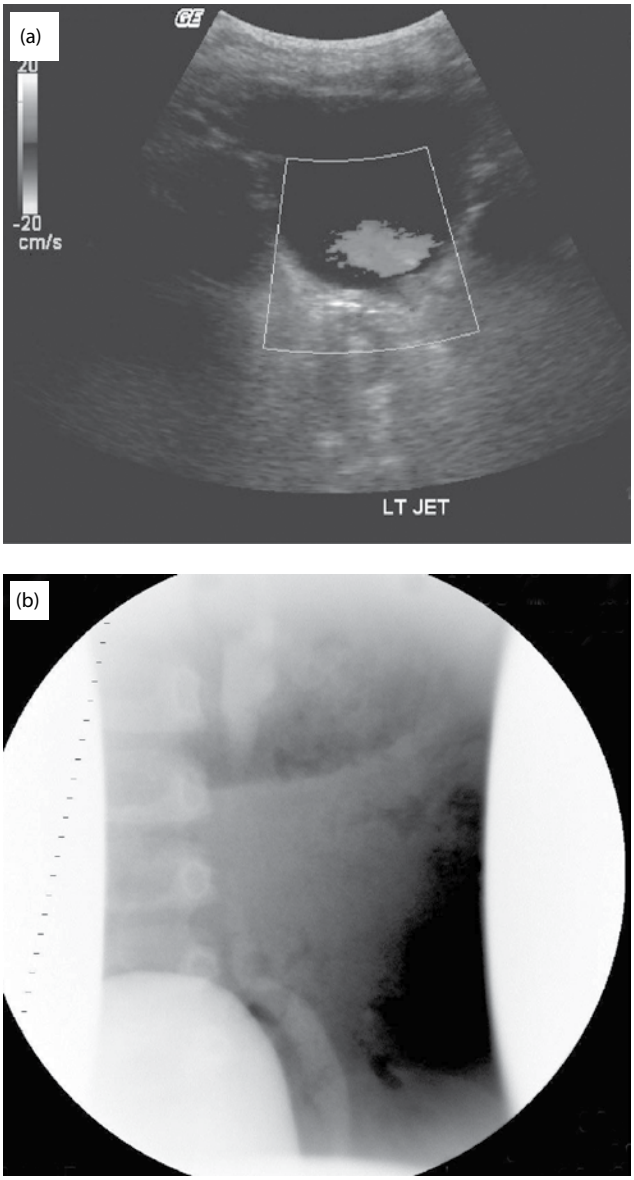

FIGURE 46.11 (a) Ultrasound 3 months post-Dx/HA copolymer injection with normally positioned left mound and ureteral jet exiting from top of mound. (b) A VCUG 3 months postinjection demonstrating persistent left VUR.

was a significant mound volume loss. In 15%, the mound was in the perfect location in spite of persistent VUR (Figure 46.10). Other studies have also confirmed that a malpositioned mound can be seen in both successful and unsuccessful injections, implying that other factors, such as bladder dynamics and UVJ maturation, may be at play in the success of an endoscopic injection (Figure 46.11).[148] In a study by Dave et al., multiple variables were analyzed with respect to injection success.[149] On multivariate analysis, higher injection volume, surgical experience, and treatment of lower UTI symptoms were associated with a higher success rate of VUR correction. Similarly, Kirsch identified several factors affecting the success of endoscopic injection for VUR, citing injection volume, surgeon experience, and the HIT as important variables.[150] Additionally, it has been advocated that since a normal mound appearance alone does not predict successful correction of VUR, loss of ureteral hydrodistention is a more objective measure of a successful injection. Sorensen et al. studied injection volume using a Pediatric Health Information System (PHIS) database over the period 2003–2008 and found a threefold increase in the number of patients in which three or more vials of Dx/HA were used.[151] Interestingly, while there was an increase in the average vials used in all institutions, the most pronounced was at those institutions doing the most cases, implying a directed plan to inject higher volumes of material.

CONCLUSION

With a technology that is reproducible and at least a single agent that is widely available for endoscopic correction of reflux that appears safe, the obvious question that is raised is, where does this fit in the management of children with VUR? This question must be addressed in light of the present-day concerns for the use of long-term antibiotics with growing patterns of resistance. Studies have questioned the effectiveness of long-term antibiotic prophylaxis,[152] and the potential for long-term complications.[153]

The use of the Dx/HA copolymer has been shown to be a cost-effective alternative to open surgery for persistent VUR in children on a prophylactic antibiotic program.[154] However, publications by Benoit et al. analyzed the cost-effectiveness of Dx/HA compared with traditional management with antibiotic prophylaxis or open surgery.[155,156] Dx/HA appeared to be more cost-effective than ureteral reimplantation for lower grades of reflux in children meeting the criteria for traditional surgical therapy. However, in cases of increasing grades of VUR, which require an increased volume of Dx/HA, injection therapy loses its cost-effectiveness. Regarding antibiotic prophylaxis, in theoretical models simulating clinical scenarios, up-front injection therapy with Dx/HA was not as cost-effective as traditional management consisting of ureteral reimplantation for those failing antibiotic prophylaxis.

The effectiveness of endoscopic therapy requires that its approach be presented to parents as an up-front treatment in lieu of antibiotics. However, there have been a paucity of studies looking at long-term outcomes in a comparative analysis between antibiotic therapy and endoscopic correction. Studies that have shown endoscopic treatment with the Dx/HA copolymer to be more effective than antibiotic prophylaxis have often been of relatively short duration, raising the criticism of an adequate clinical trial. Additionally, is the outcome of VUR resolution the only outcome we should be concerned with? These questions will only be answered with multivariant prospective trials, which are difficult to perform in children. It is possible that endoscopic correction may change our approach to children with secondary reflux as well. Traditionally, children with neurogenic bladders or dysfunctional voiding and VUR are approached by managing the bladder dysfunction initially and reserving correction of VUR for those children with upper tract deterioration or breakthrough pyelonephritis. One could argue, however, as this population has a high rate of breakthrough UTIs and renal scarring,[157] for correcting the VUR endoscopically while ongoing and often tedious efforts at bladder rehabilitation are undertaken, thus protecting the upper tracts from pyelonephritis and potential scarring. This approach may have merit in light of the observation of Läckgren and Stenberg on the improvement in dysfunctional voiding in children treated primarily with endoscopic injection of the Dx/HA copolymer without bladder management, implying that the reflux itself may contribute in some way to the abnormal bladder function.[108] Clinical trials in these scenarios would be most valuable.

In the integration of new technology and new concerns in the management of children with VUR, it would be helpful if we were better able to identify groups at high and low risk for renal scarring and tailor our management accordingly. With further progress in clinical research of VUR, we may be able to withhold therapy for certain low-risk groups, while taking a very aggressive approach, by either endoscopic correction or open ureteral reimplantation, for patients at high risk of renal scarring from VUR and infection.

CHAPTER 47

Basic Science of Prostatic Development

Ellen Shapiro and Hongying Huang

INTRODUCTION

The fetal prostate is a proliferative organ and represents an excellent model for the study of morphogenesis, hormonal imprinting, and epithelial–mesenchymal interactions in the genitourinary tract. Events associated with fetal prostate development and in utero influence may alter growth in adulthood and will likely provide insights into the mechanisms giving rise to benign and malignant growth of the prostate.

EMBRYOLOGY OF THE PROSTATE

The prostate develops from the endodermal urogenital sinus (UGS), which is derived from the terminal end of the hindgut or *cloaca*, which is Latin for "sewer." Septation of the cloaca by the urorectal septum begins at about 28 days of gestation.[1] The rectum and primitive UGS form by the 44th day. The primitive UGS proximal to the mesonephric duct develops into the vesicourethral canal, whereas the region distal to the mesonephric duct becomes the definitive UGS. The UGS adjacent to the bladder (pelvic urethra) differentiates into the lower portion of the prostatic and membranous urethra.[2]

Prostate growth and development are dependent on androgen production by the fetal testes, which begins at about the eighth week of gestation.[3] Unlike development of the Wolffian duct (WD) derivatives, which are dependent solely on testosterone, the differentiation of the UGS is dependent on the 5α-reduced form of testosterone, dihydrotestosterone (DHT). DHT is essential for the growth and development of the prostate.[3,4,12,15] By 10 weeks, the prostatic ductal network develops from solid epithelial outgrowths, or prostatic buds, which evaginate from the endodermal UGS immediately below the bladder and penetrate into the surrounding urogenital mesenchyme (UGM).[5]

The prostatic ducts rapidly lengthen, arborize, and canalize. By 13 weeks, 70 primary ducts are present and exhibit secretory cytodifferentiation.[5]

Within the fetal prostate lies the utricle. Although the embryological origin of the utricle is thought to be a remnant of the fused caudal ends of the Müllerian ducts (MDs), compelling evidence from Shapiro et al. indicates that the utricle forms as an ingrowth of specialized urothelium lining the dorsal wall of the UGS.[6] Utricular formation is occurring during complete caudal MD regression (Figure 47.1). Since utricular development from the UGS is similar to that of the vagina in the female fetus, it has been appropriately referred to as the "sinus vagina." Since testosterone inhibits the formation of the lower vagina in the female, formation of an enlarged utricle in some males with severe hypospadias may be due to inadequate virilization of this region of the UGS at a critical time during early gestation.[7]

Hofkamp et al. studied the ACI (August × Copenhagen) rat, which is a model for urogenital anomalies, including renal agenesis and ipsilateral hypoplasia of the WD derivatives.[8] These investigators focused on prostatic development in those ACI rats with ipsilateral hypoplasia of the WD structures. They showed that those affected ACI rats had a significant decrease in total fetal prostate volume (40%, $p < 0.005$) and region-specific differences when compared with normal control ACI rats that had no WD anomalies. Interestingly, the ipsilateral testis was devoid of normal seminiferous tubules, while the contralateral testis was completely normal.

WDs are stabilized by androgens, and the prostate is dependent on the diffusion of testicular androgens via ejaculatory ducts (EDs) and the vas deferens for growth and stabilization. Prostatic budding occurs in response to an androgen-dependent secretion of growth factors by the periurethral mesenchyme.[9] Therefore, alterations in WD development can potentially limit the levels of androgens required for normal induction of prostatic budding and morphogenesis and postnatal growth.

PROSTATE MORPHOLOGY

In 1912, Lowsley studied the human fetal prostate and noted that the branching ductal system consisted of five distinct groups.[5] These lobes were termed the posterior, lateral (two), anterior, and middle lobes. The ducts of the posterior lobes originate from the floor of the prostatic urethra distal to the openings of the EDs and grow posteriorly. The epithelial buds of the two lateral lobes branch lateral to the verumontanum. The ducts of the middle lobe originate on the posterior urethra proximal to the openings to the EDs. The anterior lobe buds branch anterior to the verumontanum.

Xia et al. qualitatively examined prostate growth, histogenesis, and secretory activity in normal fetuses ranging in age from 20 weeks' gestation to 1 month (postnatal).[10] Sharply delineated "lobules" were not recognized. Two zones were identified, the inner submucosal zone (IZ) and

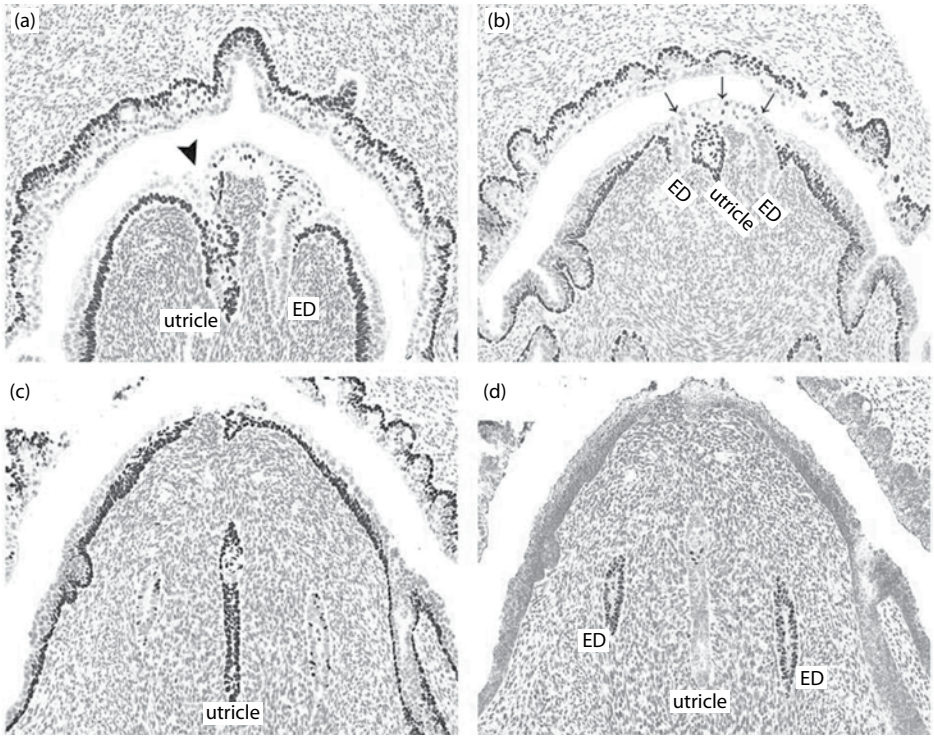

FIGURE 47.1 Cross section of human fetal prostate, age 15 weeks, demonstrates (a and b) two different specimens showing the evaginated p63 (basal cell marker)-positive cells that form the utricle (arrowhead) and only weakly staining basal cells in the UGS between the EDs (arrows), and that (c) the p63-positive cells of the utricle continue to grow into the midline of the mesenchyme and surround the small solid remnants of the MDs in its path, which (d) also express Pax-2 (marker for MDs and WDs). The EDs are also Pax-2 positive. ×200.

the peripheral zone (PZ). The IZ was characterized by a concentric mass of fibromuscular connective tissue (CT) containing ducts at various stages of development. The PZ contained less concentrically organized fibromuscular CT with secondary ducts, gland buds, and groups of acinar glands. Lowsley's work, together with Xia's observations, lends support to the current concept of the morphology of the adult prostate gland that exhibits three zones: central, transition, and peripheral zones, which correspond to three distinct sets of ducts. This is important since prostatic diseases are region specific, with prostate adenocarcinoma developing primarily in the PZ and benign prostatic hyperplasia (BPH) developing primarily in the transition zone. The development of BPH is important to understand since growth of new acini in this condition deviates from the normal development of most organs.[11] The prostate is the only organ that demonstrates new growth as part of the aging process. The new acinar architecture, though, is unlike that of the fetus since the ducts of the fetal prostate branch parallel and away from each other, rather than toward each other, as seen in BPH nodules.

ENDOCRINOLOGY OF PROSTATIC DEVELOPMENT

Development of the prostate is androgen dependent, and DHT is the active intracellular androgen.[3,12] The 5α-reductase deficiency syndrome is a form of autosomal recessive 46, XY Disorder of Sexual Development characterized by severe penoscrotal hypospadias, a blind vaginal pouch, and normal testes with normal epididymes, vasa deferentia, and seminal vesicles.[13] The EDs terminate in the blind-ending vagina, and the prostate is small or undetectable. The selective effects of testosterone and DHT are defined since the defect in virilization during embryogenesis is limited to the UGS and the anlagen of the external genitalia.

Although there is no compelling molecular evidence for homology between specific rodent prostatic lobes and human prostatic zones, the rodent has been extensively studied to further our understanding of prostatic development. Imperato-McGinley and coworkers demonstrated prostatic bud formation in the rat model of 5α-reductase deficiency.[14] This finding was unexpected since finasteride, a 5α-reductase inhibitor, did not completely abolish prostatic differentiation, which suggests that budding may have different thresholds of response for DHT. Further studies showed that flutamide, a nonsteroidal antiandrogen, in high enough doses to feminize the external genitalia of the male rat, failed to inhibit prostatic development, while cyproterone acetate (CA), a steroidal antiandrogen, inhibited prostatic bud development and external genitalia development. Low-dose DHT could induce prostatic buds in female fetuses. The WDs could not be abolished in males with CA, and high-dose antitestosterone treatment failed to inhibit prostatic buds. Although DHT is important for prostatic growth, the developing prostate may be responsive to exceedingly low levels of DHT or other androgens.[14]

Also, some aspects of postnatal prostatic growth may be independent of androgens, as castration in the rat during this period does not completely inhibit prostate development.[15,16] This suggests that other nonandrogen growth factors, such as peptide growth factors, are capable of mediating arborization and growth of prostatic ducts.[17] These findings suggest that varying phenotypes occur and are species dependent.

This concept is supported by the observations of Mahendroo and colleagues, where unexpected virilization in male mice lacking steroid 5α-reductase enzymes was observed.[18] These mice had normal external and internal genitalia and were fertile but had smaller prostates and seminal vesicles than controls. As expected, high testosterone levels were found in target tissues. DHT administration led to an increase in seminal vesicles and coagulating gland wet weights in the 5α-reductase type 2–deficient mouse and an increase in the prostate size, seminal vesicle, and coagulating gland in both the 5α-reductase type 1– and type 2–deficient mouse. When DHT was administered to the mouse deficient in only 5α-reductase type 2, no increase in prostatic size occurred, while DHT administered to the 5α-reductase type 1– and type 2–deficient mouse resulted in an increase in prostatic size. Androgen-dependent gene expression was decreased in the seminal vesicles lacking one or more of the 5α-reductase enzymes, but was restored with testosterone or DHT. These studies show that only testosterone is needed for differentiation of the male UGS in the mouse, and synthesis of DHT serves largely as a signal amplification mechanism.

Using immunohistochemistry, we studied human fetal prostates, gestational ages 7–22 weeks, and stained representative tissue sections with antibodies to the androgen receptor (AR) and 5α-reductase.[19] At 7 weeks, we demonstrated AR and 5α-reductase expression in the peripheral stroma, above the EDs, while only AR was seen in the UGS luminal epithelium. By 9 weeks, AR expression was ubiquitous in the stroma and suprabasal cells of the UGS but was observed in the basal cells of only the central dorsal UGS below the EDs. Stromal 5α-reductase expression was significantly increased and was observed throughout the UGS. By 11–13 weeks, AR expression increased in the stroma, especially in the periphery. Epithelial AR increased from the base to the apex, with AR observed in all cell layers of the UGS, ducts, and acini, except for the basal cells of the UGS and ducts above the EDs, which remained negative. 5α-Reductase expression was observed throughout the stroma except in the ventral SM, ventral periurethral stroma, and posterior periphery, where expression was diminished (Figure 47.2). Epithelial 5α-reductase expression increased from the base to the apex, with no expression in the ductal epithelium of the posterior lobe (Figure 47.3). The lateral lobes showed only distal duct and acini expression, while the ducts emanating from above the EDs expressed 5α-reductase throughout their epithelium. By 22 weeks, AR expression was ubiquitous, with the greatest staining in the epithelium and the posterior and posterolateral peripheral stroma, while 5α-reductase was almost undetectable.

We concluded that epithelial AR expression is significantly greater below the EDs than above the EDs at each gestational age up to 22 weeks, when no difference in the AR expression pattern is observed in the gland and 5α-reductase is almost absent.[19] In contrast, UGS and ductal epithelial 5α-reductase are expressed in a gradient fashion from the apex to the base or bladder neck. This suggests a regional reciprocal relationship between select areas of stromal and epithelial AR and 5α-reductase expression. This detailed localization study supports other investigations that have suggested that DHT serves largely as a hormonal signal amplification during prostate development.[18,19]

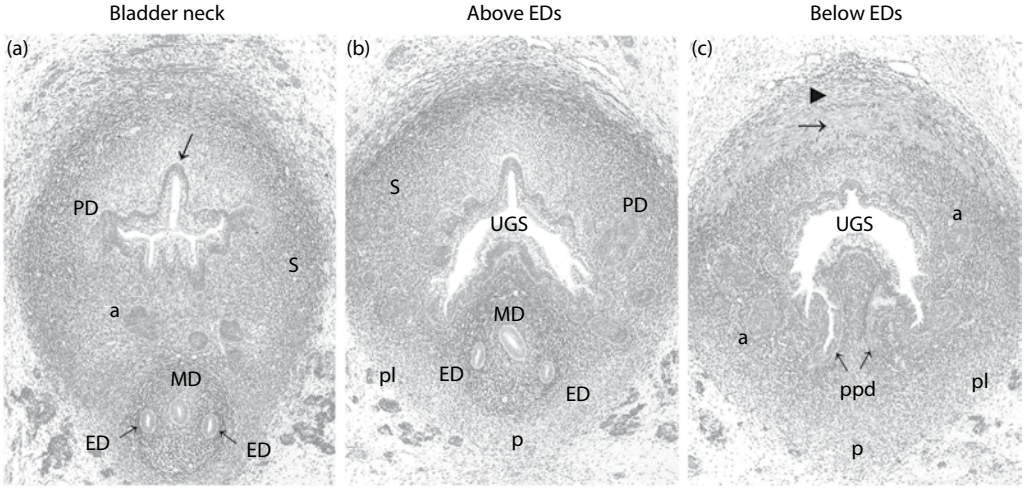

FIGURE 47.2 Cross section of human fetal prostate, age 11 weeks, showing (a) bladder neck region with significant 5α-reductase expression throughout the prostatic stroma and the central stroma surrounding the EDs and MDs. Expression is noted in the basal epithelium of the UGS (arrow) and in the prostatic ducts (PDs) and acini (a); (b) region between the bladder neck and the entrance of the EDs into the UGS with similar stromal 5α-reductase expression except posteriorly (p) and posterolaterally (pl), and much less UGS, prostatic ductal, and acinar expression; and (c) region below the entrance of the EDs into the UGS with no 5α-reductase expression in the UGS epithelium, posterior lobe ducts, or lateral acini. (There is no 5α-reductase expression in the posterior (p) and posterolateral (pl) stroma or in the SM (arrow) or SKM (arrowhead) in the anterior stroma. ×100; stroma (s), Posterior prostatic ducts, ppd.)

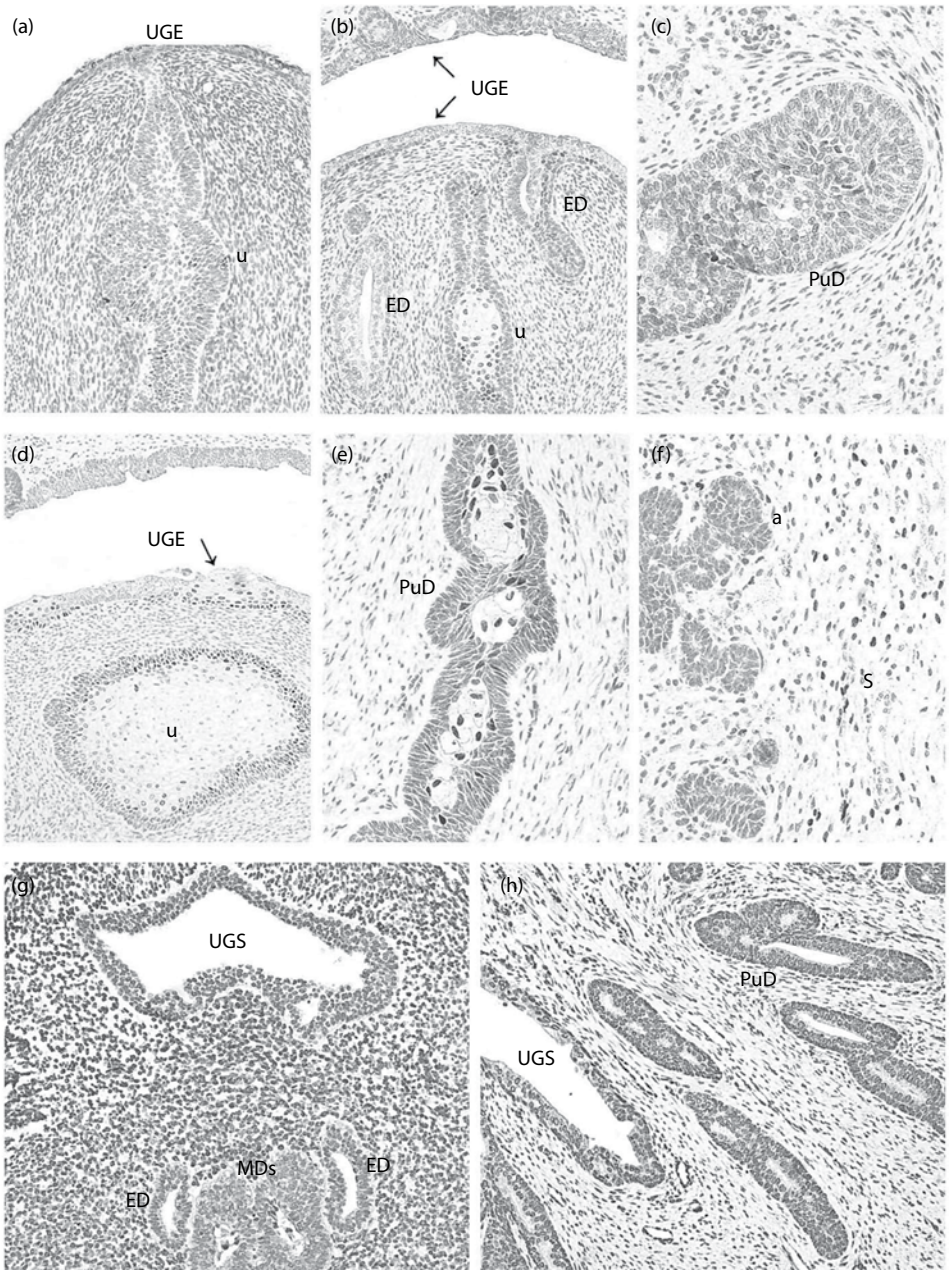

FIGURE 47.3 Cross section of human fetal prostate showing (a) ERα expression at 15 weeks in the ventral UGE and utricle (u) (×200); (b) ERα expression at 21 weeks in the UGE (arrows), utricle, and EDs (×200); (c) periurethral ducts (PuD) (×400); (d) ERα expression at 22 weeks in the UGE (arrows) and utricle (×200); (e) periurethral ducts (×400); (f) peripheral stroma with no staining of the acini (×400); and ERβ expression throughout the epithelium and stroma at (g) 7 weeks and (h) 24 weeks. ×200; stroma, s; peripheral acini, a.

There have been recent studies characterizing the prostatic stem cell or progenitor cells.[20–22] Using a murine model, Goto et al. identified two populations of cells in different regions of the prostatic ducts using an in vivo prostate reconstitution assay.[20] The first population had significant growth potential and was located in the proximal region of the ducts and in the urethra. The survival of these cells was androgen independent, and the cells were capable of regenerating prostatic tissue. The second population had less growth potential, was found in the intermediate and distal ductal regions, and was androgen dependent.

Wu et al. examined lymphoid enhancer-binding factor 1(LEF1), which is a major mediator and a target in the canonical Wnt/β-catenin pathway.[21] Canonical Wnt signaling is active during the development of the human fetal prostate. These investigators showed that LEF1 is expressed in the basal layer of the UGS by 8 weeks, prior to bud formation, while AR is expressed in the luminal cells. During prostate morphogenesis, LEF1 is expressed in the tips of the buds and the periphery of the solid ducts, but is not expressed in the stroma. This suggests a role in branching morphogenesis. In addition, using a murine model treated

with an AR inhibitor, Wnt/Lef1-positive basal progenitors were shown to repopulate the luminal compartment. In this model, Wnt/Lef1 activity identified an androgen-independent population of prostate progenitor cells. These observations also suggest that Wnt/Lef1 activity is important in organ maintenance and regeneration.

McNamara et al. recently studied the steroidogenic enzyme expression in the human fetal prostate.[22] Steroidogenic enzyme expression has been shown to be upregulated in a subset of castration-resistant prostate cancer.[23] They hypothesized that these enzymes are involved in de novo androgen synthesis. This study focused on the steroidogenic enzyme c17, which has two active sites. One site is 17-hydroxylase, which catalyzes the conversion of pregnenolone to 17-OH pregnenolone and progesterone to 17-OH progesterone. The second active site, 17,20 LYASE, catalyzes the next step in the conversion of testosterone 17-OH pregnenolone to dehydroepiandrosterone and 17-OH progesterone to Δ4-androstenedione. The expression of this marker, c17, in prostate cancer may identify more aggressive disease. These investigators showed significant c17 expression in both proximal ductal and acinar epithelial cells and some stromal cells of all the fetal prostates examined between gestational weeks 8 and 22. This suggests that c17 is expressed in a subset of progenitor cells, and that prostate cancer cells with similar expression have a more primitive, potentially more aggressive, subpopulation.[22] The expression of this marker, c17, in prostate cancer may identify more aggressive disease. These findings and the findings of other investigators have translational implications for the elucidation of the biology of both benign and malignant proliferative prostatic diseases.

STROMAL–EPITHELIAL INTERACTIONS

Stromal and epithelial interactions that occur in the developing prostate are androgen dependent.[15] Lasnitzki et al. performed tissue recombinant experiments by combining mesenchyme isolated from fetal rat or mouse UGS with fragments of prostate or bladder epithelium.[24] These tissue recombinants are grafted under the renal capsule of recipient animals and form prostatic ductal tissue. Cunha and Lung have utilized testicular feminization syndrome (*Tfm*) mice to elucidate the roles of epithelial versus mesenchymal AR in prostatic development.[25] *Tfm* results in complete failure of the prostate to develop due to defective or absent AR. The WDs undergo degeneration, and the external genitalia are feminized despite normal testosterone levels. Therefore, *Tfm* mice have deficient AR and fail to develop prostates. When tissue recombinants constructed of wild-type mesenchyme and *Tfm* epithelium are exposed to androgen as a result of grafting of the recombinants into intact male hosts, normal prostatic morphogenesis ensues.[24–26] When the *Tfm* mesenchyme is combined with either the *Tfm* or the wild-type epithelium, the prostate does not form. From these studies, they concluded that there is a critical role for mesenchymal AR in prostate development, and that many androgen effects on prostatic epithelium do not require epithelial AR but are elicited by the paracrine action of AR+ mesenchyme. It is interesting to note, though, that mouse prostatic epithelial ARs are not expressed until postnatal day 1, while human prostatic epithelial ARs are present in the urogenital epithelium (UGE) as early as 7 weeks' gestational age.[19,27,28] Prostatic epithelial ARs are required for the expression of AR-dependent secretory proteins during postnatal development.

Allgeier et al. examined the androgenic regulation of ventral epithelial bud number and pattern in mouse UGS.[29] Control mice are known to have two rows of three or four prostatic buds at birth conform to a relatively sharp bimodal distribution on the left–right axis. The mechanism underlying androgen regulation of ventral bud number and patterning is unknown. Using UGS from *Tfm* males and flutamide (antiandrogen)-treated mice, these investigators showed initiation of small ventral buds, which suggests that this process, in mice, may be androgen independent. Surprisingly, DHT treatment of *Tfm* males significantly increased the expected number of ventral buds per UGS in *Tfm* males, and the distribution of the buds appeared to be broadly bimodal. These studies demonstrate that UGSs from *Tfm* males are androgen responsive. These results also suggest that ventral UGS bud number responds biphasically to androgen stimulation.[29] Baseline number is defined when androgens are at baseline or very low, with increased androgenic stimulation leading to an increased number of ventral buds. Nonetheless, additional androgenic stimulation leads to a reduced ventral bud number to the baseline.

Tissue recombinant experiments have also been used to examine epithelial–mesenchymal interactions on the differentiation and organization of prostatic smooth muscle (SM).[30] Experiments combined adult prostatic epithelium with UGM or seminal vesicle mesenchyme (SVM), or bladder epithelium with UGM or SVM. Prostatic ducts developed in all tissue recombinants when UGM was used with either epithelium. SM cells also organized into sheets resembling prostate. When SVM was combined with either epithelium, the prostatic ducts were surrounded by thick SM cells resembling seminal vesicle. The SM was unorganized in grafts of SVM or UGM. These experiments suggest that male UGM dictates spatial organization, but SM differentiation is induced by epithelium. Urothelium may also direct the organization of SM tissue, since urothelium is thought to be a potent inducer of SM differentiation. Cunha et al. have shown that the proximal segments of prostatic ducts near the urethra express urothelial membrane antigen and have associated thick layers of SM cells surrounding them.[12]

All these tissue recombinant experiments show that interactions between the mesenchyme and epithelium are reciprocal.

HORMONAL IMPRINTING

For more than half a century, the role of natural and synthetic estrogens in prostate development and the effects of hormonal imprinting have been studied.[31–33] Estrogens alter the hypothalamic pituitary gonadal axis, resulting in decreased androgen levels and subsequent regression of the prostatic epithelium.[34,35] Investigations have focused

on the correlation between estradiol and prostatic development in fetal mice, depending on their intrauterine position; the effects of experimental increases in estradiol in mouse fetuses; the inhibition of prostate development following administration of high-dose estrogens; and the opposing effects of high- and low-dose estrogen on prostatic development.[36]

It has been postulated in humans that the early testosterone surge at 30–60 days of life may be a critically important "imprinting" event that may have an impact on the gland's propensity for future abnormal prostatic growth and disease. Hormonal imprinting has been studied in the rat.[37] Naslund and Coffey showed that early hormonal surges are requisite for normal adult prostate growth in the rat, and that an alteration in the normal endocrine events that occur shortly after birth can have significant and permanent effects on the androgen sensitivity and growth of the adult prostate.[38] These hormonal surges are thought to affect prostatic growth by altering the properties of the prostatic stem cells. Recently, Tsujimura et al. have shown that the proximal region of the mouse prostatic ducts is enriched in a subpopulation of epithelial cells that have a number of properties of stem cells: they are slow cycling, they possess high in vitro proliferative potential, and single cells are able to reconstitute complex highly branched glandular structures in vitro that contain basal and luminal cells.[39] The absolute number of these stem cells is important because it ultimately determines the size of the gland. Therefore, hormonal events occurring before puberty can imprint or program the prostatic size, androgen sensitivity, and function and maintenance of the stem cells.

Prins and others have shown that brief exposure of rodents to estrogens during the neonatal period leads to permanent irreversible and dose-dependent effects on the prostate gland's morphology, cellular organization, and function.[2,3,40,41] If estrogenic exposure is high, the permanent imprints include reduced prostatic growth, epithelial differentiation defects, altered secretory function, and aging-associated dysplasia similar to prostatic intraepithelial neoplasia (PIN). This process, referred to as estrogenic imprinting or developmental estrogenization, is used as a model to evaluate the role of exogenous and endogenous estrogens as a potential predisposing factor for prostate diseases later in life.[40,41]

Prins's study also examined the effects of neonatal estrogen exposure on the development of the AR.[41,42] Estrogen receptors (ERs) have been shown to be strongly expressed in the mouse prostate mesenchyme.[43] While the stroma is strongly ER+, the prostate SM is weakly to negatively stained after differentiating from mesenchyme. Fibroblasts remain strongly ER+. There are no ERs in the epithelium of the prostate. Brief exposure to neonatal estrogen downregulates AR and permanently alters its expression, as well as retards ductal development.[41,42] SM development is generally unaffected, as is the development of basal cells. Estrogenization does not inhibit epithelial cell differentiation (determined by the appearance of luminal cell cytokeratins) completely, indicating that initiation of cytodifferentiation precedes elevated AR expression rather than increasing AR, triggering cytodifferentiation. These experiments suggest that functional differentiation is dependent on AR expression in epithelial cells.

Although this response is mediated through alterations in steroid receptor expression, other downstream mechanisms in the signaling cascade that mediate prostate ductal morphogenesis may be involved. The Sonic hedgehog (*Shh*) gene encodes a secreted glycoprotein that is expressed at many sites in the vertebrate embryo and participates in the molecular signaling for the development of the notochord, limb, hindgut, and genitourinary tract.[44,45] Loss of *Shh* function results in severe defects in neural and skeletal development, growth inhibition, and embryonic lethality. Using a murine model, *Shh* is expressed in the prostatic anlage of the UGS, and that expression is stimulated by testosterone. Pu et al. show that highly localized *Shh*-patched *gli* expression, along with regulation of downstream morphogens, participates in dichotomous branching during prostate morphogenesis.[45] Neonatal exposure to high-dose estadiol suppressed *Shh*-patched *gli* and blocked ductal branching in the dorsal and lateral prostate lobes.

Barnett et al. studied *Shh* expression in the human fetal prostate ages 9.5–20 weeks' gestation.[46] *Shh* expression was present in the prostatic urothelium, prostatic ducts, and glandular epithelium at 9.5, 11.5, 13, and 16 weeks and in the prostatic buds by 11.5 weeks. Staining was observed in the EDs, MDs, and anterior SM and skeletal muscle (SKM). Staining intensity diminished after 16 weeks, as testosterone levels declined to baseline, and was almost absent by 18 and 20 weeks, suggesting a direct relationship between testosterone levels and *Shh* expression.

Other studies of the effects of estrogen on the prostate have used the induction of squamous metaplasia (SQM) as a reliable marker for estrogen action on the gland.[35,47] Risbridger et al. studied this transformation of the epithelium and showed proliferation of basal cells and the expression of K10.[35] They also showed that mice lacking the stroma and/or epithelial ERα did not develop SQM.[35] These studies suggest that stroma and epithelial ERα are required for the induction of SQM in the prostate gland.

Shapiro et al. examined the immunolocalization of ERα and ERβ in the human fetal prostate (Figure 47.3). ERα expression was not detected until 15 weeks, with sparse staining in the utricle.[48] By 19 weeks, increased ERα expression was seen within luminal cells of the ventral UGE, basal cells of the dorsal UGE, the utricle, distal periurethral ducts, peripheral stroma, and the posterior prostatic duct. K14 is detected in the basal cells of the UGE and in several posterior acini. At 22 weeks, ERα expression is more intense in all these areas. ERβ is expressed throughout the UGE, EDs, MDs, and entire stroma at 7 weeks. Intense ERβ staining is observed in these areas and the prostatic buds by 8 weeks, with persistent intense staining through 22 weeks. The work of Shapiro and associates shows the earliest expression of ERα (15 weeks) and ERβ (7 weeks), and that the induction of SQM in the UGE, distal periurethral ducts, and utricle is associated with ERα expression in these areas, while the induction of SQM in peripheral prostatic acini is associated with peripheral stromal ERα expression. This suggests important estrogen signaling pathways in the human fetal prostate via ERα that involve epithelial–epithelial and epithelial–stromal interactions. Also, the timing of the appearance of SQM is thought to be associated with the decline in testosterone

levels after 18 weeks, when the Leydig cells are known to regress.[49] This results in an imbalance of the hormone milieu with a predominance of estrogens, which may then induce metaplastic changes.

The role of ERα and ERβ in prostatic development has been further elucidated in studies of the estrogen receptor α knockout (ERKOα) and estrogen receptor β knockout (ERKOβ) mouse, respectively.[50,51] Couse and Korach studied neonatal diethylstilbestrol (DES) exposure in males using both ERKOα and ERKOβ knockout cell lines.[51] The ERKOα males were completely resistant to the effects of neonatal DES exposure, and the ERKOβ response was similar to that of the wild type, with significant decreases in the AR levels and seminal vesicle size, increased stromal mass, marked epithelial hyperplasia and dyplasia, and lymphocytic infiltration. They conclude that the initial effect of DES resulting in the downregulation of AR levels is mediated by ERα. Therefore, the ERKOα males did not show any of the effects of neonatal DES, but unlike the wild type, the AR levels recover in the adult ERKOβ males.

Other investigators suggest an association of ERβ in the pathogenesis of prostate cancer since ERβ expression is downregulated in prostate cancer, supporting its role in prostatic cellular homeostasis.[52] We show that ERβ expression is intense during the early period of prostatic ductal morphogenesis and may be critical in maintaining normal glandular growth and proliferation.

Hofkamp et al. studied the effects of murine fetal exposure to estrogenic ultraviolet filters found in sunscreen and cosmetics.[53] They showed that fetal exposure to 4-methylbenzylidene camphor (4-MBC), which binds to ERβ in vitro but binds to ERα in vivo, resulted in a significant increase in tissue volume in the prostate and accessory sex glands. In the caudal region of the dorsal prostate ducts, there was a significant increase in volume due to an increased number of ducts budding from the UGS. This finding was in contrast to the increased ductal volume of the ventral prostate that resulted from increased branching morphogenesis, resulting in an increase in distal tip volume. These studies show that environmental endocrine disruptors alter normal prostate development.

Taylor et al. reviewed the mechanisms for the effects of estrogenic environmental chemicals and drugs on the developing male urogenital system.[54] There is now evidence that estrogens at very low concentrations during the early stages of prostate development can stimulate both fetal and neonatal prostate growth and lead to prostate disease in adulthood. Bisphenol A (BPA) is an environmental endocrine-disrupting chemical found in plastics, epoxy linings of food and beverage cans, and numerous common household products that bind to both the ER receptor subtypes and AR.[55] BPA is of great interest since it can be detected in >90% of people. In a fetal mouse model of UGS mesenchymal cells in culture, BPA disrupts prostate development by stimulating the expression of several genes involved in epithelial proliferation and inhibiting genes involved in apoptosis. The treatment with BPA or estradiol affected genes with cellular functions relevant to steroid hormone signaling and metabolism and to inter- and intracellular communications that promote cell growth. It is then easily conceivable that BPA is capable of disrupting the development of the entire male reproductive tract in the mouse. Since the "plastic revolution" began in the 1970s, males exposed to significant levels of environmental chemicals are just starting to approach the age where prostate disease would be expected to occur.[54,55] A comprehensive review by Hu et al. describes the effect of lifelong reprogramming by possible epigenomic alterations in human prostate stem or progenitor cells due to developmental estrogenization or transient adult exposure.[56] Recent studies indicate that these stem cells and early-stage progenitor cells may be direct carcinogenic targets and the cell of origin for the initiation and promotion of malignant prostate diseases in aging men.[56,57]

PROSTATE MORPHOMETRY

Shapiro et al. developed a technique for quantifying the cellular elements of the prostate that involves double immunoenzymatic staining and computer-assisted color image analysis.[58,59] The only comprehensive study of prostatic morphometry in the prepubertal male has been reported by Shapiro et al.[60] Quantitative morphometric studies were performed on pediatric and other nonhyperplastic prostate specimens obtained from 45 males ranging in age from 2 days to 40 years. The entire group was stratified based on age into categories reflecting the neonatal, childhood, peripubertal, adolescent, and young adult periods. Double immunoenzymatic staining using antiactin and anti-prostate specific alkaline phosphatase (PSAP) was used to label the tissue components.[59] Color image analysis demonstrated age-related changes in the density of SM that appear to parallel serum testosterone levels that vary due to the postnatal testosterone surge and the rise in testosterone at the onset of puberty.[3,61]

A progressive decrease in SM area density throughout childhood, prepuberty, and puberty was observed. The density of SM significantly increased following puberty and throughout adolescence and early adulthood. There was a concomitant increase in CT from the neonatal period throughout childhood, prepuberty, and puberty and a decrease after puberty and throughout adolescence and early adulthood. Since the changes in SM and CT were inversely related, the percent contribution of the stromal compartment to the total gland remained constant. No significant changes were seen in the epithelium or glandular lumen during these periods. The stromal-to-epithelial ratio remains constant from birth to age 40 in nonhyperplastic glands and is similar to those in asymptomatic and symptomatic BPH tissues. These morphometric observations suggest that BPH is not a unique stromal process.[60] These studies demonstrate that the stromal compartment is a dynamic structure, and the relationship between changes in cellular content and hormone milieu may be important to our understanding of growth of the prostate from birth to age 40 and the subsequent development of BPH.

Shapiro et al. compared prostate development in normal human male fetuses and those with myelomeningocele (MMC) at 20 weeks' gestational age.[61] Immunohistochemical staining was performed using Masson's trichrome and antibodies to SM and SKM actin. S-100 protein for Schwann cell localization and neurofilament protein was also performed. These studies

demonstrated a marked decrease in the peripheral innervation to the prostate in MMC. Trichrome and SM actin staining also showed that SM in MMC specimens was less well differentiated. Prostatic size, ductal morphogenesis, and SM were decreased when compared with controls. At the level where the EDs enter into the prostatic urethra, the mean cross-sectional area was 6.79 and 11.91 mm^2 in the MMC and normal prostate, respectively. Control prostates showed posterior peripheral SM surrounding acini, which subsequently become cannulated, as well as SM surrounding the EDs and along the periphery. In MMC prostates, SM was absent in the periphery where ductal branching and formation of acini normally occur. The other areas of SM were also poorly formed. They concluded that there is a global defect in the development of SM in MMC prostate at 20 weeks' gestation. Since the peripheral nerve density was diminished in the MMC prostate, an intact nervous system may be important in the SM and ductal morphogenesis of the developing prostate.

SUMMARY

The foundation for our understanding of the development of the human prostate was derived from human fetal studies reported by Lowsley and by unraveling the biochemical basis for the 5α-reductase deficiency syndrome. Tissue recombinant studies, genetic knockout studies in nude mice, and meticulous step sectioning of fetal prostates with immunohistochemical staining gestation have greatly enhanced our understanding of prostatic development. Future studies in novel animal models will provide important insights into the mechanisms of altered endocrine signaling pathways due to exposure to endocrine-disrupting chemicals. These altered pathways in prostate development lead to lifelong reprogramming of prostatic structure and gene expression, which may predispose aging men to the development of malignant prostate disease.

CHAPTER 48

Basic Science of the Urinary Bladder

Darius J. Bägli and Karen J. Aitken

INTRODUCTION

Although the urinary bladder is an outwardly simple hollow organ, it is unique. No other organ is evolutionarily programmed to fill with fluid over hours at low pressures and then contract on demand to evacuate its contents. The bladder is the only autonomically innervated organ under voluntary control. Indeed, the sociobiologic etiology and reasons for the existence of this unique behavior have been argued for decades. Although the ability to accommodate a fluid volume is thought to largely represent a passive phenomenon, this is not the case. Recruitment of active neuromechanical properties is crucial for the maintenance of low intravesical pressures during filling, and to this end, the character of the surrounding cellular and extracellular matrix (ECM) elements can either facilitate or compromise this function. It demonstrates a remarkable integration of neuromuscular, mechanical, and physical properties that are crucial for its normal function. Bladder contraction (emptying), on the other hand, is largely an active neuromuscular process, although it is also influenced by the physicochemical nature of the ECM and obviously depends on the overall mass and optimal functional status of bladder smooth muscle cells (bSMCs). Underlying the homeostasis of the bladder is cell biology governed by appropriate cell signaling in response to the mechanical and structural environment. These signaling responses to the environmental cues lead to maintenance or changes in gene expression and cellular function. This chapter reviews some of the biologic concepts related to normal bladder development and function, a complex orchestration of events that, if disturbed, can lead to a significant functional disharmony that places both continence and renal function at risk.

BLADDER DEVELOPMENT

The urogenital sinus develops from the dividing cloaca to form the bulk of the urinary bladder, with its endoderm giving rise to the urothelium, and the surrounding mesenchyme to the lamina propria, submucosa, smooth muscle layer, and adventitia. A smaller and albeit crucial part of this organ—the trigone—originates from a combination of bladder and ureteric muscle and, in a recent study, endoderm.[1–3] Specific signals are required for the cellular orchestration to proceed. For example, BMP7 and c-Jun N-terminal kinase (JNK) are required for the apical–basal direction of endodermal cell division, leading to cloacal septation.[4] Also, retinoic acid signaling in the urogenital sinus is required for a fully formed urinary bladder, although the caudal portion of the sinus will still form a normal urethra without retinoic acid. Cloacal and bladder expansion is accompanied by an increase in the volume of mesonephric urine, an ultrafiltrate containing growth factors similar to serum,[5,6] which provides the first mechanical cues (pressure and strain) through the increasing volumes to the cloaca and primitive bladder[7] as the vesicoallantoic canal closes off to form the median umbilical ligament. In males, the caudal portion of the urogenital sinus contributes to the valve system.

The initial formation of the vesicoureteric junction (VUJ) in the bladder begins with the nephric ducts and then the relocalization of the ureteric ducts by intercalation of fingerlike protrusions of ureteric cells into the caudal aspect of the bladder wall.[8–11] After the ureter joins the bladder, the common nephric duct regresses through an ill-defined process, which differs in females and males. In the *sal1* model, the lack of remodeling of the common nephric duct is associated with posterior urethral valves (PUVs). As such, malformation of the VUJ appears to have a gender-specific and heterogeneous genetic basis in humans.[12–19] A more caudal ingrowth of the initial mesonephric ducts leads to altered localization of the ureters.[20,21] In animal models, the expression and activation of a variety of molecules, including LAR family kinases,[22] *raldh2*, *gata3*,[23–25] *pax2*, *emx2*,[26] urothelial uroplakin IIIa, and ureter-specific *robo2*, are required for proper incorporation of the ureters into the trigone and formation of the VUJ.[9,13,27]

It is not completely clear how neuronal cells develop in the bladder, although in other tissues neurons develop alongside the vasculature or differentiate from mesenchyme (e.g., in the gut). However, neurotrophic factors (NGF, NTs 3–5, and BDNF) increase in a spatiotemporally controlled fashion from prenatal to postnatal periods, when neural reflex pathways are reorganized.[28,29] Another less defined region of the bladder, the adventitia or serosa, is composed mainly of fibroblasts, which are more numerous in exstrophied bladders. It is not clear whether the serosa is more specialized than adventitial layers in other organs, but serosal fibroblasts do play a role in experimental obstruction.

Early in gestation, the undifferentiated bladder mesenchymal cells are highly proliferative[30] and strongly

express genes relevant to retinoic acid or ephrin signaling, cell cycle genes, and midkine.[31] Through spatiotemporal interactions with the surrounding primitive urothelium and hedgehog signaling,[32,33] differentiation begins. Bladder mesenchyme expression patterns shift toward genes involved in differentiation of smooth muscle cell markers that will come to signify their smooth muscle lineage—including α- and γ-smooth muscle actin, desmin, and smooth muscle myosin[34]—in a process that coincides with changes in expression of specific ECM proteins, such as collagen, fibronectin, and laminin.[35] Particular molecules in the urothelium, including *shh* and *p63*, have been identified that are critical for normal bladder muscle development,[33,36] through their regulation of smooth muscle regulatory factors, e.g., *msx*.[37] Mutations or alterations in the expression of the above pathways and desmoplakin-related genes have been identified in cases of bladder exstrophy.[38–40] The early specific epithelial–mesenchymal–ECM interactions among the different developing cell types and their surrounding environment are critical for orderly differentiation and development. For example, collagen type IV, laminins, and fibronectin have been found in the basal lamina during development and are probably important in mediating interactions and forming a barrier between the developing urothelium and its underlying mesenchyme.[3]

Other ECM molecules, such as the structural collagens, are expressed differently between the lamina propria and the detrusor muscle fibers,[41] and interact with adjacent cells via specific cell surface receptors, the most important of which are believed to be the integrins.[42] The cell–matrix transduction of different stimuli through different mechanoreceptors (integrins, cell adhesion molecules, and selectins) regulates cellular proliferation and differentiation, as well as modulates ECM synthesis.[42] Consequently, normal prenatal bladder development not only results from a complex interaction of ECM and developing cells but also depends on appropriate mechanical stimulation. As gestation progresses, ECM cellular interactions vary with the multiple factors regulating the mechanical distension stimulus. Compliance appears to increase gradually,[43] as the bladder wall thickness and composition change,[44] with appropriate innervation that responds to increased demands of micturition as the fetus grows. Later, the bladder acquires a pattern of cyclical emptying.

CONTRACTION AND RELAXATION

As storage and emptying alternate, the complex function of the detrusor muscle demands integrated control of perhaps its most important cellular component, the smooth muscle cell. During filling, bSMCs must relax and elongate over a considerable length of time (hours) to accommodate the urine volume at low pressures. Under normal low-pressure filling conditions, the bladder will expand and unfold its matrix[45] and cells, leading to increased anisotropy in particular regions of the bladder.[46,47] Conversely, during micturition a rapid change occurs, leading to coordinated and synchronized force generation and cell shortening. By means of dense innervation and abundant intercellular communications (gap junctions), these activities—contraction and relaxation—respond to various transmitters and modulators that activate different cellular pathways.[48]

Contraction of bSMCs is mainly the result of interaction between the contractile proteins, actin and myosin, in a manner similar to that of other muscle cells in the body. In an energy-dependent process, a multistep enzymatic reaction allows for the cross-bridging and attachment of these two proteins in a cyclical fashion, following the same general scheme proposed for skeletal muscle. ATP is the immediate energy substrate, and is crucial for membrane pump Ca^{2+} handling, phosphorylation events, and cross-bridge cycling. The cellular concentration of ATP is therefore essential, and is maintained by mitochondrial respiration, glycolysis, and conversion of the high-energy compound phosphocreatine. Regulation of free Ca^{2+} in the cytosol is a highly energy-dependent process. Activation of the contractile apparatus by myosin light-chain kinase is modulated by cytosolic Ca^{2+}, whose concentration is regulated by Ca^{2+} channel pumps in the sarcoplasmic reticulum and plasma membrane. Furthermore, relaxation of smooth muscle involves restoration of the membrane gradients via β3 adrenergic receptor stimulation and downstream opening of the several potassium (K^+) channels, including BK channels.[49,50] Significant energy expenditures are required to maintain these Ca^{2+} gradients. Therefore, mitochondrial function is yet another factor essential for the normal generation of the contractile force by bSMCs.

Even though different isoforms have been described for both actin and myosin, the functional significance of the isoforms and their differential regulation remains unclear. Smooth muscle myosin is composed of a pair of heavy chains and two pairs of light chains. Through alternative splicing, vertebrate smooth muscle myosin heavy chains can be expressed in two C-terminal isoforms (SM1 and SM2) and two N-terminal isoforms (SMA and SMB). Some studies suggest that the SM1 isoform creates better contractile filaments than SM2, and that SMB is associated with increased ATPase activity, increased shortening velocity, and more phasic contractions than the SMA isoform.[51–53] Although it remains possible that the presence and relative concentrations of actin and myosin vary with developmental state and in response to obstruction or other pathologic processes,[53–56] their function not only supports the contractile apparatus but also helps to define the cytoskeleton. Indeed, the cytoskeletal framework of the bSMCs forms a dynamic structure, with linkages to the ECM. At the same time, these points of linkage, or adhesion complexes with the ECM, mediate intracellular signaling that leads to gene expression, cell migration, cell growth, apoptosis, and adaptation.[48,57,58] Although a relatively novel finding in urology, this paradigm has been appreciated in other biologic systems where it governs cell–matrix relationships in multiple ways.[59]

MECHANOTRANSDUCTION

Cycling between filling and emptying continually exposes the bladder to homeostatic levels of mechanical stimulation, with force transduction to the cells and their surrounding environment. Homeostatic levels of mechanical

stimulation in the bladder allow for maintenance of cellular phenotype, while defunctionalization (such as bilateral ectopia and urinary diversion) leads to decreased detrusor growth.[60] As a conditioning and modifying process, forcible changes in cell shape induced by various combinations of stretching, contraction, pressure, and membrane and cytoskeletal deformation eventually lead to alterations in gene expression (Figure 48.1). The macroscopic changes often appreciated in the bladder wall are thus the result of transcriptionally mediated tissue remodeling and activation of different molecular pathways. The process of converting physical forces to biochemical signals and integrating these signals into a cellular response (e.g., transcription or movement, e.g., contraction) is known as mechanotransduction.[61] It is an important concept in bladder development, homeostasis, and the bladder's response to different pathologic stimuli. Critical to this process is the signaling system mediating mechanotransduction, which can lead to both short- and long-term changes in gene transcription and cell behavior, involving feedback loops to regulate the responses. In disease, the intensity, duration, and feedback of the mechanotransduction responses may become dysregulated.

Some of the earliest-described mechanoresponsive molecules involved in the bladder's response to distension were prostacyclins.[63] The production of prostacyclins was later found to occur through mitogen-activated protein kinase (MAPK)–induced cyclooxygenase 2 (COX-2) activity.[64] Depending on the particular species of prostanoid produced, prostacyclins activate signaling pathways, and affect muscarinic responses and bladder contractility[65–67] either directly or through cross talk with the urothelium.[68] The bladder, among other mechanosensitive organs, derives mitogenic stimuli from mechanical stimulation through the activation of members of the MAPK family—the JNK,[69,70] p38 MAPK,[71] and extracellular signal-regulated kinase (ERK)[72]—as well as phosphoinositide 3-kinase (PI3K)/AKT,[73,74] STAT3,[75,76] calcineurin,[77–79] NFATc,[80] β-catenin,[81] and mTOR.[82] Through these pathways, signals are transmitted to activate various transcription factors responsible for cell growth, hypertrophy, and survival. Less studied are the mechanosensitive pathways that may be important for cellular differentiation. It has, however, been noted that the duration, cyclicity, and matrix context of mechanical strain are critical for the mitogenic signaling to occur in bladder smooth muscle, as well as other tissues[72,83,84] (for a review, see Aitken and Bagli[85,86]). It is probable that the pathways are multiple and perhaps redundant; however, it is currently believed that integrins play an important role in these series of

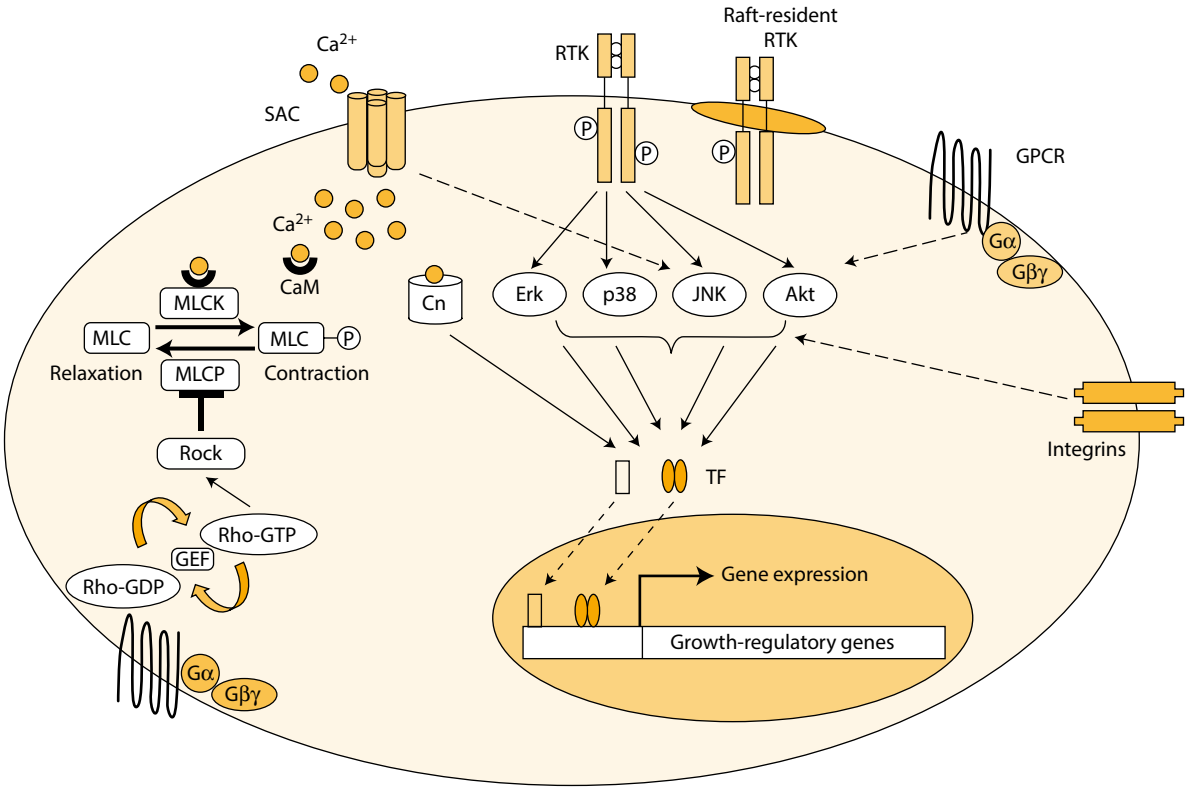

FIGURE 48.1 Signaling cascades in bSMCs: external stimuli are transduced by SACs, receptor tyrosine kinases (RTK), G-protein-coupled receptors (GPCR), and integrin subunits. SAC-mediated calcium (Ca^{2+}) entry promotes calmodulin (CaM) binding and activation of myosin light-chain kinase (MLCK), leading to MLC phosphorylation and initiation of smooth muscle contraction. MLC phosphatase (MLCP)–induced relaxation is inhibited by Rho-associated kinase (ROCK). Ca^{2+} influx also activates calcineurin (Cn), leading to dephosphorylation and nuclear translocation of transcription factors (TF). RTK activation promotes activation of the MAPKs Erk, p38 stress-activated protein kinase 2 (SAPK2), JNK, and Akt. These signaling intermediates in turn promote activation and nuclear translocation of TF, and alterations in gene expression. (Adapted from Adam, RM. *Nephron Exp Nephrol* 2006;102:e1–7. With permission.)

events.[87] These linkage molecules are almost ubiquitous, acting as a relay between the matrix and different cells. Individual tissues thus display different complex responses to mechanical stimulation, the eventual response modulated by the type of mechanical stimulation, as well as by the signaling molecules and transcription factors expressed by that particular tissue.[61] As a group, these ECM receptor molecules provide a physical link between cell membranes and surrounding structural ECM proteins, such as collagen, laminins, vitronectin, and fibronectin. In particular, the integrins represent a large and versatile family of heterodimeric transmembrane mechanoreceptors capable of transducing a wide range of alterations in the cell microenvironment.[88] Growth factors can further stimulate cell responses through integrins by either mutual interaction, or integrin clustering with growth factor receptors. This process is tightly regulated through expression of different integrin subunits specifically modulated by different growth factors and/or ECM molecules under different developmental and pathologic situations. Even though much of the current knowledge about these molecules remains to be revealed in relation to the bladder, their importance in response to bladder distension and dynamic alterations in ECM expression has been demonstrated.[42]

Integration of mechanotransduction to the cytoskeletal machinery occurs through several mechanisms. Homeostatic levels of distension activate muscarinic responses through PI3K and rho kinase, leading to activation of myosin light-chain kinase. Finally, mechanotransduction in bladder muscle also occurs through stretch-activated ion channels (SACs), which respond to strain by increasing intracellular calcium (Figure 48.1).[87] This is regulated in part by β3-adrenergic signaling, which activates large-conductance BK channels, and by other K^+ channels to restore the resting membrane potential and return smooth muscle cells to a relaxed state.[49,89–91]

Distension of the bladder may affect other cell types as well. Working with this hypothesis, several studies have examined the participation of urothelial-, submucosal-, and interstitial-type cells in mechanotransduction. The proximity of basal urothelial cells to afferent neurons makes their responses to mechanical stimulation potentially important for neuronal responses. For instance, COX-2 expression via PKCζ activity is increased through mechanical stimulation of urothelial cells.[92] Another way that the urothelium contributes to the integration of mechanical stimuli is through stretch- and pressure-induced activation of the muscarinic, purinergic, nitric oxide, calcium, and vanilloid channels, the latter providing a possible link between mechanical strain to pain or inflammatory pathways of the bladder.[93,94] In addition to urothelial cells, other cell types may play a neuromodulatory role, e.g., interstitial cells of Cajal,[95–99] $PDGFRa^+$ cells,[100] and suburothelial cells.[101] Mechanical stimulation of stromal cells with urothelial cells can propagate formation of a full-thickness differentiated urothelium with complete barrier function.[102,103] This is likely through the stimulation of the stroma to produce the fibroblast growth factor and nerve growth factor, as the urothelium itself is not known to proliferate in response to cyclic stretching.

SMOOTH MUSCLE GROWTH

The generation of contractile force is one of the principal roles for bSMCs. Beyond the immediate effect of recruitment and longer contraction times, bladder response to increased work demand (i.e., increased outlet resistance) results in an increase in bSMC mass through hypertrophy (increase in cell number) and hyperplasia (increase in cell size). bSMC growth has been shown to increase in response to growth factors, such as basic fibroblast growth factor (FGF2),[104–106] platelet-derived growth factor BB (PDGFB),[74] and heparin-binding EGF-like growth factor (HBEGF),[107] though other mitogenic signals (e.g., mild hypoxia) may be important. In many instances, the transcription of specific genes eventually leads to increased cell mass and/or number and is mediated through MAPKs,[108] STAT3, AKT, and mTOR, although other kinase signaling families are probably involved (Figure 48.1). These bioactive peptides contribute to tissue expansion through autocrine and paracrine signaling mechanisms. It has become increasingly clear that diverse signals can participate in a number of positive and negative feedback loops, which may amplify or reduce the initial stimulus, differentially contributing to specific DNA transcription, protein synthesis, and inactivation of proapoptotic pathways. There exists considerable interest in the modulation of the bSMC mitogenic response, as it is believed that progressive increase in smooth muscle mass is a key component of bladder dysfunction. Currently, management of bladder wall thickening is based on the use of anticholinergics, such as oxybutynin and tolterodine. Interestingly, besides its well-described antimuscarinic effect, oxybutynin inhibits serum-induced bSMC proliferation and gene expression in vitro, giving us another potential explanation for its proven clinical efficacy.[109] Other molecules, such as botulinum toxin, which target the muscarinic pathways, have appeared in experimental clinical use based on an acceptable clinical response in other conditions.[110–113] Known to have a chemodenervating effect based on skeletal muscle studies, the different toxin serotypes (BTX A–G) target different proteins involved in the SNARE (soluble N-ethylmaleimide-sensitive factor attachment protein receptor) complex (Figure 48.2).[110] The mechanism of action in smooth muscle, however, may be more complex, as new evidence suggests an antinociceptive and neuromodulating effect.[112,114,115] Recent clinical trials in pediatric and adult populations have demonstrated variability in the degree of efficacy for inhibition of spasticity and improvement of quality of life.[116–122]

Once the pathways of the mitogenic response are better elucidated, specific inhibitors may lead to clinical trials. In one example, a recent area of interest has been the regulation of compensatory bladder hypertrophy with calcineurin inhibitors, such as cyclosporine and FK506 (tacrolimus). Initial evidence suggesting modulation of muscle hypertrophy has been described in a bladder outlet obstruction animal model.[77] mTOR signaling was also shown initially to be beneficial for preventing muscle growth and remodeling in vitro,[82] and recently to prevent remodeling, overgrowth, and hypertrophy of bladder muscle in vivo.[124] This type of in vitro to in vivo

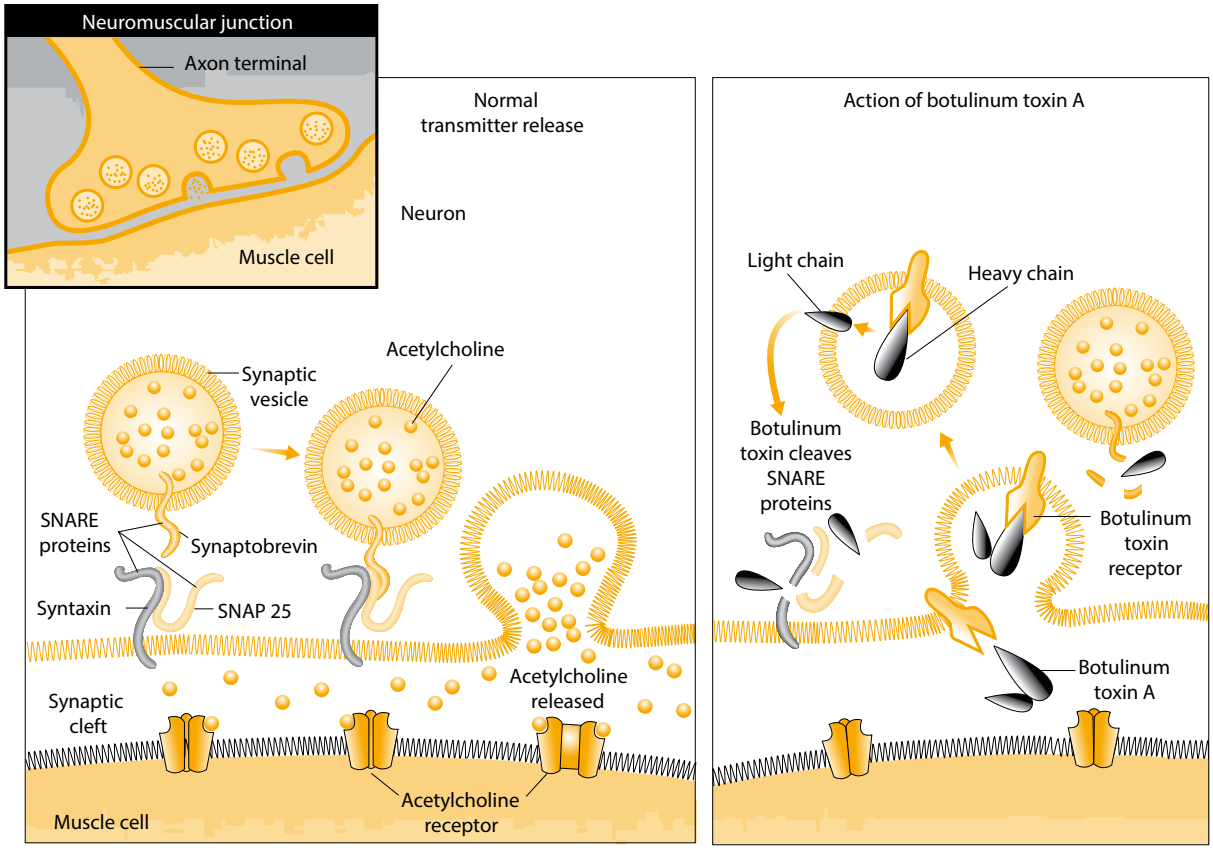

FIGURE 48.2 Under normal conditions, acetylcholine is packaged in vesicles that fuse with those of the nerve terminals, releasing the transmitter into the synaptic cleft. This process is mediated by a series of proteins, collectively called the SNARE proteins. Botulinum toxin cleaves the SNARE proteins, preventing assembly of the fusion complex and thus blocking the release of acetylcholine. (Adapted from Rowland LP. *N Engl J Med* 2002;347:382–3. With permission.)

work may lead to translational venues for new pharmacologic therapies.

Several elegant studies have suggested that different stretch-induced growth factors contribute to bladder impedance pathology, by increasing hypertrophy, although these proteins are by no means the exclusive mediators of bSMC mechanical responses. For instance, studies of the COX pathway have suggested that COX-2 expression—active during bladder development[125]—is reexpressed during bladder distention[64] (making COX-2 inhibitors potential pharmacologic inhibitors of stretch-induced bSMC proliferation). These observations suggest that obstruction response may reactivate certain fetal gene expression patterns. Teleologically, this may represent an effect to restore the function originally intended during development, such as concurrent growth and differentiation. Convergence of these protein and enzymatic pathways in the regulation of bladder obstruction has yet to be demonstrated.

EXTRACELLULAR MATRIX REMODELING

As the bladder develops, or adapts to different stimuli, the ECM also remodels in concert with the changes described for bSMCs (for a review, see Aitken and Bagli[85,86]). An important group of enzymes—the matrix metalloproteinases (MMPs)—are crucial in this process of altering the ECM structure and function. They are multifunctional proteases that degrade ECM proteins, liberate or modulate the bioactivity of growth factors and cytokines of other proteases, and alter the biophysical characteristics of the matrix. A cascade of events is initiated in the setting of excessive distention or high-pressure emptying, slowly resulting in thickening of the bladder wall. In conjunction with bSMC hyperplasia and hypertrophy, there is an increase in collagen synthesis, with deposition of collagen I and III,[126] associated with increased expression of MMP-2 and MMP-9, which are MMPs known to have an active role in matrix turnover in animal models.[127] While collagen expression may increase, the enzymes responsible for remodeling are also altered. With increased MMP-7 expression and activity in the bladder, the collagen type I and III fibrils appear to be decreased in integrity, leading initially to an increased intraluminal volume in the bladder.[124]

While the bladder matrix contributes to the physicomechanical characteristics of bladder dysfunction, it is proving to directly orchestrate bSMC biologic responses as well. The prototypical matrix protein in the bladder is fibrillar collagen. Stretching bSMCs promotes collagen production, and bladder obstruction models have demonstrated

the new expression of both protein and collagen mRNA within the muscle bundles. Mostly, types I and III are associated with the detrusor, although 19 different collagen types have been identified so far in other tissues, some with structural roles and others that associate with the structural types. For example, type XII collagen contributes to cross-linking type I fibrils during fiber assembly and may contribute to stiffness of tissues. Furthermore, type XII mRNA expression increases during mechanical distention of the whole bladder.[128] Diverse matrix alterations (accumulation, breakdown, redistribution, and structural rearrangements) are all occurring when tissues are remodeled during development, as well as during response to injury or wound repair. In fact, many biologic mechanisms in development are recapitulated during repair. MMPs are enzymes with the ability to edit matrix collagen, as well as many of the other ECM proteins. Although MMPs are now known to perform a variety of functions, they are best known for their originally described ability to break down (proteolyse) the ECM during morphogenesis, cell (tumor) invasion, and wound repair. Increased MMP activity or production has been described during bladder development and bladder obstruction in animal models. However, it now appears that the alterations in collagen may directly stimulate bSMC growth. When collagen is denatured experimentally, it elicits a strong proliferative response in bSMCs. Similarly, when collagen is chemically proteolysed by MMPs, bSMC growth is stimulated.[72] The proteolytic fragments released from the degradation of fibrillar collagen generate different signals than intact collagen, and potentially modulate bladder remodeling and bSMC growth by differential signaling pathways.[82,129]

It is likely that the receptors on the surface of all cells, including bSMCs, which permit cell–matrix attachment, are recognizing new epitopes in ECM macromolecules exposed as a result of protease activity. Inhibition of matrix receptors, such as the integrins, can potentially prevent bSMC proliferation in response to proteolysed matrix. Since bSMCs themselves are producing the enzymes (MMPs) responsible for matrix rearrangement, a powerful dynamic reciprocity is being revealed wherein bSMCs cause matrix alterations, which can then directly stimulate bSMC growth. Since natural regulators or inhibitors of these molecules also exist in the bladder (tissue inhibitors of MMPs [TIMPs]), we begin to appreciate a complex set of balanced mechanisms that depend on cell–matrix interactions. These processes are probably disturbed during bladder obstruction responses.

Finally, an integral yet poorly understood and sometimes overlooked part of the ECM is composed of proteoglycans and glycosaminoglycans. For instance, they may serve as ligands for some of the collagens present in the bladder wall and mediate response to injury or hyperdistention.[128] Most of the current research regarding these molecules has been directed toward the urothelium, use in reflux, and the protection of this layer against noxious stimuli, which is probably disrupted in conditions such as interstitial cystitis.[130] The accumulation of ECM proteoglycans and glysosaminoglycans is a known integral part of the early phases of tissue response to injury, conditioning changes in the ECM that may serve to direct the later deposition of the structural collagens. Evidence for a role in bladder wall remodeling comes from studies on the receptors for the ubiquitous glycosaminoglycan, hyaluronic acid, a molecule that appears to play a role in bSMC collagen gene expression and regulation during distention.[128,131]

NEUROTRANSMITTERS AND NEUROTROPHIC FACTORS

Bladder function is tightly regulated mainly under the influence of nervous and hormonal control systems. To date, the muscarinic receptors seem to be the most important class of receptors involved in the activation of detrusor contractions.[48,132] The human bladder expresses all known cholinergic muscarinic receptors (CHRM1–5),[133] with a predominance of CHRM2 and 3 subtypes,[134] depending on the species studied. The CHRM3 receptor is the primary receptor linked to stimulation of detrusor contraction through activation of phosphoinositide hydrolysis and generation of inositol triphosphate, although CHRM2 quantity predominates in the human bladder by a ratio of at least 3:1 over CHRM3. Interestingly, human bSMCs demonstrate a requirement for lipid raft and cholesterol during muscarinic signaling not seen in other species. Notwithstanding the unclear functional role of the M2 receptor, it is interesting to note that its expression and activity further increase in experimental pathologic states and by M3 selective antagonist treatment, potentially facilitating bladder contractions and muscle hypertrophy.[135–138] Interest in the M2/M3 receptor differences has been rekindled after the recent introduction of subtype-selective pharmacologic agents, i.e., M3-specific antagonists solifenacin and darifenacin.[139]

Other pathways are clearly important in modulating the M2/M3 response or even instigating contractile responses on their own in normal and pathologic circumstances. Prostacyclins have long been known to initiate contractile responses. Also, adenyl cyclase purinergic and androgen signaling can alter muscarinic activation. Endothelin acting on the ETA/B receptors is able to initiate contraction in bSMCs in nonmuscarinic pathways. Other neurotrophic factors and cooperative receptors—such as the NGF, BDNF, Ca^{+2}, and K^{+} channels and adrenergic receptors—have been gaining relevance.[48,140–143] While neurons in the interstitial spaces transmit signals to the bSMCs, the urothelium can engage in the contractile process, through transient receptor potential vanilloid 4 channel (TEPV) and purinergic signaling. However, an understanding of the pre- and postnatal development of these other pathways is needed to clear the way for new approaches to disease. Regarding congenital disorders, the issue is compounded by the limited understanding of neural control and maturation during development. Fetal human studies have shown variation in some receptor subtype expression when compared with adults, as is the case for P2X receptors.[144] In contrast, fetal versus adult reports describe little difference in cholinergic innervation in response to stimulation by muscarinic receptors, suggesting functional capacity early in life.[145] PUVs and experimental bladder obstruction, however, result in altered capacity for contractility in response to acetylcholine.

POSTERIOR URETHRAL VALVES AND CONGENITAL BLADDER OUTFLOW OBSTRUCTION

How the underlying molecular signaling cascades mediate survival, contractility, growth, and cell death can help lay the foundations for understanding how extrinsic pathologies mediate intrinsic bladder responses. PUVs represent an archetypical form of increased resistance to urinary flow in humans. In the pediatric sphere, this is somewhat analogous to the impedance generated by benign prostatic enlargement in the adult male. Whereas similar clinical bladder responses are noted between these two pathologies, multiple factors probably differentiate childhood from adult obstructive uropathies. PUV bladder trabeculation and altered function represent a spectrum of pathology that may derive as much from its timing during gestation as from the degree of impedance. Experimental observations on extrinsic manipulation of the bladder neck would suggest that while extrinsic obstruction models do reproduce some of the structural and functional consequences seen in clinical PUV bladders, they may also unwittingly distract from the true nature of the problem at the molecular level.

The "valve" bladder has long been viewed as the bladder's response to a mechanical problem. bSMCs must simply work harder to expel urine. They must mount an increased contraction effort. In doing so, the bladder phenotype (structure and function) changes. Finely tuned neurosensory perception of pressure and stretch, which accompanies higher than expected voiding pressure, is related through reflex arcs and may increase efferent motor demands on the detrusor. Furthermore, abnormalities in the outlet region of the bladder neck and sphincter areas, which harbor the valves themselves, may give rise to neurodevelopmental changes that directly influence bSMC function. Nevertheless, the apparent normalization of PUV bladder morphology and function can occur when valves are ablated, suggesting that bSMCs retain the capacity for normal function despite the creation of an outlet defect during gestation. In contrast, bSMCs from neurogenic bladders appear to harbor more permanent phenotypic changes, which are retained during in vitro culture compared with normal bSMCs.[146,147] It is not known if obstructed bSMCs retain hypertrophic phenotypic changes as well, although obstructed bSMCs in experimental models do not completely return to normal function and morphology after release of the obstruction.

During development and the periods of normal unobstructed emptying, bSMCs are programmed to accept and work against a range of elevated intravesical pressures. The resistance afforded by PUV increases this pressure. Whether indirectly through a stretch- or tension-neural receptor mechanism and/or directly via smooth muscle cell stretch or mechanoreceptors, alterations in muscle membrane ion channels, muscarinic activity, or changes in smooth muscle cell shape, bSMCs contract more forcefully. As inefficient emptying progresses, the excessive bladder storage may actually overstretch the detrusor muscle to excess degree and duration; indeed, this may become a dominant insult that erodes bladder function.

Clearly, the role of physical stretch and tension in bSMC biology is more complex and difficult to sort out from a mechanistic point of view than it first appears. We now appreciate that stretch operates under different conditions in different pathologies, and may contribute to bladder alterations at different points in natural history of any given obstructive uropathy. The paradox is that although mechanical stretching of bSMCs in vitro may generate clinically familiar responses generated by hypercontraction or excessively stretched bSMCs in vivo, it may do so through physiologically irrelevant or unrelated molecular mechanisms. To determine whether the physical stimulus of stretch per se can predict and elucidate relevant changes in bSMC phenotype, mechanical stretch of bSMCs in vitro should be followed by studies in vivo. Studies of this nature have provided compelling information and suggest that bSMCs alone may be a primary cellular recipient of relevant stretch (mechanical) stimuli in vivo.

LIMITATIONS OF RESEARCH TOOLS: IN VIVO, EX VIVO, AND IN VITRO MODELS

The study of any biologic problem is often dependent on the availability of appropriate models. More importantly, suitably framed segments or aspects of each problem should guide investigation. As previously mentioned, these emerging segments include proteins and molecules, which affect smooth muscle cell growth and phenotype, the influence of mechanical and neural stimuli, and the role and regulation of the bladder ECM components. Clearly, these areas of investigation will intersect and new segments of the problem are to be anticipated. Although none of the molecules currently reported to influence bSMC growth and behavior in the context of bladder obstruction have affected clinical practice yet, they may hold keys to appreciating how bSMCs work and respond to pathogenic stimuli. There are, however, conceptual shortcomings to the use of in vitro, ex vivo, and in vivo animal models as a means of deciphering the intricacies behind normal and pathologic bladder function and development. Experimental conditions differ in timing, reversibility, stretching parameters, and cyclicity,[71,72,82,148,149] as well as the nature (extrinsic vs. intrinsic) of the obstructive stimuli. In some instances, the in vitro and ex vivo models are recapitulated in vivo, while in others, the in vivo models do not respond as positively to treatments. Assessments of potential pharmacotherapies in experimental in vivo models most often begin soon after obstruction during the initial inflammation, hypoxia, and stretch injury, rather than close to or soon after the time of surgical reversal of obstructions, as would occur clinically. Therefore, the results observed are potentially not directly translatable to treatment of the detrusor in congenital anomalies.

THE PROMISE OF TISSUE ENGINEERING AND STEM CELLS

As the full potentials of molecular mechanisms and therapeutics, prenatal diagnosis, and sheer curiosity about

bladder disease are awakened and converge in the coming decade, we can expect new and frankly unexpected approaches to emerge for the treatment and even prevention of obstructive bladder pathologies. Increasingly, intense research has focused on the fields of regenerative medicine and tissue engineering, as the principles of bioengineering, biomaterials, and cell transplantation are applied to construct biologic substitutes that would restore function in diseased urologic tissues.[150] This process has uncovered that, perhaps not unexpectedly, the biology of the bladder is every bit as complex and enigmatic as that of the other vital body systems.[151] It has proven difficult to regenerate all the functional layers of the bladder, as the engineered tissue needs to have optimal mechanical and structural characteristics while being biocompatible and capable of eliciting enough neovascularization to survive once implanted. Much of the available data are based on in vitro and promising animal models[86,152] that take into consideration the developmental and environmental stimuli that are necessary for the appropriate growth and differentiation of bSMCs[153–156] and fully functional urothelial sheets.[102,157]

Another avenue has explored the potential for various sources and types of stem cells to regenerate or de novo tissue engineer functional tissue. Regarding de novo tissue engineering efforts with stem cells, many of them have faced the same issues as using endogenous bSMCs and urothelial cells. Stem cells do not always differentiate as expected, although the potential of recapitulating development through the use of pluripotent or multipotent stem cells remains a desirable but difficult goal.[158,159] In contrast, exogenously derived stem cells may provide a supportive role in the tissue, encouraging the endogenous cells to repair the tissue.[160] Regeneration can also occur through endogenous precursor and progenitor cell populations, including those in the lamina propria, the interstitial detrusor regions, and the urothelium itself.[161–166]

A further issue is that autologous cells from patients with nonmalignant disease do not perform as well as normal controls, including urothelial cells.[167,168] A greater understanding of these lasting changes in cell physiology of autologous donor cells, which may be due to an underlying defect in the cells predisposing the organ to dysfunction, self-sustaining transcriptional networks, or even epigenetic change, will be crucial for tissue engineering and regeneration efforts.

CONCLUSION

The past decades have witnessed a changing view of the bladder, from a simple organ that contracts in order to volitionally eliminate urine, to a complex unit responsive to fine neuromodulation and smooth muscle–ECM interaction. As such, the approach to bladder dysfunction is shifting from a symptomatic basis (based solely on treating urinary tract symptoms, incontinence, high intravesical pressures, and capacity) to measures aimed at preventing end-stage damage to affected organs (which requires aggressive and morbid interventions, such as augmentation cystoplasty or renal transplantation). In the latter approach, the tendency is to prevent the overgrowth of smooth muscle, inflammatory and fibroproliferative responses, and its consequent loss of compliance, contraction inefficiency, and hyperdistention. Even though great advances have been made in the past few decades, understanding molecular mechanisms behind bladder development and the bladder's transcriptional and epigenetic responses to abnormal mechanical states remains a fertile area for research and development. As such, our molecular understanding of the pathophysiology of the bladder is moving us closer to translatable goals of newly targeted therapies for bladder conditions.

Embryology of the Anterior Abdominal Wall, Bladder, and Proximal Urethra

Steven E. Lerman, Irene M. McAleer, Alan L. Kaplan, and George W. Kaplan

ANTERIOR ABDOMINAL WALL

During the first 3 weeks of development, the embryo is a plate of cells, the embryonic disk, whose ventral surface is a membrane called the somatopleure. The anterior abdominal wall is at first represented by the somatopleure of the overhanging head and tail folds. The somatopleure closes concentrically from the cranial, caudal, and lateral margins, centering on the future umbilical ring (Figure 49.1).

In the sixth week of development, the midgut closes and the body stalk reduces in relative size. The somatopleure is invaded by mesoderm from myotomes on either side of the vertebral column. This mesoderm migrates laterally and ventrally as a sheet (Figure 49.2).

The primordia of the two rectus abdominis muscles form laterally and begin to move toward the midline during the seventh week. At that time, the mesoderm laterally splits into three sheets, eventually producing the external oblique muscle, the internal oblique muscle, and the transversus abdominis muscle. These layers are all recognizable during the seventh week (Figure 49.3). In the infraumbilical area, the formation of three muscle layers is preceded by invasion of secondary mesoderm that arises from the primitive streak just behind the cloaca. This secondary mesoderm then surrounds the cloaca and invades the body wall caudal to the body stalk, providing primary closure to the body wall between the phallus and the body stalk and forming part of the anterior bladder musculature as well (Figure 49.4).[1] Between the 7th and 12th weeks of development, the rectus abdominis muscles meet in the midline except around the umbilicus. During this same time, the secondary mesoderm forming the lower abdominal wall is reinforced externally by invading somatic mesoderm that forms the muscular layers of the lower abdominal wall.

The exact genetic and cellular elements necessary for abdominal wall development are for the moment unclear. Mycotoxins, given to mice in early development, result in extensive abdominal wall defects, suggesting that failure of cell proliferation, cell migration, and/or production of extracellular matrix materials within the mesoderm itself can lead to abdominal wall defects. Other elements necessary for normal fusion and closure are (1) synthesis of a glycoprotein surface coat on each opposing fold to promote adherence, (2) apoptosis of some cells while others migrate in, and (3) cell-to-cell contact to permanently bond two sides together.[2] *The important urologic anomalies resulting from faulty embryogenesis of the abdominal wall are the Eagle–Barrett (prune belly) syndrome and exstrophy of the bladder or cloaca. Neither of these is an arrested stage of normal embryogenesis.* The Eagle–Barrett syndrome seems most likely to be due to faulty mesodermal development during the 6th to 12th week, as several mesodermal elements (abdominal wall, ureter, bladder, and testes) are usually involved.[3] Recent reports of prune belly syndrome with chromosome 17q12 deletions involving the HNF1 gene (a gene that regulates mesodermal and endodermal development) would support this theory and suggest a genetic basis for the problem.[4,5] Another theory states that the Eagle–Barrett syndrome is a deformation of the abdominal wall produced by distended viscera or increased intra-abdominal pressure.[6] Support for this theory is found in the observation that fetal ascites can result in congenital hypoplasia of the abdominal wall.[7] In addition, there is a report of a mutation of muscarinic acetylcholione receptor M3 producing a problem with bladder contraction and a prune belly–like syndrome in five brothers.[8] A third theory attributes the urinary abnormalities to a primary abdominal wall defect resulting in decreased intra-abdominal pressure.[9]

Exstrophy may result from a failure of the secondary mesoderm to cover the infraumbilical abdominal wall. Rupture of the cloacal membrane prematurely could also produce such a failure. Should this occur in the fifth week, cloacal exstrophy could result.[10] If this does not occur until the seventh week, so that some of the secondary mesoderm is in place, classical bladder exstrophy might result. Still later (the 10th or 11th week), failure of invasion by somatic mesoderm might result in superior vesical fissure or epispadias. There have been sporadic reports of familial instances of the exstrophy–epispadias complex. There also have been studies that suggest that there may be a site on chromosomes 4 and 19 that contains a gene for an autosomal recessive form of the exstrophy–epispadias complex.[11]

Lower Urinary Tract

The development of the lower urinary tract is closely interrelated with that of the genital tract and the hindgut, but for clarity, the genital tract is discussed later.

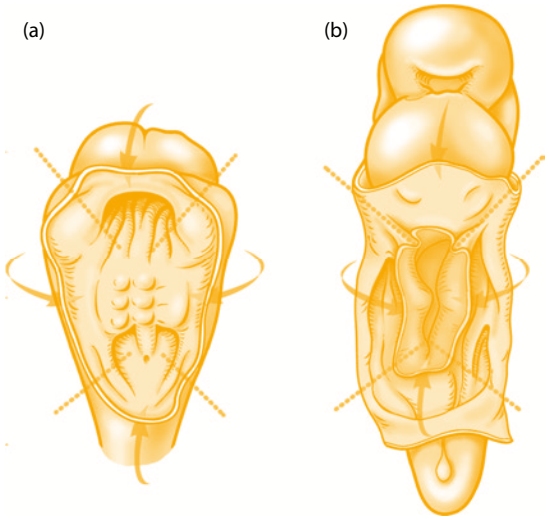

FIGURE 49.1 Ventral views of human embryos of 2 and 3 mm. The body stalk has been cut distal to the site of the future umbilical ring. Arrows show the direction of infolding; dotted lines indicate the arbitrary boundaries of the four infoldings. (Reproduced from Gray SW, Skandalakis JE. *Embryology for Surgeons*. FIGURE 49.3 Diagrammatic transverse hemisection through the abdomen or thorax of a 7-week human embryo. (Reproduced from Arey LB. *Developmental Anatomy*, 6th edn. Philadelphia: WB Saunders, 1974. With permission.)

During the first 3 weeks, the cloaca develops from endoderm as a blind caudal expansion of the hindgut (Figure 49.5). The hindgut meets the ectoderm of the body wall at the cloacal membrane. This membrane extends caudally from the primitive streak and is turned under by the tail fold. It extends from the tail bud to the body stalk. As the mesoderm grows, the area of the cloacal membrane is decreased. The cloaca gives off a ventrally directed allantoic stalk and receives the mesonephric duct laterally and extends caudally as the tail gut.

The cloaca, during the fifth week, is divided by opposing walls of the hindgut in the allantois, meeting in a saddle-shaped notch with its apex pointing caudally. This notch fills in with mesenchyme to form the urorectal septum. This septum pushes caudally as a fold and advances, dividing the cloaca into the primitive rectum posteriorly and a urogenital sinus anteriorly (Figure 49.6).

Various regions of the urogenital sinus are recognizable in the sixth week: the allantois, bladder, pelvic, and phallic portions of the urogenital sinus. The pelvic portion of the urogenital sinus lies cephalad to the entrance of the mesonephric duct but below the bladder, whereas the phallic portion of the urogenital sinus lies caudad to the entrance of the mesonephric duct and extends distally toward the genital tubercle.

By the seventh week, the ureters empty into the bladder by a process in which nephric ducts, after the ureteral buds have appeared, are absorbed into the urogenital sinus and acquire four separate openings into the sinus (Figure 49.7). The mesonephric ducts are shifted further caudad in the sinus and come to lie close to each other at Müller's tubercle, while the ureters shift cephalad and laterally into the bladder. It is then that the trigone is formed. The trigone is temporarily mesodermal but fills in with urogenital sinus

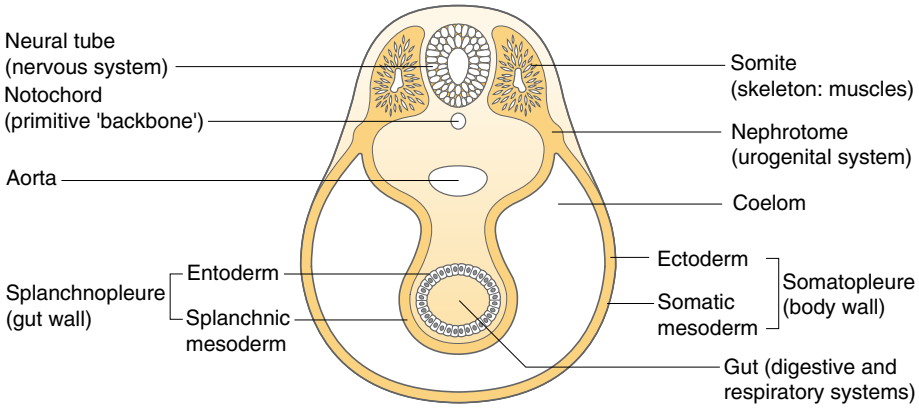

FIGURE 49.2 Diagrammatic transverse section of a vertebrate embryo. (Reproduced from Arey LB. *Developmental Anatomy*, 6th edn. Philadelphia: WB Saunders, 1974. With permission.)

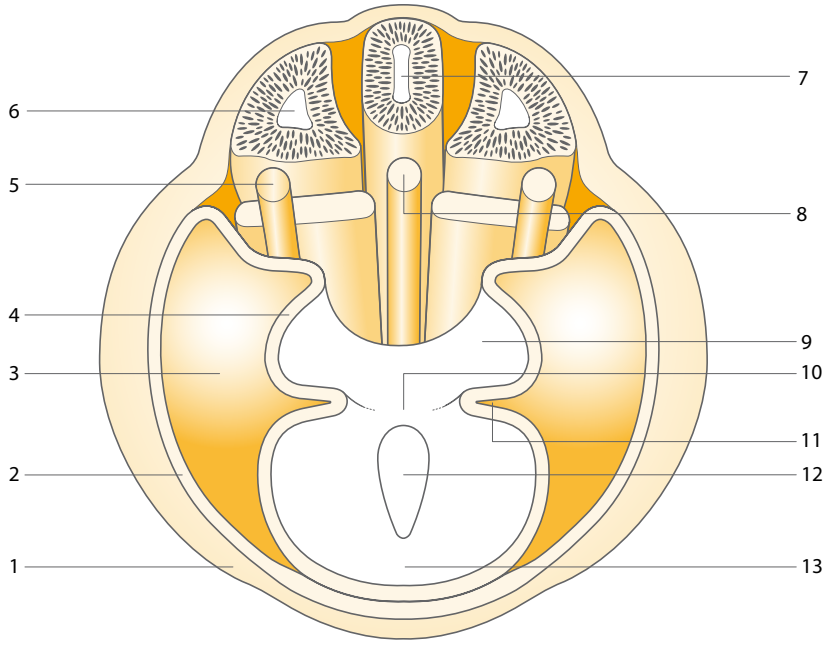

FIGURE 49.4 Disposition of mesoderm at the caudal end of a somite embryo as viewed working down from inside the caudal end of the embryo: (1) surface epithelium; (2) somatic layer of the lateral plate mesoderm; (3) coelomic cavity; (4) visceral layer of the lateral plate mesoderm; (5) nephrogenic cord; (6) somite; (7) neural tube; (8) notochord; (9) unsegmented paraxial mesoderm; (10) primitive streak; (11) site of developing urorectal septum; (12) site of cloacal membrane; (13) infraumbilical abdominal wall. (Reproduced from Glenister TW. *Br J Urol* 1958;30:117. With permission.)

epithelium, so that it, too, is eventually endodermal. The bladder epithelium at this time consists of a single layer.

The urorectal septum reaches the cloacal membrane and divides the cloaca into the urogenital sinus and the rectum; the cloacal membrane then ruptures (Figure 49.6). The caudal edge of the urorectal septum, which is covered with endoderm, is exposed as the perineal body. It merges with lateral folds flanking this fissure and becomes covered with ectoderm. It is eventually marked by a median raphe and becomes the perineum. Hillocks behind the anus encircle this area and form the anal canal, which eventually becomes lined with ectoderm.

In the eighth week, the bladder muscle begins to appear as a longitudinal layer on the dorsal surface of the bladder. By the ninth week, the bladder cavity begins to expand into a sac, the apex of which (the urachus) is elongated.

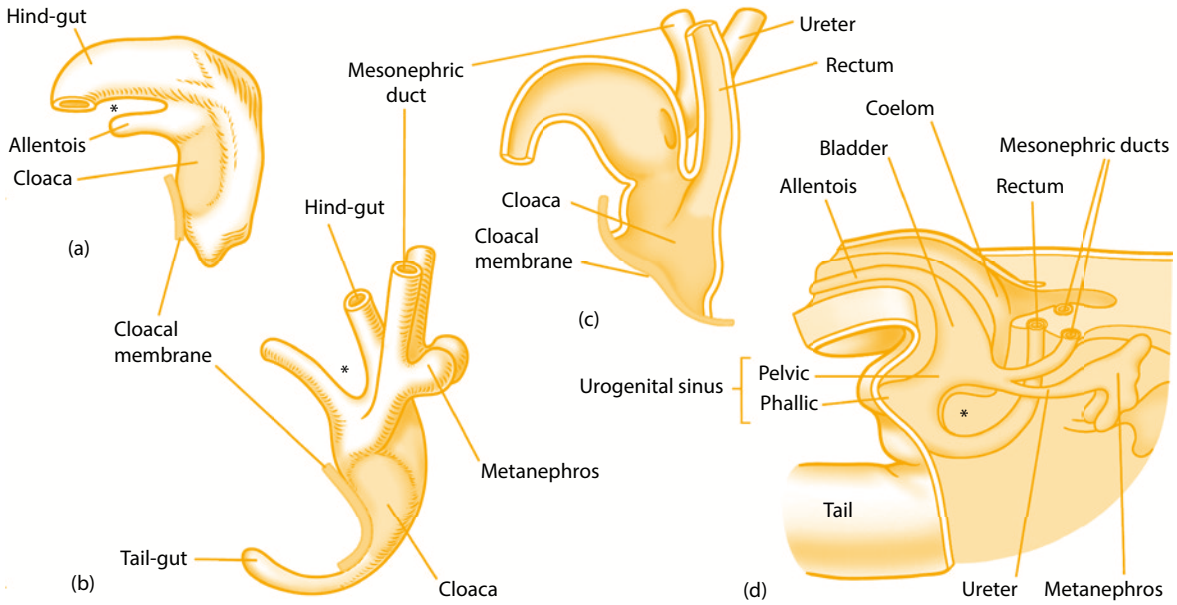

FIGURE 49.5 Division of the human cloaca: (a) 3.5 mm stage; (b) 4 mm stage; (c) 8 mm stage; (d) 1 mm stage. The asterisks in (a), (b) and (d) indicate the cloacal septum. (Reproduced from Arey LB. *Developmental Anatomy*, 6th edn. Philadelphia: WB Saunders, 1974. With permission.)

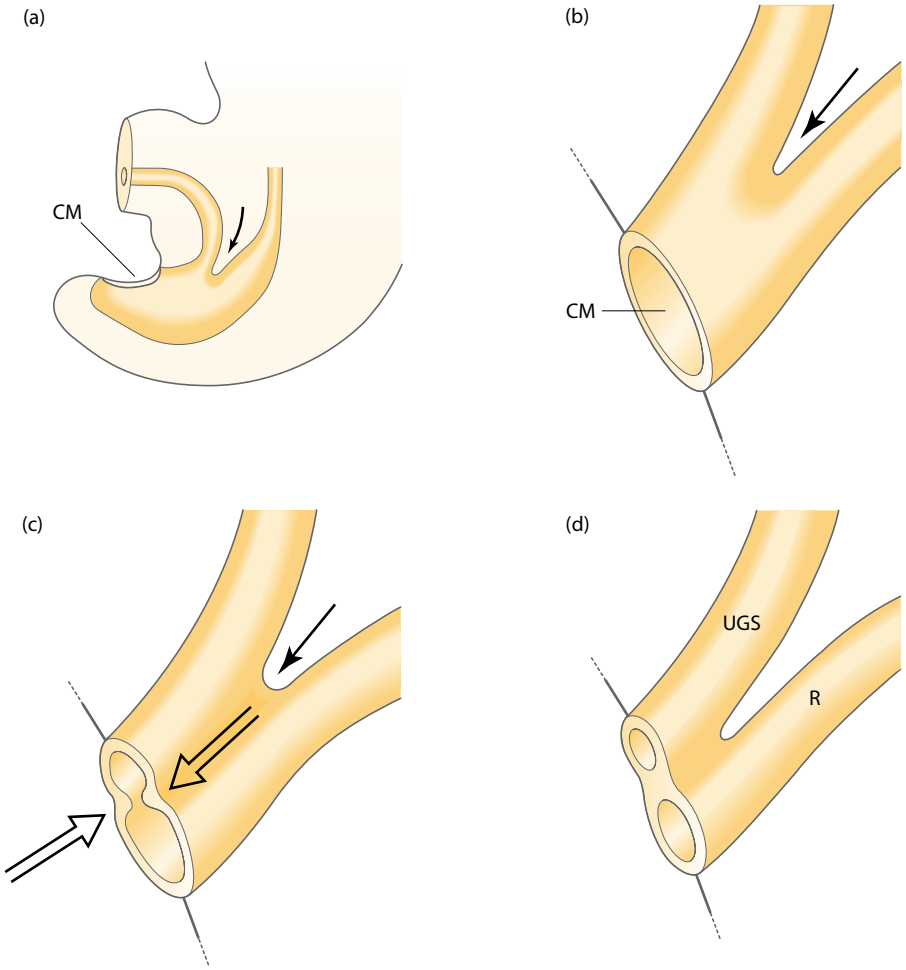

FIGURE 49.6 Septation of the cloaca. (a) Lateral view of caudal embryo (CM, cloacal membrane). Septation of the cloaca occurs in a coronal plane as Tourneux's fold (b) extends to the cloacal membrane from above, and (c) as Rathke's plicae extend towards each other from the sides. (d) Septation establishes the primitive urogenital sinus (UGS) and rectum (R). (Reproduced from Stephens FD, Smith ED. *Anorectal Malformations in Children*. Chicago: Year Book, 1971. With permission.)

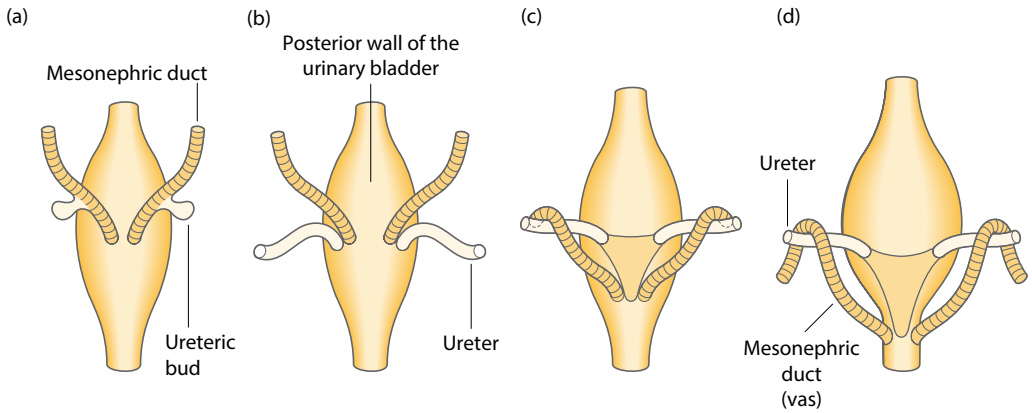

FIGURE 49.7 (a–d) Dorsal views of the bladder to show the relationship of the ureters and mesonephric ducts during development. Initially, the ureters are formed by an outgrowth of the mesonephric duct, but with time they assume a separate entrance into the urinary bladder. Note the trigone of the bladder formed by incorporation of the mesonephric ducts. (Reproduced from Sadler TW. *Longman's Medical Embryology*, 7th edn. Philadelphia: Williams & Wilkins, 1996. With permission.)

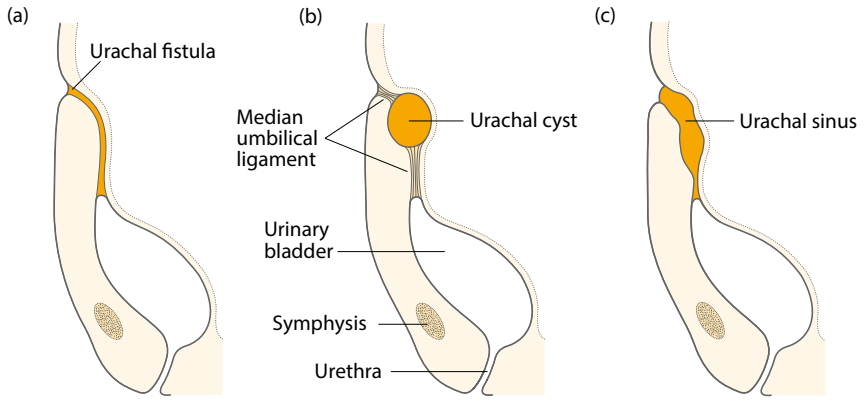

FIGURE 49.8 Diagrams of (a) urachal fistula, (b) urachal cyst, and (c) urachal sinus. The sinus may or may not be in open communication with the urinary bladder. (Reproduced from Sadler TW. *Longman's Medical Embryology*, 7th edn. Philadelphia: Williams & Wilkins, 1996. With permission.)

The urachus is continuous with the allantoic stalk at the umbilicus. The bladder and urachus elongate as the infraumbilical body wall forms from the somatic mesoderm.

In the 12th week, the bladder epithelium becomes transitional, and its muscular wall is formed from mesenchyme. The smooth muscle of the urinary tract is acquired in an ascending fashion from bladder to intrarenal collecting system.[12] The bladder epithelium over the ureteral orifice forms Chwalla's membrane, which temporarily covers and occludes the ureteral orifice. Chwalla's membrane perforates and the ureter becomes continuous with the bladder. By the 16th week, the bladder is completely muscularized and the urachus is closed.

Agenesis of the bladder is a rare anomaly that may arise because the allantoic stalk fails to develop.[13] However, if migration of the ureters and formation of the trigone are the events that induce enlargement of the allantoic stalk, then bilateral failure of ureteral migration with resultant ureteral ectopia would result in the same anomaly.

Urachal anomalies (patent urachus, urachal cyst, urachal sinus, and urachal diverticula) may be encountered clinically (Figure 49.8). Some result from a general mesodermal failure (the urachal diverticulum of the Eagle–Barrett syndrome);[3] however, most seem to result from delayed closure of the urachus. Lower urinary tract obstruction before 12 weeks of age (by virtue of bladder distension) could prevent closure.[14] There is, in addition, a definite association of patent urachus with upper tract problems, and therefore the entire urinary tract should be investigated.[15] Urachal cysts and sinuses presumably result from incomplete closure of the urachus.

Duplications of the bladder and urethra are usually associated with other hindgut and lower spinal cord duplications. Hence, it would appear that these result from a splitting of the hind end of the embryo at a very early stage of development, distinct from the lower abdominal wall defect resulting in exstrophy.

Ureteral ectopia, vesicoureteral reflux (VUR), and paraureteral diverticula appear to arise because the ureteral bud appears at a locus on the mesonephric duct more craniad or caudad than normal. As the ureter is incorporated into the urogenital sinus, its final site would be more craniad and lateral or caudad, respectively. The former results in VUR and diverticula, whereas the latter results in ureteral ectopia.[16]

Ectopic ureteroceles probably result from abnormalities of the ureteral bud, in addition to ectopia, and are often associated with renal dysplasia.[16] Intravesical (simple) ureteroceles are thought to be due to the persistence of Chwalla's membrane beyond the time when urine flow begins.[17]

Posterior urethral valves (type 1) may result from persistence of the path of migration of the mesonephric ducts distal to Müller's tubercle, so that they cross the urogenital sinus and enter anteriorly. Persistence of this portion coupled with anterior fusion might then produce the diaphragm known as valves.[18] Another type of valves (type 3) seems to result from persistence of the cloacal membrane at the junction of the end of the phallic portion of the urogenital sinus and the bulbomembranous urethra.[19]

CHAPTER
50

Radiologic Assessment of Bladder Disorders

Douglas E. Coplen

INTRODUCTION

Congenital anomalies and abnormalities of the urinary bladder can be a significant cause of morbidity in infants and children. The function of the bladder may adversely affect the upper urinary tract and may impact urinary continence. Radiologic evaluation of the bladder and adjacent structures gives useful diagnostic information that directs therapeutic intervention. In children, ultrasonography is usually the initial diagnostic study. Fluoroscopic imaging (voiding cystourethrogram [VCUG]) is frequently obtained as indicated by the clinical history and ultrasound findings. Cross-sectional imaging (computerized tomography [CT] and magnetic resonance imaging [MRI]) is often used in complex cases where other imaging does not clearly define the anatomy.

Ultrasound is ideally suited for the evaluation of children with symptoms suggestive of a bladder or lower urinary tract abnormality because it is painless, is associated with no radiation exposure, and provides excellent anatomic definition of the bladder. For this study, a partially distended bladder is preferable. The clear differentiation between the anechoic urine and the bladder wall and surrounding structures enhances its diagnostic utility (Figure 50.1).

If upper urinary tract dilation is identified during an examination, the ultrasound should also include imaging after bladder emptying since the degree of bladder distension may affect the upper tract findings. Doppler ultrasound can be used to identify ureteral jets (urine flow into the bladder) (Figure 50.2) that are evidence of antegrade flow into the bladder.[1] Postvoid views can be obtained to assess bladder emptying and bladder wall thickening. Bladder volume can be estimated by ultrasound using the empirical equation Bladder volume = 0.7 × Width × Length × Depth.[2]

The VCUG is the best method of fluoroscopic bladder imaging. The study consists of direct opacification of the bladder with iodinated contrast medium that is usually instilled through a urethral catheter. Preferably both filling and voiding views are obtained during the study. Dynamic visualization of the bladder may give very useful information regarding bladder function and disordered elimination. Voiding views are especially important in the male since abnormalities of the bladder outlet and urethra greatly impact the bladder.

If IV contrast is utilized for upper tract imaging, the excreted contrast gives passively filled bladder images. While this avoids urethral catheterization, the contrast is dilute and opacification of the bladder and urethra is often poor and may result in a nondiagnostic study.

CT and MRI give improved spatial resolution when compared with more commonly utilized imaging modalities. Images are obtained in an axial mode, but can be reformatted in both the sagittal and coronal planes. With current software, both planar reconstructions and three-dimensional reconstructions give excellent resolution.[3]

Superior soft tissue resolution is an advantage of MRI over CT. On T1-weighted images, the bladder wall may be indistinguishable from the urine, but on T2-weighted studies, fluid-filled structures like the bladder are very well defined (Figure 50.3).[4] Because of prolonged acquisition times, sedation is required in younger children. MRI is very expensive when compared with ultrasound and fluoroscopy and should probably be reserved for complex cases where anatomy is not well defined using other modalities.

BLADDER ENLARGEMENT

An enlarged bladder may be identified on physical examination. While bladder distension may be a normal finding prior to voiding, it may be indicative of significant bladder or urethral pathology. Congenital anomalies, such as spinal dysraphism and prune belly syndrome, should be evident on exam and help with the differential diagnosis. A thickened bladder wall on ultrasound is suggestive of bladder outlet obstruction, although when the bladder is markedly distended, wall thickening may not be readily apparent (Figure 50.4).[5] Ureteral dilation in the presence of bladder distension and a thin bladder wall are suspicious for high-grade vesicoureteral reflux (Figure 50.1).

A VCUG gives both the anatomic detail and functional information that define the etiology of bladder distension. Views of the urethra are essential in the evaluation of these children. Bladder trabeculation and cellules are commonly identified in children with posterior urethral valves or neurogenic bladder. Children with prune belly syndrome or megacystis or microcolon usually have large smooth-walled bladders (Figure 50.5).

URACHAL ABNORMALITIES

The urachus, sometimes called the median umbilical ligament, is usually obliterated by the 12th week of gestation.

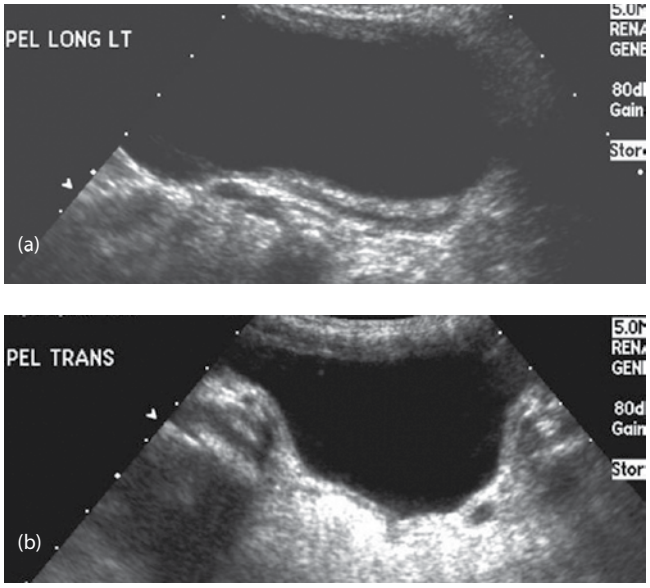

FIGURE 50.1 Bladder ultrasound obtained in a male with isolated bladder distension identified during pregnancy. Note the clear definition of the lumen and bladder wall on ultrasound. A dilated left ureter is seen posterior to the bladder. The child had bilateral grade V reflux but no infravesical obstruction.

In theory, a patent urachus may occur in the presence of bladder outlet obstruction, but no evidence of obstruction is identified in the majority of cases.[6] Occasionally, a patent urachus is identified at birth when there is free discharge of urine through the umbilicus (Figure 50.6). More commonly, only a tiny fistula is present and the umbilicus is enlarged or edematous. In these situations, the differential diagnosis includes omphalitis, "normal" hypertrophic granulation tissue, and a patent omphalomesenteric duct. Ultrasound may identify an inflamed tract (Figure 50.7). A fistulogram with radiopaque contrast is often diagnostic. Voiding cystourethrography is helpful in fully evaluating the lesion and any associated bladder outlet obstruction (Figure 50.6).

Partial obliteration of the urachus results in a urachal cyst. These are usually asymptomatic but occasionally become infected and are identified during the evaluation of lower abdominal pain, fever, and voiding symptoms.

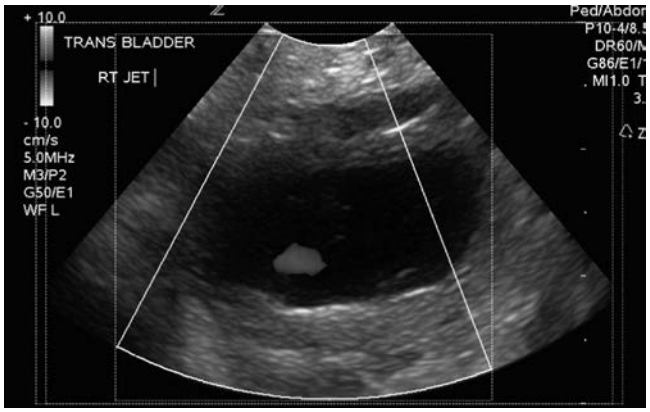

FIGURE 50.2 Bladder ultrasound utilizing Doppler to demonstrate urine flow from the right ureter into the bladder.

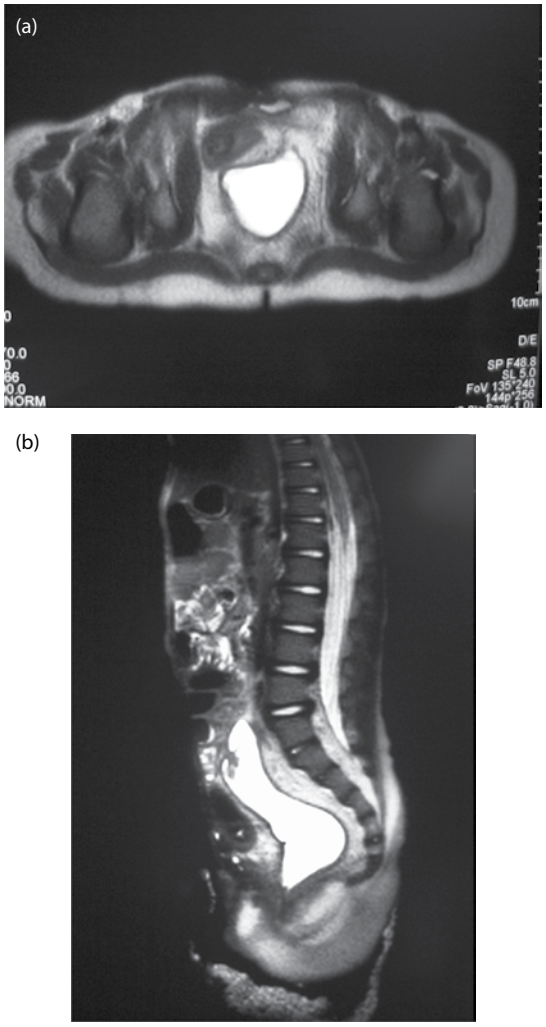

FIGURE 50.3 MRI obtained on a 6-year-old male with apparent history of bladder exstrophy based on physical examination. He is incontinent of both urine and stool per "rectum," but these do not appear to be mixed. The study clearly defines the lower tract anatomy. The ureters are reimplanted into a sigmoid segment (filling defect in bright structure (b)). The rectum is visualized anterior to the sigmoid "bladder" that has been pulled through posterior to the rectum (a).

FIGURE 50.4 Postvoid ultrasound in a boy with posterior urethral valves. There is a small postvoid residual, and marked bladder wall thickening is clearly apparent.

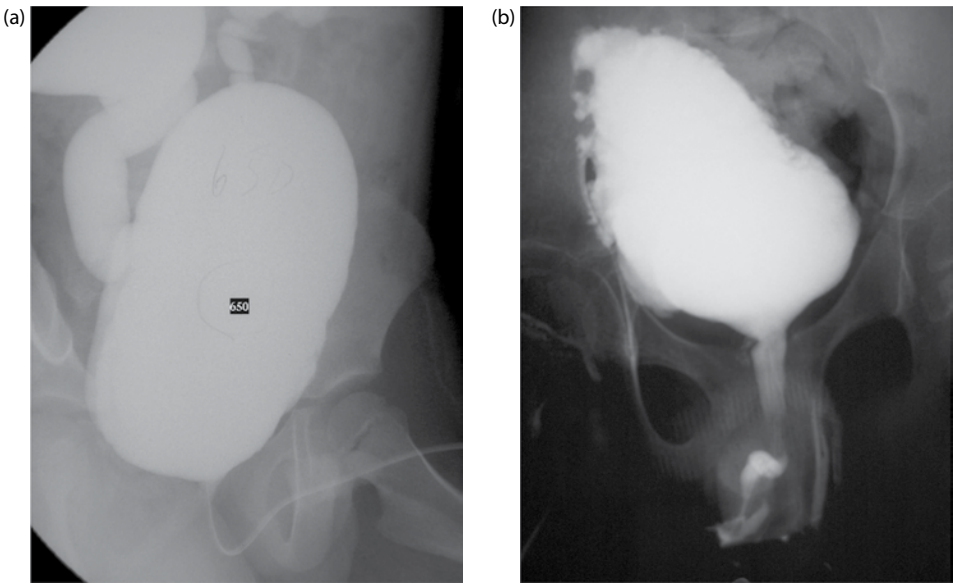

FIGURE 50.5 VCUG in two boys with bladder enlargement: (a) Bilateral high-grade reflux with a smooth bladder wall and no outlet obstruction. (b) Marked bladder trabeculation and "Christmas tree" deformity in a boy with spinal dysraphism.

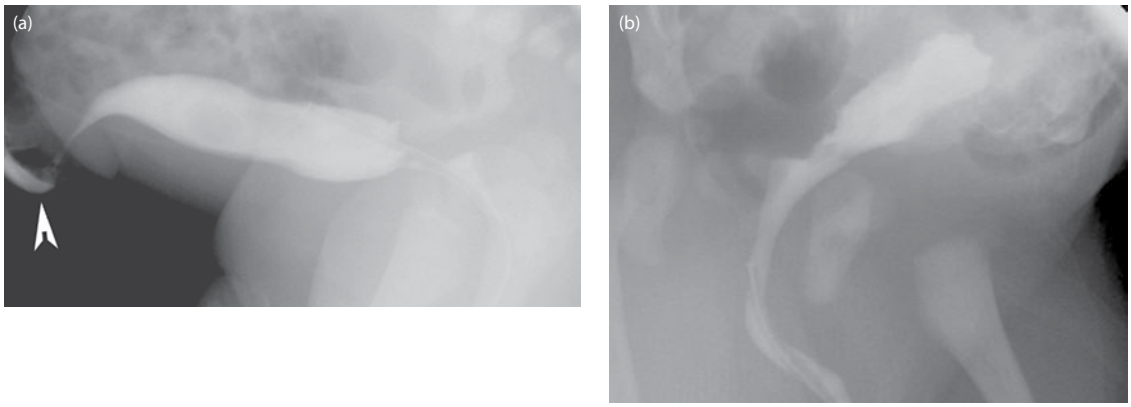

FIGURE 50.6 Newborn male with copious clear fluid drainage from the umbilicus. (a) Transurethral instillation of contrast shows free drainage out of a patent urachus onto the lower abdominal wall (arrow). (b) Voiding views show a normal urethra with no evidence of bladder outlet obstruction.

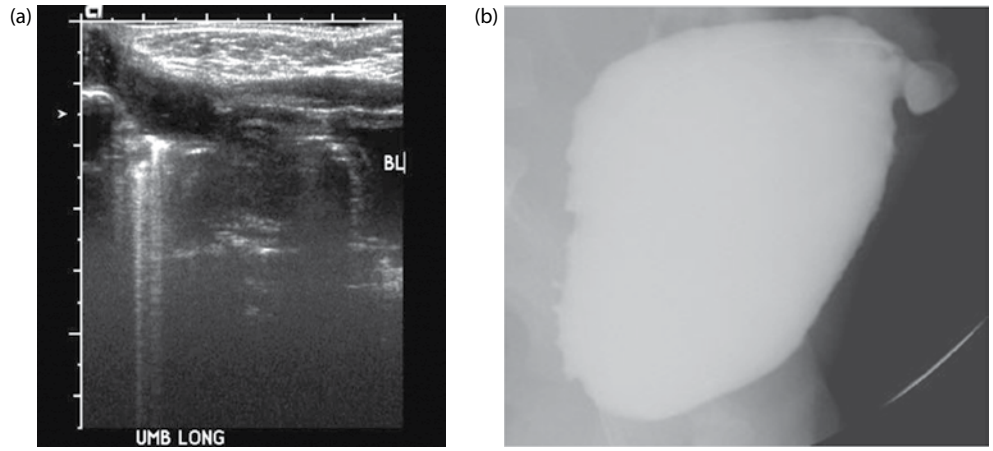

FIGURE 50.7 Imaging in a 1-month-old male with a moist umbilicus. (a) The ultrasound shows a well-defined tract from the umbilicus down to the dome of the bladder (BL). The tract expanded during a bladder contraction (real-time imaging), documenting a communication with the bladder. (b) Catheterization through the tract with a 3.5 Fr feeding tube and instillation of contrast confirm communication with the bladder.

FIGURE 50.8 This is a 14-year-old male with lower abdominal pain, pyuria, and an infected urachus. CT shows an inhomogeneous mass (a) cephalad to the bladder (bl). Anterior bladder wall inflammation and thickening can be seen.

The diagnosis can be made by ultrasound. CT may be useful in defining the extent of the cyst and evaluation of adjacent structures (Figure 50.8).

A urachal diverticulum is often an incidental finding on a VCUG that does not require treatment. A large diverticulum is commonly identified in prune belly syndrome and rarely may require excision if it is a source of significant urinary stasis (Figure 50.9).

BLADDER DIVERTICULUM

A bladder diverticulum is the result of a weakening in the muscular layer of the bladder wall. This may be congenital, but it can be acquired in the presence of bladder outlet obstruction or dysfunctional voiding. In children, the diverticulum is most commonly periureteral. Diverticula are most commonly identified during the evaluation of urinary tract infections, and they may theoretically be a significant source of urinary stasis. The fluid-filled extravesical structure identified on ultrasound is definitively differentiated from a dilated ureter on a VCUG (Figure 50.10). The oblique bladder views localize the location of the diverticulum and whether it is broad based.

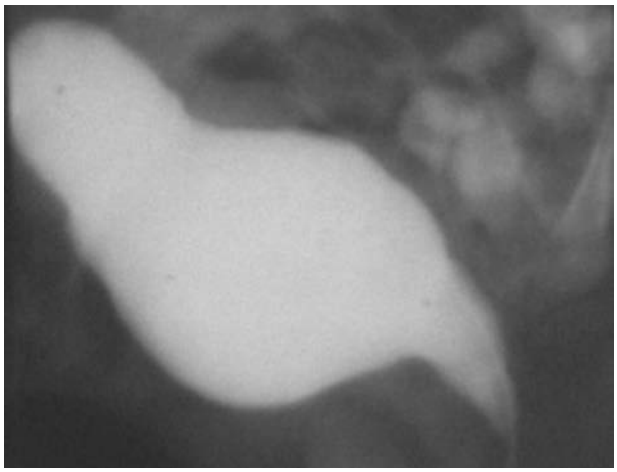

FIGURE 50.9 VCUG in a boy with prune belly syndrome. A wide-mouthed urachal diverticulum is evident. The open bladder neck and tapering distal to the prostatic urethra are typical of prune belly syndrome.

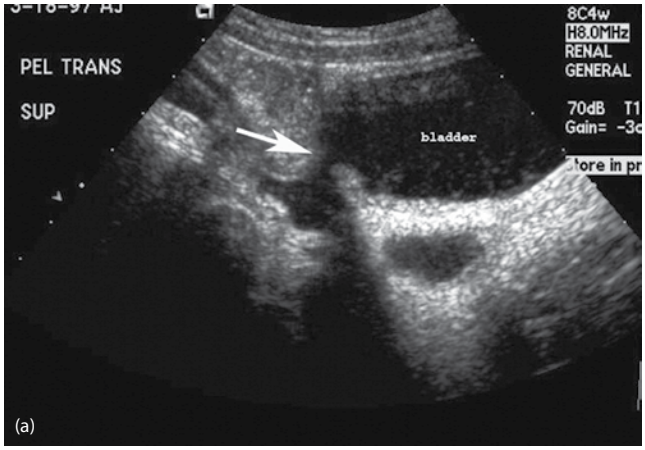
BLADDER MASSES

Bladder masses are distinctly unusual in children. Presenting symptoms are usually related to outflow obstruction (strangury). Occasionally, gross hematuria is identified by the parents, but most children with gross hematuria have no identifiable anatomic abnormality and have a nephrologic source of bleeding. Ultrasound is the initial test of choice in children because it is noninvasive and will usually identify an intravesical or infravesical abnormality. If



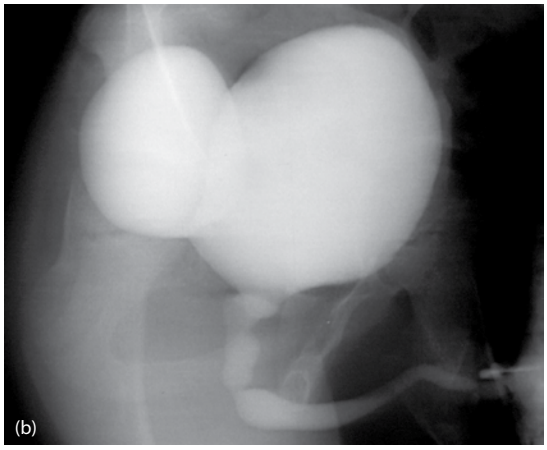


FIGURE 50.10 This bladder diverticulum was identified in a 7-year-old male with recurrent staphylococcal cystitis. On ultrasound (a), it is evident that the tubular structure does not extend cephalad and is not a ureter. The arrow delineates the connection between the bladder and diverticulum. On a VCUG (b), the lateral view confirms an origin low on the bladder base consistent with a congenital periureteral diverticulum.

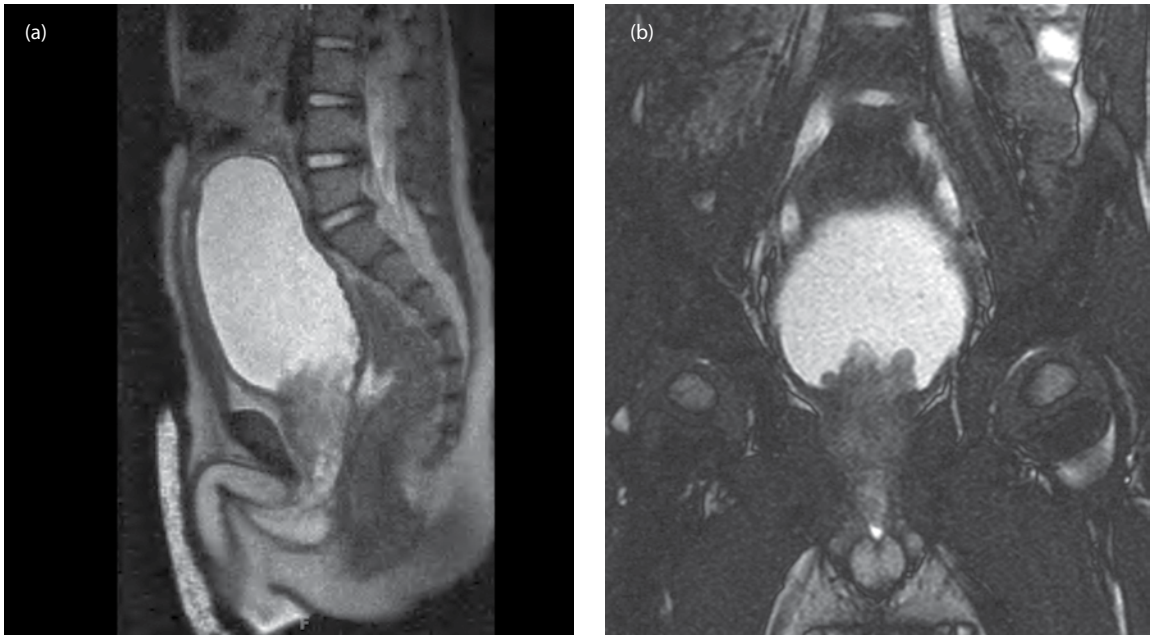

FIGURE 50.11 Rhabdomyosarcoma detected during evaluation of strangury. Ultrasound showed a bladder mass. Sagittal (a) and coronal (b) imaging shows a prostatic-based tumor. There is no definite evidence of extraprostatic extension.

an abnormality is identified, then cross-sectional imaging is usually obtained, although in some clinical situations, an endoscopic evaluation is the next best step.

Rhabdomyosarcoma is the most common bladder malignancy in children. Most present with obstruction and a palpably distended bladder and/or lower abdominal mass. An ultrasound usually reveals a mass at the base of the bladder. MRI offers the best detail in relation to other pelvic organs and is the preferred study for radiologic staging (local and metastatic) (Figure 50.11).

Transitional cell carcinomas of the bladder and fibroepithelial polyps are very rare in children. They are usually well visualized on ultrasound because they usually have a narrow stalk and project into the lumen of the bladder (Figure 50.12).

BLADDER CALCULI

Historically, bladder calculi were related to dietary intake. However, stones are now identified in up to 50% of children after bladder augmentation.[7] They are often identified during routine follow-up imaging but are sometimes associated with hematuria, bladder pain, or urinary infections. On sonography, stones are echogenic foci with associated shadowing (Figure 50.13). Stones

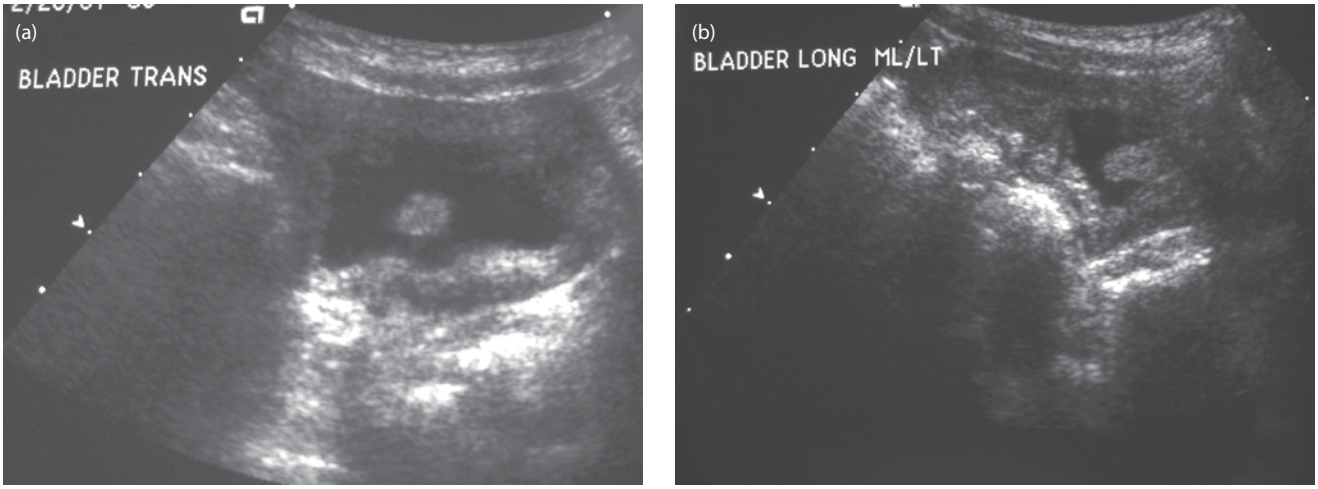

FIGURE 50.12 A fibroepithelial polyp identified in a 2-year-old male with intermittent urinary retention. Transverse views (a) show a "free-floating" mass that extends across the bladder neck on longitudinal views (b) of the bladder. The bladder wall is thickened, consistent with intermittent obstruction.

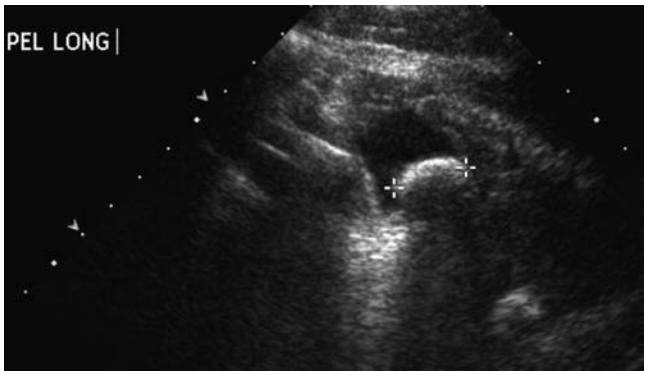

FIGURE 50.13 Bladder calculus in an augmented bladder. A curvilinear shadowing defect is evident on the bladder base.

are usually mobile on the dependent portion of the bladder. Moving the patient into a lateral decubitus position will confirm movement. Images are better if the bladder is partly distended since stones may be in some mucosal folds and confused with echogenic stool that is often present in the true pelvis of these children. A kidney, ureter, and bladder (KUB) helps define the number of calculi.

While ultrasound is not the best imaging study for upper tract stones, it can be useful in the evaluation of distal ureteral calculi that are not readily apparent on plain films. A dilated distal ureter is easily visualized behind the bladder, and a shadowing and echogenic focus at the ureterovesical junction confirm the presence of a stone. If the ureter is not dilated or the stone is proximal to the bladder, ultrasound is usually not useful.

BLADDER RUPTURE

Bladder perforation may occur with blunt abdominal trauma and/or pelvic fractures. Children with a history of bladder augmentation may have spontaneous perforation in the absence of any identifiable trauma. A high index of suspicion is required in the evaluation of children with a history of bladder augmentation and abdominal pain. A VCUG is diagnostic in most cases, but a thorough technique, including postdrainage films, is required to identify smaller perforations. The irregularities normally present in the augmented bladder increase the chance of a false-negative study, and CT scan improves the diagnostic accuracy. Passive bladder distension is inadequate. Retrograde distension with diluted (4%–5%) contrast is necessary to appropriately evaluate for perforation using CT cystography (Figure 50.14).[8] A CT cystogram should be obtained when a perforation is suspected and a VCUG is normal.

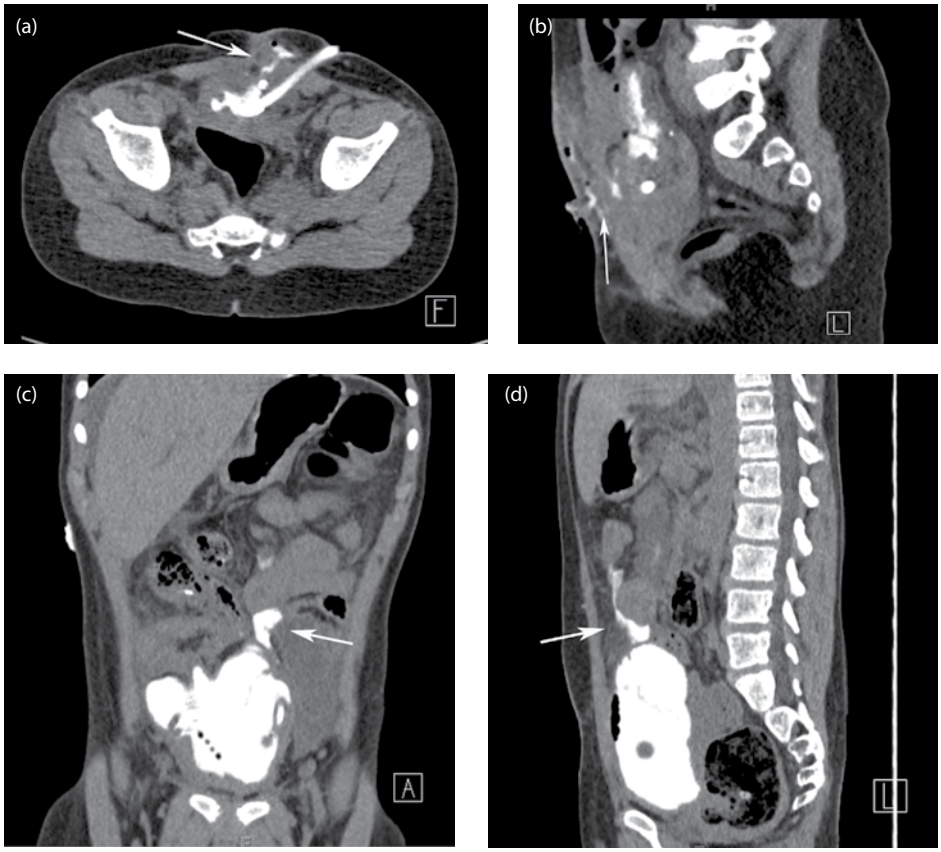

FIGURE 50.14 An extraperitoneal bladder perforation is demonstrated 1 week after augmentation cystoplasty in a patient with bladder exstrophy (a and b). A spontaneous intraperitoneal bladder perforation after augmentation cystoplasty is demonstrated by contrast that outlines the intestines (c and d).

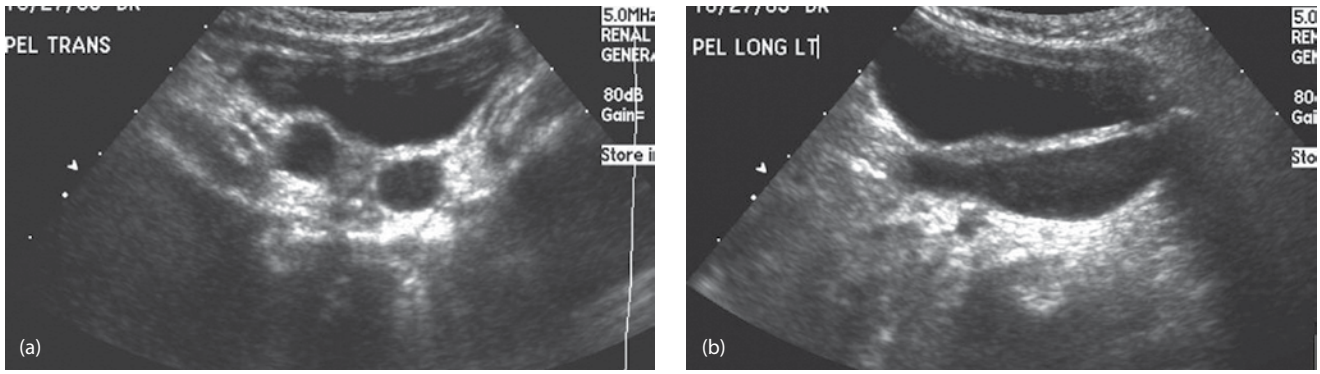

FIGURE 50.15 Bladder ultrasound in a female with recurrent febrile urinary tract infections. Transverse views (a) reveals dilation of distal ureters bilaterally. A longitudinal view (b) shows the dilated ureter coursing distal to the bladder neck. The child had bilateral duplications with upper-pole ectopia.

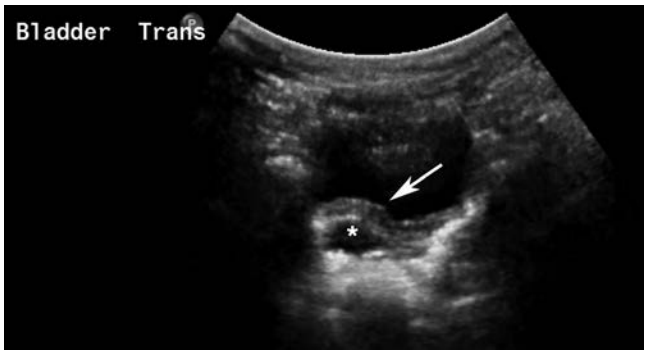

FIGURE 50.16 Pseudoureterocele. A dilated ureter (asterisk) deforms the bladder base. The ureteral wall is very thin compared with the bladder wall (arrow).

URETERAL ABNORMALITIES

Anomalies of the distal ureter are frequently identified during bladder imaging. The normal ureter should not be visualized on ultrasound imaging. When a dilated ureter is identified, it may be indicative of urethral, bladder, or ureterovesical junction pathology.

Megaureter is a generic term applied to an enlarged ureter. Ultrasound easily identifies the presence of these dilated ureters (Figure 50.15). A megaureter can be obstructed or nonobstructed, and refluxing or nonrefluxing. While ultrasound identifies the dilation, a VCUG and renal scintigraphy are required to classify the megaureter.

Ectopic insertion of the ureter occurs most commonly in the setting of renal duplication. The duplication is usually easily identified on ultrasound evaluation of the upper tract because the lower pole of the kidney is not associated with a dilated ureter. Longitudinal ultrasonic bladder views frequently demonstrate a ureteral insertion distal to the bladder neck. Occasionally, the dilated ureter deforms the posterior bladder wall and can be confused with a ureterocele. This pseudoureterocele can be differentiated by noting that the anterior aspect is the same thickness as the rest of the bladder wall, as opposed to the thin, typically imperceptible ureteral wall (Figure 50.16).[9]

Ureteroceles are cystic dilations of the intravesical segment of the ureter. Ureteroceles have a unique appearance

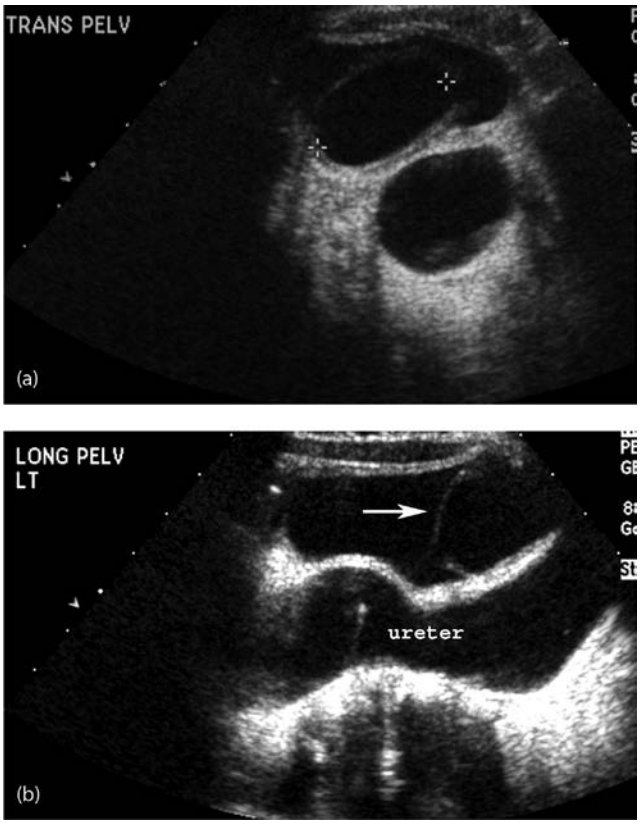

FIGURE 50.17 Bladder ultrasound images in an infant show a thin-walled cystic mass in the bladder, as demonstrated by the calipers. On this random view (a) after a recent void, the ureterocele takes up most of the bladder. A longitudinal views (b) show the dilated ureter associated with the ureterocele (arrow).

on ultrasound. They are thin-walled cystic masses at the bladder base (Figure 50.17). These are usually simple, but are occasionally bilobed or lobulated. In the presence of infection, they may contain echogenic debris. Occasionally, a large ureterocele is not identified if the child has just voided because the apparent bladder urine is actually within the ureterocele, with no urine outside the ureterocele in the bladder. Ureteroceles are usually associated with a dilated ureter posterior to the bladder wall. Intravenous urography and cystography usually reveal a

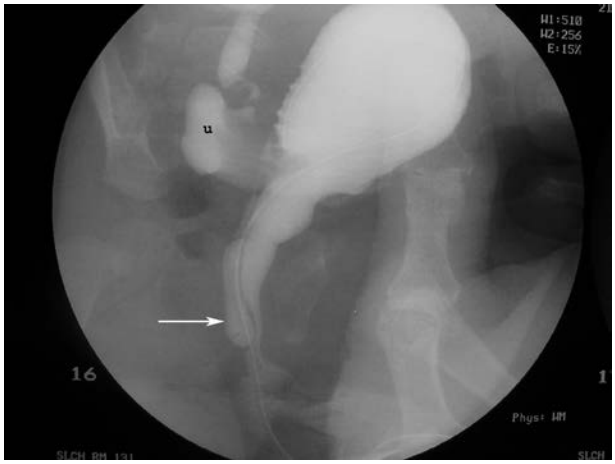

FIGURE 50.18 Cystogram in a female with a ureterocele. A tongue-lie extension is demonstrated on the voiding views (arrow). The ureterocele (u) everts during voiding because of the muscular deficiency in the right hemitrigone.

nonopacified filling defect in the bladder. There may be a significant detrusor defect, and the ureterocele often everts during bladder filling on a VCUG, resembling a diverticulum (Figure 50.18).[10]

CHAPTER
51

Urodynamics of the Lower Urinary Tract

William E. Kaplan and Edward Gong

INTRODUCTION

The pediatric urologist manages myriad diseases that lead to urinary tract dysfunction. While noninvasive testing is preferred for assessment of urinary tract function, invasive urodynamic studies can provide useful information and should be judiciously utilized. Patients with neurogenic bladder, particularly those who may require surgery for bladder problems, most often require invasive urodynamic testing for appropriate decision-making.

Most children referred for urodynamic studies already have a specific pathologic diagnosis (spinal dysraphism, spinal cord injury, cerebral pathology, etc.) but require a more definitive neurologic classification for appropriate therapy. Many patients with voiding dysfunction require urodynamics to determine whether their urinary problems are neurologic or functional in origin. In addition, patients are referred for urodynamics when other diagnostic studies, such as radiography, are equivocal.

The expansion of pediatric urodynamics in the late 1970s and early 1980s came about because of the need to understand the volume–pressure relationships of the urinary tract. The introduction of clean intermittent catheterization in the 1970s[1] opened the creative gates for the management of children with dysfunctional storing and emptying of their urinary tracts. However, correct characterization of the pathology by urodynamics was critical.

Adult diagnostic techniques needed modification for children, and what began with work on flow rates by Gierup et al.[2] progressed to sophisticated flow and electromyographic studies by Blaivas et al.,[3] and to the introduction of surface monitoring of the pelvic floor by Maizels and Firlit.[4] An additional valuable contribution of correct filling rates by Joseph in 1992,[5] and sedation techniques, emphasized the importance of a more focused approach for children.

This chapter focuses on pediatric urodynamic studies that best categorize neurologic and nonneurologic bladder pathology and help to define the best treatment modalities.

INDICATIONS FOR URODYNAMIC STUDY

Evaluation and characterization of bladder dysfunction in neurogenic bladder disease (NBD) is the most accepted indication for urodynamic evaluation in children. Early and repeat evaluation of children with NBD has helped identify children at high risk for urinary tract deterioration.[6] Medical and surgical management of patients with NBD has been guided by urodynamic evaluation in addition to clinical symptoms and radiographic imaging. Initial urodynamic studies performed on a neonate have proven beneficial in preventing bladder deterioration. Repeat urodynamic evaluation should occur with clinical changes, such as new-onset hydronephrosis, increase in incontinence, recurrent urinary tract infections (UTIs), voiding changes, or increase in postvoid residual.

While NBD is the most accepted usage for urodynamic study, children suffering from nonneurogenic bladder disease (NNBD) can also potentially benefit from urodynamic studies. Patients with failed initial treatment for NNBD have been shown to have a high frequency of pathological findings on urodynamic studies, which has led to alteration of the treatment strategy based on urodynamic findings.[7]

Finally, children with anatomic bladder dysfunction, such as posterior urethral valves (PUVs), anorectal malformations, or bladder and cloacal exstrophy, may potentially benefit from urodynamic evaluation. Patients with PUVs may benefit from early urodynamic studies. Casey et al. demonstrated that PUV patients with early initial urodynamic studies that demonstrated high voiding pressures or small capacity benefited from early initiation of anticholinergic medications.[8] Furthermore, proper long-term urodynamic assessment may assist in medical and surgical management of children with evolving bladder disease with PUVs.[9]

MEDICAL HISTORY

Urodynamic studies should be an adjunct to good clinical practice. A thorough history and physical examination must precede any diagnostic study, a consideration placed on the clinical response that the study will drive (Table 51.1). In patients in whom the diagnosis is clear, e.g., spinal cord injury or myelomeningocele, eliciting a diagnosis is not usually the challenge. However, determining the best management to maintain continence and prevent renal deterioration can be exceedingly elusive. Furthermore, patients with urinary tract dysfunction with no obvious neurologic abnormality will challenge the diagnostic skill of even the most experienced pediatric urologist.

TABLE 51.1 Evaluation of children who wet

History	Prenatal, congenital history Voiding characteristics Bladder and bowel function
Physical examination	Abdomen and perineum Spine Lower extremities: Reflexes Gait Physical structure
Laboratory	Urinalysis/culture Chemistry: urine/serum
Radiography	Ultrasonography: renal/bladder Voiding cystography Flat plate abdomen/spine (AP and lateral)
Urodynamics	Flow/bladder capacity Cystometry Pelvic muscle evaluation: pads/needle Compliance: LPP/VLPP and PSBV

Abbreviations: AP, anteroposterior; LPP, leak point pressure; VLPP, Valsalva leak point pressure; PSBV, pressure-specific bladder volume.

An accurate voiding history is most important. The patient's age and expectations of urinary control may dictate the concerns about voiding habits. However, even in infants, the pattern of wet and dry diapers may be important to discovering the diagnosis. Newborns with constant dribbling or signs of overflow incontinence may have undergone a traumatic delivery, e.g., hyperextension injury to the cervical spinal cord.

Infants of diabetic mothers have an increased risk of neural tube defects. Infants of mothers with substance abuse are at increased risk for hydronephrosis. These are only a few examples that illustrate the importance of a thorough prenatal and obstetric history before scheduling and tailoring the type of urodynamics study.[10–12] Historic information, such as prematurity or global delay in physical or mental capabilities, is important. Although this information may not aid in therapy, it may help to explain to parents how delays in gaining urinary control occur. Infants with irregular bowel habits (diarrhea or constipation), in association with urinary symptomatology, should prompt careful evaluation.

As the child matures, incontinence or UTIs may become the primary symptoms. A thorough voiding history should be elicited from the child and his or her parents. It is important to engage the child, as often parents are not aware of a school-aged child's voiding and bowel elimination history when they are not at home. Frequency of wetting, voiding characteristics, presence of urgency, quality of the flow rate, and whether a child is wet are important historic features. The boy with a poor flow rate would be suspicious for having anatomic bladder outlet obstruction, whereas the girl with paradoxical incontinence (continuously damp while voiding normally) might have an ectopic ureter. In the older child, the history must include details on bowel habits, because it is clear that constipation has a direct relationship to urinary control, as well as urinary infections.[13,14]

A clear history of symptoms associated with UTI is necessary to adequately determine the need for urodynamic or other testing. The clinician should determine if the UTIs were symptomatic or associated with fevers. The collection method (voided or catheterized) for previous cultures should be ascertained. Previous culture results should be viewed and attention paid to the type of organism, resistance patterns, and colony counts.

It is exceedingly important to take a thorough bowel elimination history. Multiple studies have shown the correlation between constipation or "stool retention" and urinary symptoms. Bowel symptoms have been found in up to half of patients with voiding dysfunction.[15] Management of bowel symptoms is necessary in the treatment of children with voiding dysfunction. Rectal distention has been shown to negatively affect bladder capacity, sensation, and overactivity[16] and can potentially cloud urodynamic results. A medication list should be reviewed, as many medications can have effects on bladder contractility, as well as bowel movements.

The use of a voiding diary or 12 h home pad test may also be helpful.[17,18] However, in practice, the clinician may easily misinterpret the results if less than fastidious notes are kept, or if the pads are not changed promptly. Another potential tool to assist in the clinical evaluation of patients with voiding dysfunction is validated measures that allow for longitudinal follow-up of lower urinary tract symptoms. Several validated tools have been developed with good correlation with clinical impression of severity of disease;[19] however, significant work remains on the utility of these instruments regarding long-term management outcomes and correlation with the necessity of urodynamic testing.

PHYSICAL EXAMINATION

Before planning a urodynamic study, a thorough physical examination is essential. Children may exhibit evidence of delayed gross motor development or abnormal fine motor skills consistent with global abnormalities from in utero or birthing issues. In these children, a complete neurologic examination by a pediatric neurologist, including muscle tests and nerve conduction velocity, may be indicated.

A routine systematic approach, including having the child completely undressed from head to toe (although covered with a warm blanket and with a nurse and parent in attendance), will help to reveal general congenital defects that might contribute to syndromes that involve the urinary tract. Following the general assessment, most of the pertinent pathology is found below the umbilicus. The abdomen should be palpated for stool, although significant fecal retention can exist with a soft abdomen and an empty rectal vault.

The back, perineum, and lower extremities should be examined critically. During examination of the back, all midline abnormalities should be cause for concern. However, there is less importance if a simple dimple can be grasped with the tip of the coccyx. Obvious or subtle midline skin tags, tufts of hair, or vascular malformations may indicate underlying spinal malformations, e.g., lipomas, and spinal magnetic resonance imaging (MRI) is then indicated, though spinal ultrasound is preferred in infants prior to ossification of the vertebral bodies. A short or abnormal gluteal cleft may indicate an underlying

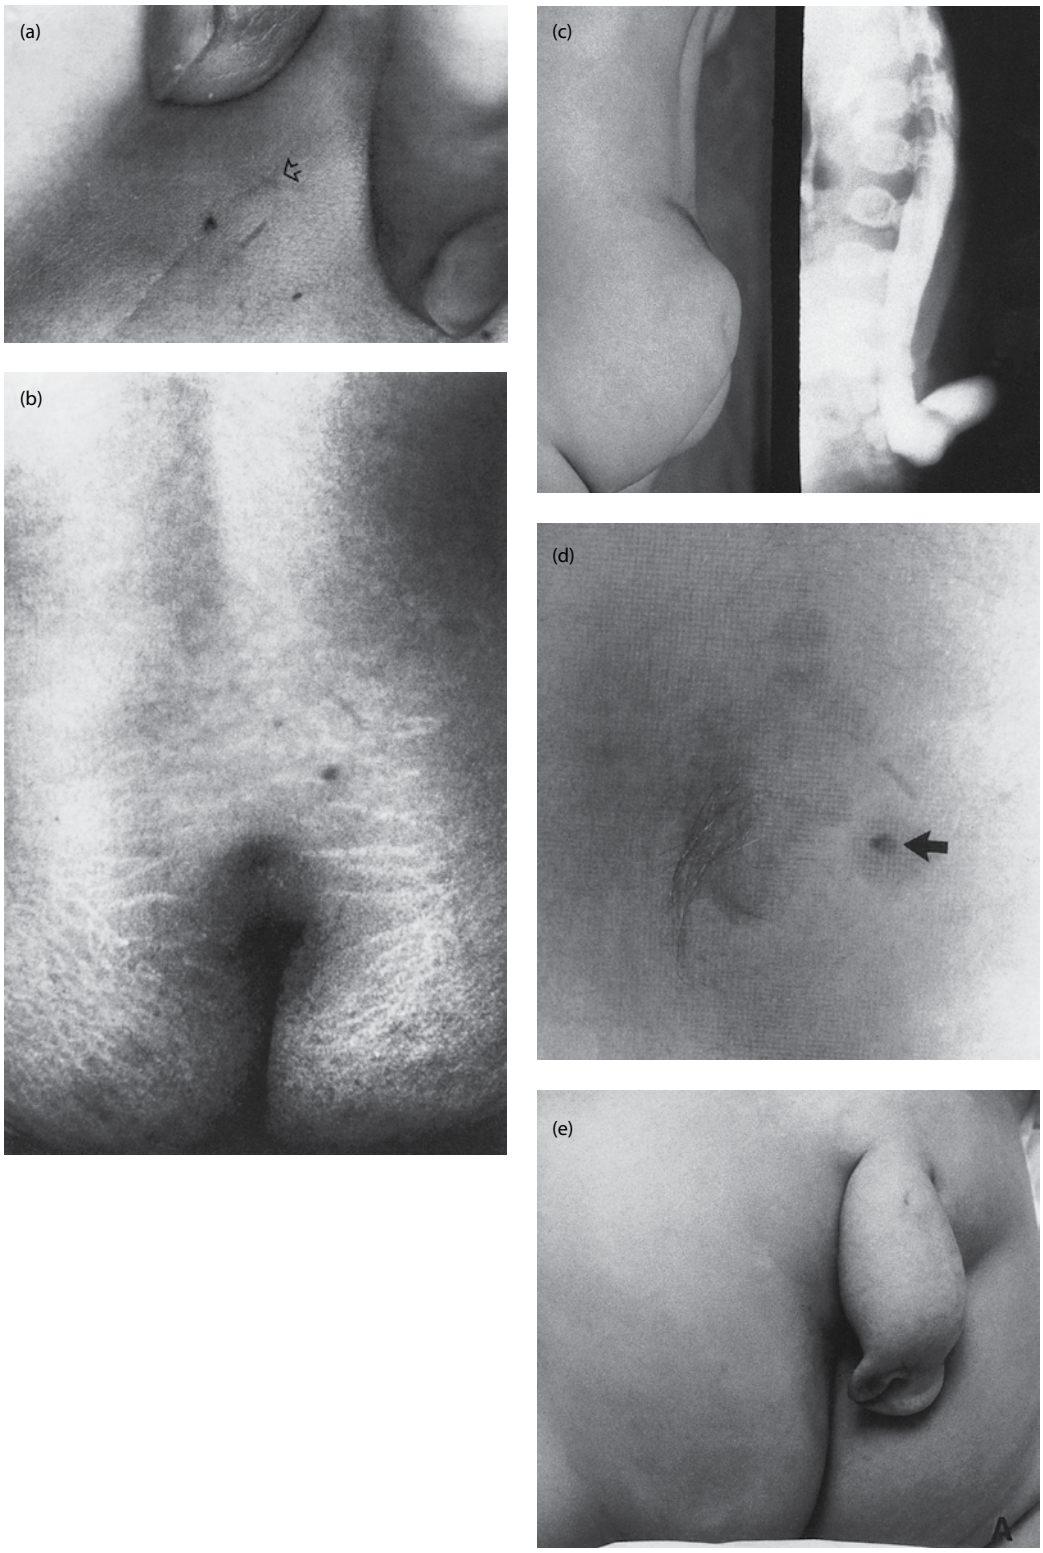

FIGURE 51.1 Cutaneous lesions discovered on midline spinal examination: (a) dermal sinus tract (open arrow) in infant who developed meningitis shortly after birth; (b) a subtle fullness of one buttock and mild scoliosis in a child with incontinence and subsequently discovered to have a lipoma; (c) an obvious sinus tract and lipoma in infant with lipomeningocele; (d) a sinus (arrow) and associated hairy patch characteristically associated with a flat capillary hemangioma; (e) an unusual appendage and dermal sinus tract.

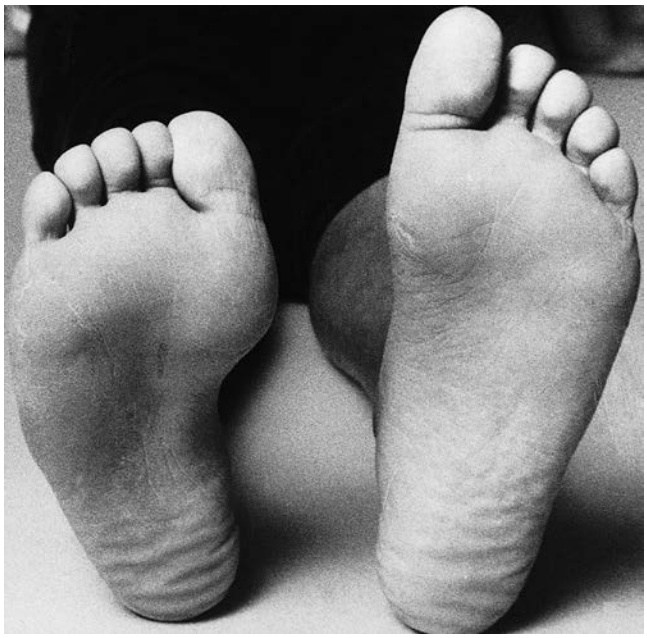

FIGURE 51.2 Leg length and foot asymmetry in a 10-year-old child with spina bifida.

sacral dysgenesis or agenesis. A flattened buttock suggests deficient gluteal muscle tone, consistent with an anorectal malformation or caudal regression syndrome (Figure 51.1).

A neurologic examination, including rectal tone, perianal sensation, and the presence or absence of a bulbocavernosus reflex, should be noted. A digital rectal examination confirms the presence of stool and rules out rare prostatic lesions. The vaginal introitus should be inspected to rule out significant labial adherence or urethrovaginal abnormalities. In the boy, the meatus should be observed and, if uncircumcised, the foreskin either retracted gently or pulled forward, so that the meatus can be inspected through the tunnel of foreskin.

The lower musculoskeletal system should be examined, and any discrepancy in muscle tone or muscle mass should be noted. It is essential to remove the shoes and socks to discover a high-arched foot or hammer claw digits, consistent with a true neurologic abnormality (Figure 51.2). A gait disturbance is noted easily in barefoot children as they walk up and down the corridor. Finally, the deep tendon reflexes should be evaluated. Exaggerated reflexes are consistent with cerebral palsy.

OFFICE-BASED TESTING

At the first office visit, a urinalysis (glucose and specific gravity) and urine culture should be obtained. Children with NBD should also undergo renal bladder ultrasound to evaluate for hydronephrosis. In children who void, this can be beneficial in determining a postvoid residual. Boys with daytime wetting should also undergo renal bladder ultrasonography to evaluate for potential PUVs. All children with febrile or recurrent UTIs should have a renal bladder ultrasound performed as well. In children with a normal renal or bladder sonogram, and no history of significant UTIs, the majority of patients will be started on a timed voiding program, with attention to bowel habits. Pharmacologic therapy, such as anticholinergic medications, is typically not considered as a first-line therapy in children with nonneurologic voiding dysfunction. In the remaining patients, a more thorough workup, including radiographic evaluation with a voiding cystourethrogram (VCUG) and urodynamic studies, is indicated.

RADIOGRAPHIC EVALUATION

Radiographic examination is used selectively. Older children with daytime wetting will undergo a renal and bladder sonogram with postvoid imaging to evaluate bladder emptying and the effects of bladder fullness on upper tract dilatation. Alternatively, if an in-office bladder scanner is available, then bladder scan postvoid residual is sufficient. If UTIs are an issue, a conventional x-ray VCUG is performed to evaluate the bladder, outlet, and urethra. This study can also document whether there is significant stool in the colon. If a VCUG is not performed, but concern exists for stool retention, a kidney, ureter, and bladder (KUB) will be obtained to evaluate stool pattern. Specific characteristics on KUB have been associated with a greater risk of lower urinary tract symptoms.[20] KUB can also be useful to assess the lower spine for bony abnormalities. Children with both fecal and urinary incontinence should have dedicated lumbosacral images. Prior to ossification of the spine, infants can be evaluated with spinal ultrasound with excellent accuracy. In patients with clearly abnormal studies, spinal MRI is performed (Figure 51.3).

FIGURE 51.3 Lumbosacral MRI. T1-weighted image indicates a long tethered spinal cord. The elongated (bowstring) cord ends in the lipoma rather than at L3.

LOWER URINARY TRACT URODYNAMICS

Lower urinary tract urodynamic studies in children include both noninvasive and invasive components. Noninvasive testing includes uroflowmetry with or without electromyography, and with or without bladder scan postvoid residual. Invasive testing includes cystometry and pressure flow studies. In the majority of cases, the child with a nonneurogenic voiding abnormality will be old enough to cooperate, tolerating a precystometrogram flow study, followed by a cystometrogram with patch electrodes and a postvoid study. Typically, the child with neurogenic disease comes to the laboratory on a clean intermittent catheterization program and is being evaluated because of increasing dysfunction (tethered cord and shunt malfunction). Voiding studies become less important, and a needle electrode electromyogram (EMG) may be more important. In all instances, a relatively clean rectum will result in a more accurate study.

NONINVASIVE URODYNAMIC STUDIES

The urinary flow rate measurement is a simple noninvasive study that is defined as the voided volume per unit time (mL/s) (Figures 51.4 and 51.5, Table 51.2).[21] This study can evaluate incontinence secondary to problems in storage or emptying. In combination with patch electromyography and bladder scan post void residual, uroflowmetry can be a powerful tool to evaluate voiding dysfunction in children. For children without evidence of neurogenic bladder, uroflowmetry with a EMG and post void residual urine (PVR) can often suffice, and invasive urodynamic studies avoided in a sensate child. Our approach to uroflowmetry with a EMG is similar to that described by Van Batavia et al.[22] Based off of a new classification system introduced by Glassberg et al.,[23] Van Batavia et al. described management of four conditions that can be identified from uroflowmetry with a EMG without the use of cystometry. The new uroflowmetry-derived conditions are as follows: dysfunctional voiding (DV), idiopathic detrusor overactivity disorder (IDOD), detrusor underutilization disorder (DUD), and primary bladder neck dysfunction (PBND). DV is characterized by pelvic floor activity during voiding with or without a staccato voiding pattern. IDOD is identified by a quiet EMG during voiding, but a shortened lag time (<2 s). DUD patients will have a voided volume above the estimated bladder capacity for age with a quiet pelvic floor during voiding with a normal flow curve. PBND is identified by hesitancy with a delayed lag time and quiet pelvic floor activity during voiding with a right-shifted flow curve.[23] These terms are derived from the International Continence Society and International Children's Continence Society (ICCS) guidelines,[24,25] but specific ICCS terminology is not appropriate, as ICCS terminology requires cystometrogram data. Children with DV during voiding are referred to biofeedback, children with IDOD may be started on anticholinergic medications, children with PBND may be started on alpha-blockade, and children with a large bladder capacity and quiet pelvic floor activity are treated with timed voiding. Stool retention management is paramount in all children.

The reliability of uroflowmetry comes from repeated studies (at least two) and is related to voided volume. Bladder capacity (BC) should be based on age rather than body surface. Although the linear formula of Berger et al.[26] and Koff,[27]

$$\text{BC(ounces)} = \text{Age} + 2$$

has been the most frequently used to estimate bladder capacity, it is clear that bladder growth from a newborn (especially in the first years) to 13 years is not linear. Kaefer et al.[28] responded to the challenge of modifying this equation with their nonlinear equation:

$$2 \times \text{Age (years)} + 2 = \text{Capacity (ounces) for children} < 2 \text{ years old and}$$

$$(\text{Age (years)} / 2) + 6 = \text{Capacity (ounces) for children} \geq 2 \text{ years old}$$

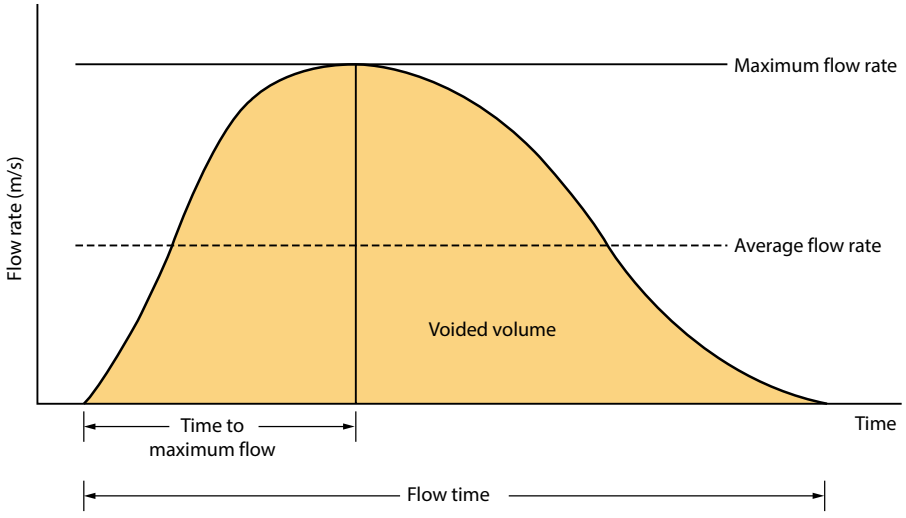

FIGURE 51.4 Idealized diagram of urine flow. (Modified from Blaivas J, Chancellor M eds. *Atlas of Urodynamics*. Baltimore: Williams and Wilkins, 1996. With permission.)

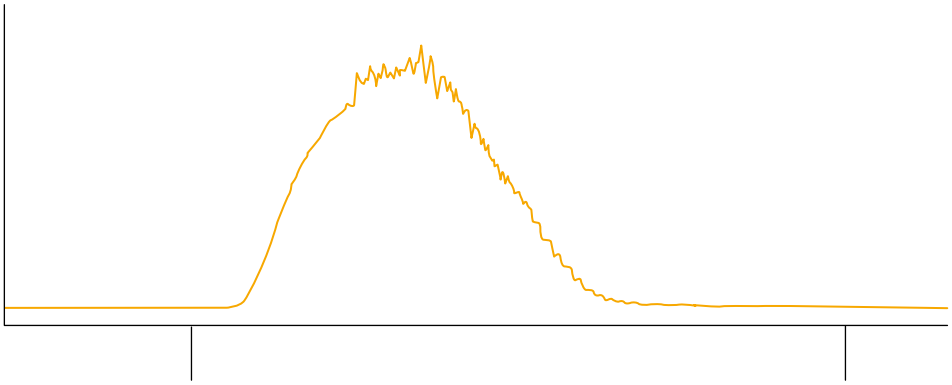

FIGURE 51.5 Normal uroflow in a 12-year-old male: maximum = 38 mL/s, average = 17 ml/s, volume = 222 mL.

TABLE 51.2 Urodynamic studies

Urodynamic study	Purpose: to evaluate:
Uroflow/residual urine	Voiding function sensation, storage, emptying of the bladder
Cystometry	Coordination/function of muscular outlet
Pelvic floor/external sphincter EMG	Bladder/outlet function
Leak point pressure: Bladder Stress (VLPP)	Storage pressure Competence of bladder neck/proximal urethra
Videourodynamics	Anatomy and function of bladder and outlet (simultaneously)

Abbreviations: EMG, electromyogram; VLPP, Valsalva leak point pressure.

In all these studies, data were based on findings in normal children. Children of <14 years of age with spina bifida and neuropathic bladders do not exhibit growth rates similar to those of normal children. In fact, on comparing bladder growth in a small group of patients with spina bifida to the linear formula of Berger, bladders of patients with spina bifida grew half as well as those without neurologic abnormalities. To calculate bladder capacity in children with myelodysplasia, the formula 24.5 × Age (years) + 62 can be utilized.[29]

Thus, in order to calculate normal flow patterns and rates, one must first know the expected bladder capacity in order to determine whether the voided volume is within the expected range. Prevoid bladder volume is measured with a bladder scanner. Accurate determination of the flow rate/voided volume is a common problem, particularly in the anxious child or in the child who voids frequently in small volumes. In general, voided volumes of <50% expected capacity should be suspect.[30,31] We recommend filling the bladder by forcing oral fluids on the way into the laboratory or by intravenous hydration. Multiple voids can be spontaneous, but furosemide administration can be helpful to ensure repeated measurements.

The most important feature of the uroflowmetry study is the shape of the curve. In a study of 180 schoolchildren aged 7–16 years, 98% had a bell-shaped flow pattern (Figure 51.4).[30] The shape of the curve had no relationship to voided volume, but the other parameters were volume dependent. Although the maximum flow and average flow can be of diagnostic interest, the shape of the flow appears to be the best screening parameter. Repeated deviations from the bell-shaped curve should prompt further studies (Figure 51.6). EMG lag time can be beneficial in determining patients with bladder overactivity (short) or PBND (long) and has been correlated with urodynamic studies.[32]

Estimation of residual urine can be an important clue to overall bladder function. Except in infants, the child's bladder should empty to completion with each void. There are multiple pitfalls when evaluating for retained urine. An anxious child in a foreign setting will not void efficiently. Furthermore, children with significant reflux may often harbor residual urine just after voiding. Thus, whereas complete evacuation can be helpful to know, an elevated postvoid residual may not signify important pathology. A bladder scan with ultrasound or placement of a catheter just prior to the cystometrogram will determine the residual urine.

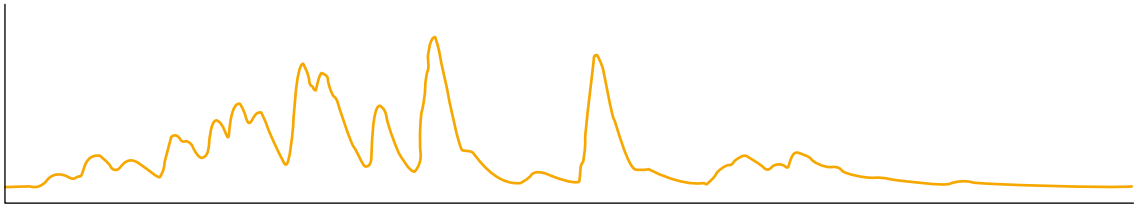

FIGURE 51.6 Abnormal uroflow in an 8-year-old male with abdominal straining and no detrusor activity.

INVASIVE URODYNAMIC STUDIES

Setup

It is most important that the child is comfortable, and that the laboratory is child-friendly (posters, movies, tablet computers, books, stickers, etc.) and temperature controlled. All voidings should be as private as possible. For the older child, a separate room with a flowmeter and a one-way mirror to observe voidings can be helpful. Given enough time and patience, most studies can be completed successfully with reproducible results. We utilize child life experts at our institution to alleviate anxiety in children based off of data extrapolated from the utilization of child life experts for a VCUG.[33] Rarely, an extremely anxious child will require sedation for urodynamic studies. However, studies have demonstrated that utility can still be derived from urodynamic studies in which children have received ketamine or midazolam.

The urodynamic portion of videourodynamics is conducted in a routine fashion, by having the child arrive at the urodynamic suite in as relaxed a state as possible. Prestudy rituals include detailed discussions with the family about expectations and methods to alleviate the child's fears during the procedures. A scout film before placement of EMG patches or catheter probes helps to assess bowel status and guides future management of constipation, if present. Severe constipation adversely affects vesicosphincter activity. If the child arrives with a full bladder, we perform a bladder scan and noninvasive flow study with patch electrodes. For the cystometry portion of the examination, the technique is the same, except that the infusant is radiographic contrast. A triple-lumen urethral catheter is slowly withdrawn, and a urethral pressure profile is obtained. We position a radiopaque marker that identifies the urethral port at the point of highest urethral pressure.

Cystometry is the pressure–volume study of the bladder that examines both the filling and storage and the voiding phases of micturition (Figures 51.7 and 51.8). Both

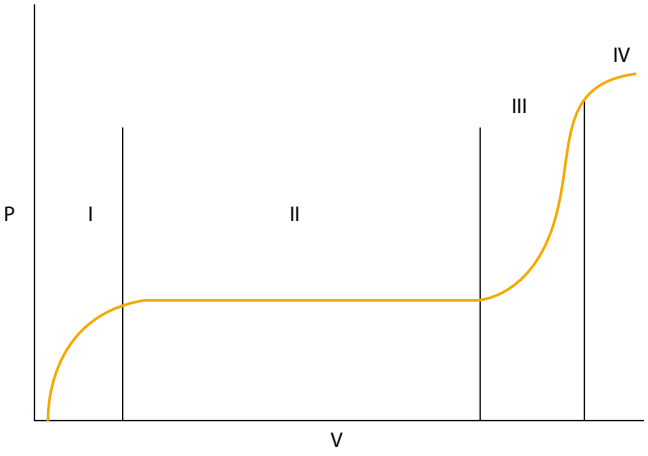

FIGURE 51.7 Cystometrogram indicating four phases and filling and detrusor activity: I, initial vesical pressure with early filling; II, stable tonus limb; III, increase in tonus at full vesicoelastic expansion; IV, voiding; P, pressure; V, volume. (Modified from Dmochowski R. *Urol Clin North Am 1996*;23:243–51. With permission.)

parameters are instrumental in the assessment of bladder health in relationship to upper tract drainage. This can be done with or without videourodynamics. If video is to be utilized, the study can be performed initially with the patient supine on a fluoroscopy table, imaged with a C-arm that eliminates the need for an expensive table, or seated in a multipositional, radiolucent micturition seat. The standing position can help delineate the bladder neck and urethrovaginal component more readily; however, many adolescent and young adult females may not easily initiate a void in the unusual standing position. In the standing position, the right posterior oblique projection provides the best image of the bladder neck. Under fluoroscopic control, the bladder, bladder neck, and urethra are visualized while the pressure is recorded.

Filling Phase and Storage Assessment

An accurate assessment of bladder storage must begin in a calm laboratory setting with the necessary techniques and props to decrease patient anxiety. The technician then passes an age-appropriate catheter. Male newborns can usually accommodate a 6 Fr short pediatric urodynamics catheter. For smaller children, a 5 Fr feeding tube can be connected to a three-way stopcock that allows for both measuring pressure and using fluid instillation. We try to take care to avoid an overly large catheter in newborns, which can obstruct the urethra and produce an abnormally high leak point pressure, as the fluid tries to leak around the catheter.[34] In older children, we use a 7–10 Fr catheter. Latex-free materials are essential for individuals with spina bifida, as they are prone to severe latex allergy and reactions.

Bladder filling is accomplished at 5%–10% of expected bladder capacity.[5] Upon placement of the urodynamics catheter, a prestudy postvoid residual is determined. At least two filling cycles should be performed for urodynamic studies, as the initial filling cycle is often inaccurate due to child anxiety. This is particularly true in the neurologically intact child. We use warm saline from a range of body to room temperature. Joseph[5] noted that a change in detrusor pressure, as well as maximum detrusor pressure, was adversely affected by increasing the rate of filling from slow (approximately 2% of estimated bladder capacity, 0–10 mL/min) to medium (approximately 20% of estimated bladder capacity, 10–100 mL/min) fill. In general, we recommend filling at less than 10 mL/min in children. Filling should continue until the child voids or develops a strong urge to void, or detrusor pressure has exceeded 40 cmH_2O without a void. Otherwise, infusion can continue to more than 150% of the expected capacity or the rate of leakage matches the rate of filling.

During the filling and storage phase, we record both intravesical and abdominal pressures. The abdominal pressure is obtained by inserting a pressure catheter into the rectum. The pressure transducers should be level with the symphysis pubis. The software from the urodynamics system then subtracts the rectal (abdominal) pressure from the intravesical pressure to obtain a true detrusor pressure. Although abdominal pressures are measured, there is no replacement for direct, hands-on, expert observation to determine the effects of straining, crying, and

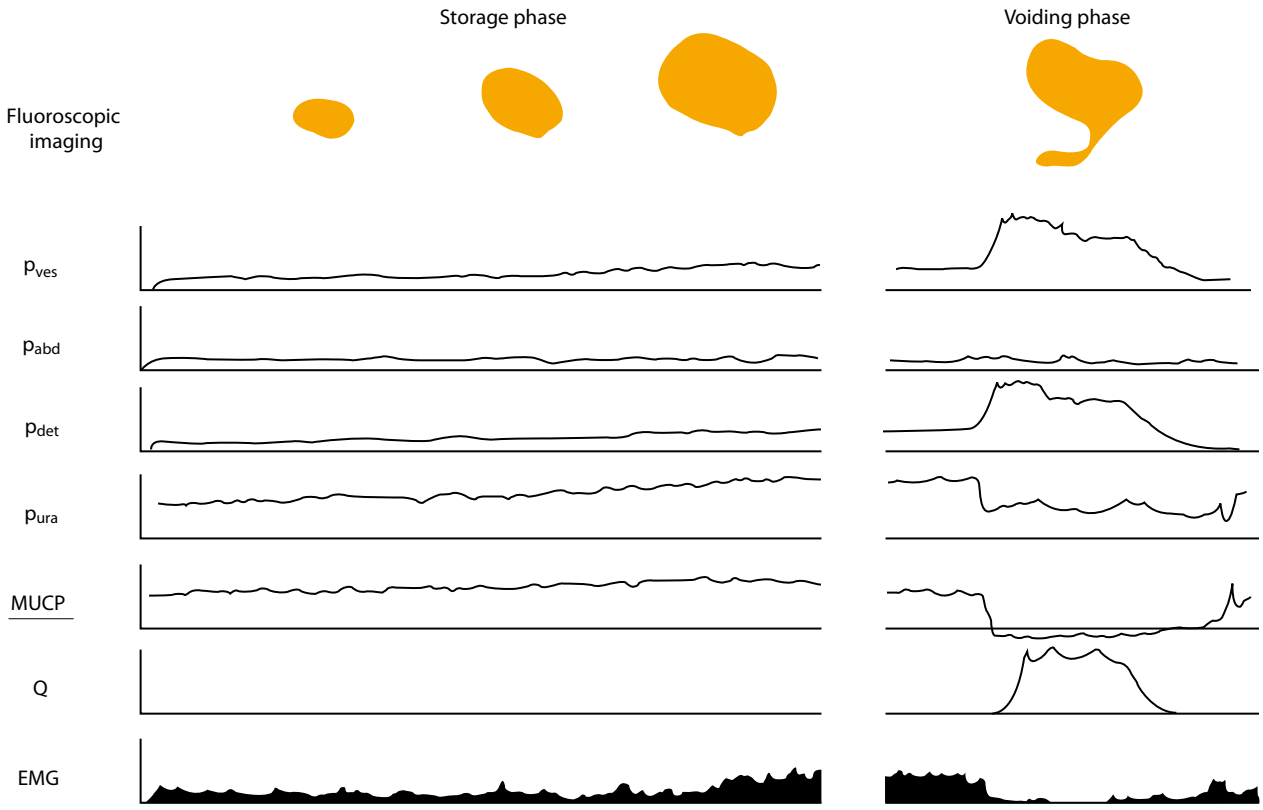

FIGURE 51.8 Idealized urodynamic tracing with accompanying fluoroscopic images. p_{ves} = intravesical pressure; p_{abd} = abdominal pressure; p_{det} = detrusor pressure; i.e., the $p_{ves} - p_{abd}$; p_{ura} = urethral pressure; MUCP = maximal urethral closure pressure; Q = urinary flow; EMG = surface electromyography. (Modified from Abrams P, Khoury S, Wein A. WHO publication. *Incontinence: 1st International Consultation on Incontinence.* Geneva: World Health Organization, 1998, 353–401. With permission.)

gross movements. These should be observed, noted, and accounted for when evaluating urodynamic results.

Valsalva and requests for repeated coughing are utilized to provoke the patient's incontinence symptoms. We examine the bladder base and urethra fluoroscopically for mobility and leakage, respectively. A postvoid residual is calculated and compared with the prestudy noninvasive residual. The videourodynamic study can accurately detect detrusor leak point pressure with straining. The importance of this finding relates to bladder compliance. If the outlet is open fluoroscopically, incontinence occurs with no change in bladder compliance. On the other hand, if the outlet is closed during a detrusor contraction (detrusor sphincter dyssynergia), incontinence may still occur, but only with elevated detrusor pressures (compliance).

Compliance

Since the late 1970s, great advances in pediatric urology have occurred in the field of bladder management. A firm grasp of the importance of bladder health or "safe" compliance became evident coincident with the introduction of clean intermittent catheterization by Lapides. The interest in neurourology blossomed with nonsurgical as well as reconstructive techniques introduced to reconfigure bladder compliance. McGuire et al.[35,36] and Houle et al.[37] described two complementary studies to evaluate lower tract function and health. McGuire et al. popularized the concept of the leak point pressure. The leak point pressure is the detrusor pressure at which leakage occurs through the outlet. It is dependent on the resistance to flow. Without fluoroscopy, the point of resistance will not be evident. It is measured by performing a slow-fill cystometrogram, noting the pressure at which the leak occurs around the catheter per urethra. It has been shown in several centers that in the myelodysplastic population, children with leak point pressures of >40 cmH_2O are at greater risk for upper tract damage (hydronephrosis and reflux) than patients who have leak point pressures of <40 cmH_2O.[37,38] Although many groups base their treatment program on this "magic number" of 40, the limitations of a single leak point pressure are considerable.

Despite its relationship to outlet resistance, measurement of leak point pressure can be misleading when used to evaluate continence capability. Specifically, a high leak point pressure implies a good chance for continence. However, in the myelodysplastic population, the leak point pressure may be high but still not correlate with significant continence in the presence of a fixed but open bladder outlet.

The leak point pressure is an accurate measure of bladder storage pressure. However, Houle et al. proposed that observing the volume at which a child can safely store urine, i.e., pressure-specific bladder volume, might better assess bladder storage characteristics. Houle et al. indicated that in normal children, 99% of bladder capacity

can be stored at <30 cmH_2O. Thus, a safe pressure of 20–30 cmH_2O was chosen and the volume noted that kept the pressure in that range.[35,39] This may be a most useful judge of compliance. Therapeutic interventions can be implemented based on this safe storage pressure. Voiding and catheterization diaries for patients may be obtained, and evacuation schedules or additions of medications (anticholinergics) adjusted accordingly. If conservative measures do not consistently allow the bladder to store in a safe zone, augmentation or neuromodulation procedures are used (Figure 51.9). It seems prudent, and it is easy to obtain the leak point pressures, both simple and stress, as well as the pressure-specific bladder volume. However, it is unclear whether these data alone should be used as a basis to intervene prophylactically or must be interpreted in conjunction with imaging (e.g., renal and bladder sonography). Both programs have their staunch advocates. Accurate studies performed in a consistent and timely manner can only benefit the current population of children and give guidance for future cost-effective management.

The stress leak point pressure measurement was an innovation to help in the assessment of continence capability. The stress leak point pressure is slightly different from the simple bladder leak point pressure and can be determined without fluoroscopy. This value is obtained by slowly filling the bladder and having the child strain as if to have a bowel movement. The lowest pressure is then noted during which leakage first occurs. We ask the child to cough vigorously while the pressure is measured. This marker helps evaluate the capability of the outlet in both the open and the poorly functioning state (e.g., the myelodysplastic child). The stress leak point pressure helps to determine whether outlet reconstructive procedures are needed to achieve urinary continence.[40]

Pressure Flow Studies

In children with intact micturation function, the urodynamic studies are not complete until at least one spontaneous void. Important features to annotate are the opening pressure (the pressure at which micturation begins), which should be low, indicating a collapsed urethra and no evidence of obstruction distal to the bladder neck. Voiding pressures are dependent on sex and age. Boys tend to have a higher voiding pressure than girls, with voiding pressures greater than 100 cmH_2O in boys less than 1 year of age. Girls have voiding pressures from 60 to 70 cmH_2O. By the ages of 1–3 years, boys decrease voiding pressure to 70 cmH_2O, while girls maintain voiding pressures of 60 cmH_2O.[41] Knowing normal voiding pressures is important, as high voiding pressures with normal or low flow rates can be indicative of anatomical or functional bladder outlet obstruction. A concomitant EMG that demonstrates no activity during voiding is particularly worrisome for anatomical obstruction. If the EMG demonstrates

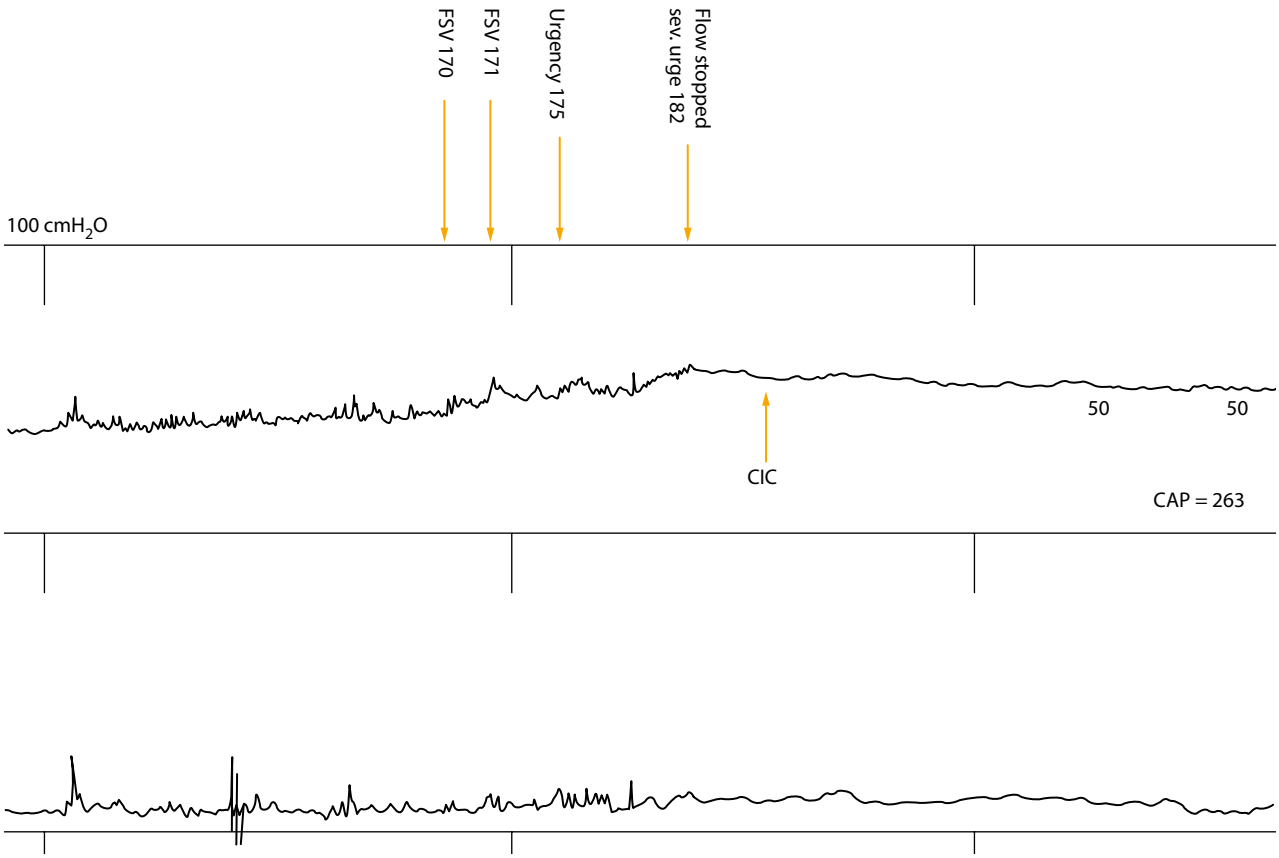

FIGURE 51.9 Urodynamic study to show poorly compliant neuropathic bladder pressure at capacity is 62 cmH_2O and patient-recorded typical catheterization volumes (CIC) that were at elevated pressures (70 cmH_2O). Failure at conservative management resulted in augmentation.

activity, this could be a functional bladder outlet obstruction, such as detrusor sphincter dyssynergia or DV. The shape of the flow curve is the most important feature to determine voiding dysfunction. A staccato voiding pattern can be suggestive of pelvic floor activity during voiding.

An EMG should be performed at the same time as detrusor pressure evaluation. The electrodes can be surface pads, wires, or concentric needles. In children with neurogenic disease and a lack of perineal sensation, we record from the external sphincter or perineal floor using needle electrodes. In boys, we place a concentric needle directly into the bulbocavernosus muscle by aiming toward the bulb of the urethra. For the external sphincter, the needle is placed through the perineal skin just below the bulb of the urethra. A finger in the rectum will help to guide the needle. In females, the external sphincter is identified by a needle placed just lateral to the urethral meatus and advanced <1 cm. To capture individual motor action potentials correctly, both an audio channel and oscilloscope are needed. A trained neurophysiologist best performs this study. This technique is the most accurate method of diagnosing the degree of denervation of the urethral sphincter and establishing the diagnosis of detrusor sphincter dyssynergia (Figure 51.10). It should be noted, however, that in the majority of children, surface pad electrodes give excellent information about a composite view of muscle activity.

In select circumstances, a urethral pressure profile is helpful. Saline is infused at a rate of 2 mL/min, while the catheter is slowly withdrawn at 2 mm/s. The urethral pressure profile measures the passive resistance of a particular point in the urethra. To obtain dynamic information of the outlet during voiding, we use micturition urethral pressure profilometry. This study is done in the midvoiding cycle to help eliminate the transient responses of the bladder neck and external sphincter during micturition. In some sophisticated laboratories, microtipped transducer catheters are used rather than saline infusion.

Videourodynamics

Videourodynamics is a technique that simultaneously combines the evaluation of the anatomy of the lower tract with recorded urodynamic studies (Figure 51.11). In our facility, computer-generated digital images are stored and urodynamic parameters are superimposed on the image. Hard copies of the storage and voiding phase are also obtained and result in a radiologic interpretation component. Regardless of the imaging technology, videourodynamics is especially useful in delineating the bladder outlet during storage and voiding and identifying the causes of incontinence. When assessing the incontinent patient without uninhibited contractions noted on the cystometrogram, the urologist may evaluate the position and function of the bladder neck and proximal urethra under fluoroscopy to determine whether the urethra's incompetence or mobility is the etiology of the wetting. Videofluoroscopy may also be used to evaluate bladder compliance in relation to vesicoureteral reflux (VUR); i.e., reflux may act as a "pop-off" valve for elevation in detrusor pressure, and knowledge of the time of reflux relative to bladder pressure can be important for proper management with clean intermittent catheterization and anticholinergics (Figures 51.12 and 51.13).

The first leak through the bladder neck is recorded. McGuire et al. used videourodynamics and the abdominal leak point pressure (ALPP), also called the stress leak point pressure, to correctly diagnose the incontinent older patient with detrusor instability or ineffective outlet, as well as the pediatric patient with complex causes of incontinence (Figure 51.14). Videourodynamics easily evaluates the neurologically normal child with pseudosphincter dyssynergia and helps in the diagnostic dilemma of the child with neurogenic disease and decreased compliance, detrusor sphincter dyssynergia, and areflexic emptying (Figure 51.15).[36]

SUMMARY

Urodynamic evaluation is a powerful tool available to the pediatric urologist. Utilized in the proper setting, urodynamic studies can be helpful in both patients with NBD and patients with NNBD. It is our preference for children with NNBD to perform solely noninvasive urodynamic testing; however, in certain cases pressure studies are helpful in clarifying diagnosis and management. Children with neurogenic bladder undergo regular

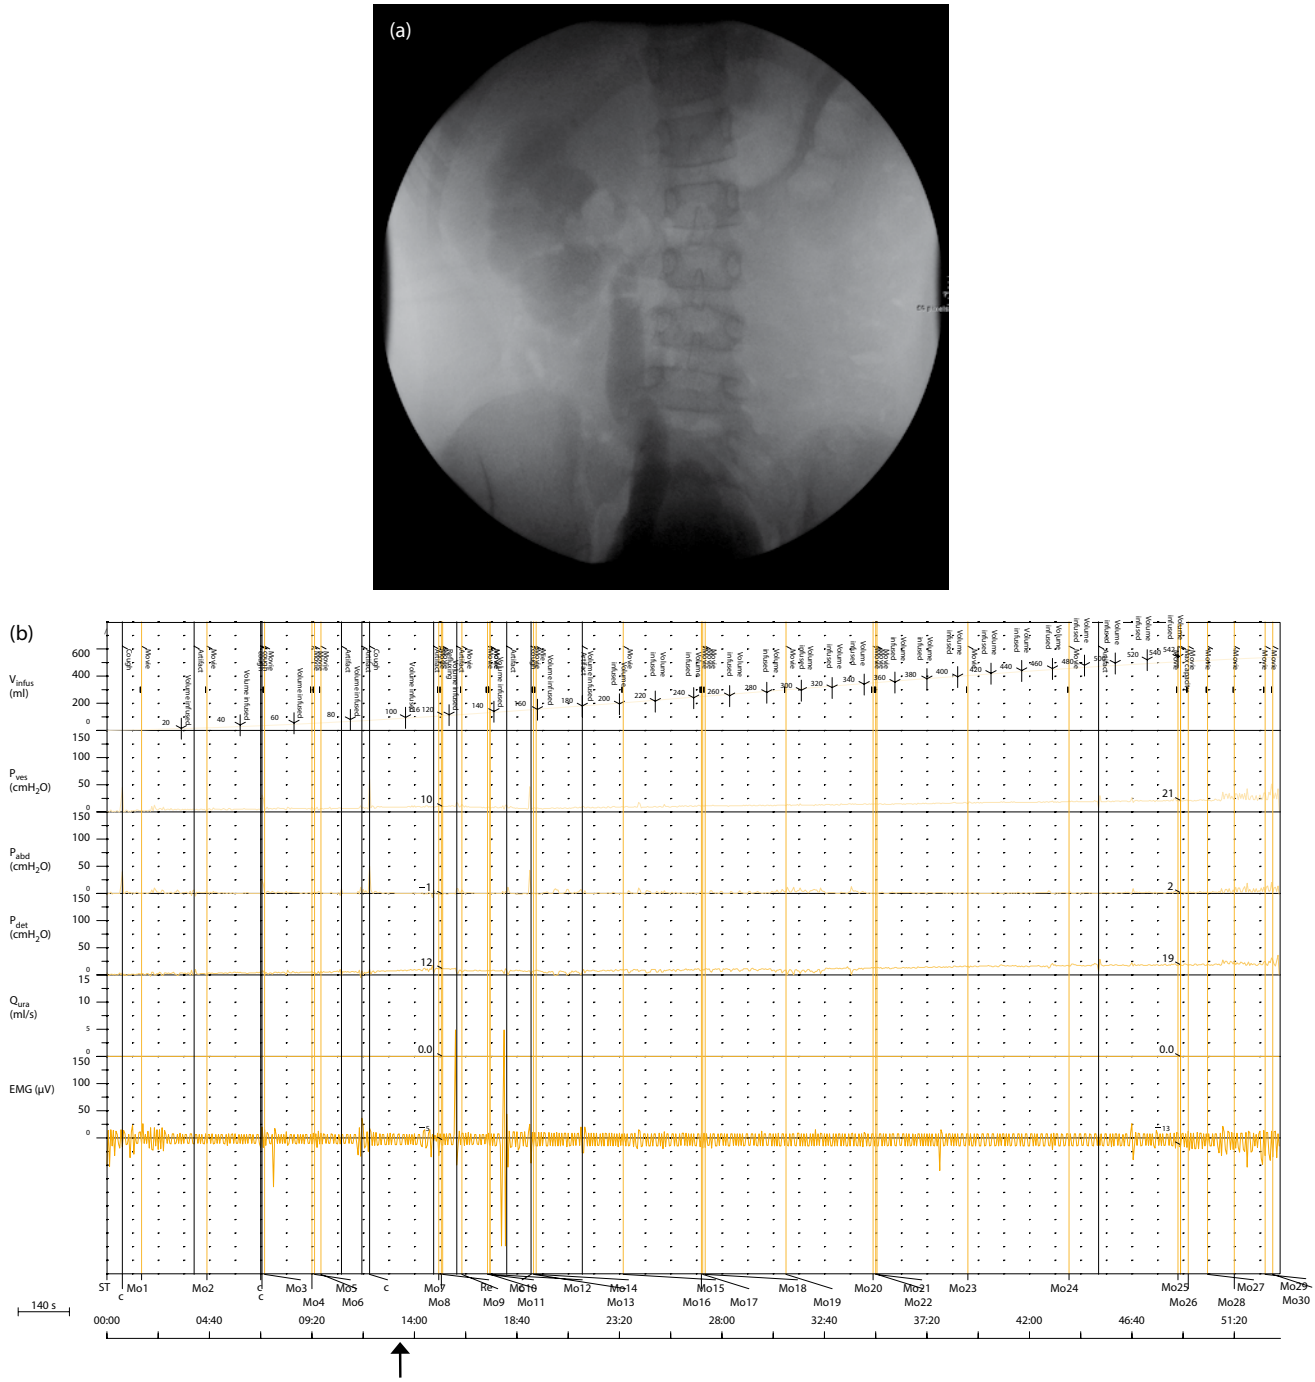

FIGURE 51.13 A 9-year-old female with dysfunctional elimination syndrome with recurrent febrile urinary tract infections. Videourodynamics revealed a bladder capacity of 875 mL, with no leakage. Her capacity pressure was 20 cmH_2O and she revealed grade 4 reflux at 117 mL (arrow) with a pressure of 10 cmH_2O. Her management included bowel management, biofeedback, and a subsequent successful subureteric injection of Deflux paste. V_{infus} = volume of infusete; P_{ves} = intravesical pressure; P_{abd} = abdominal pressure; P_{det} = detrusor pressure; Q_{ura} = urinary flow.

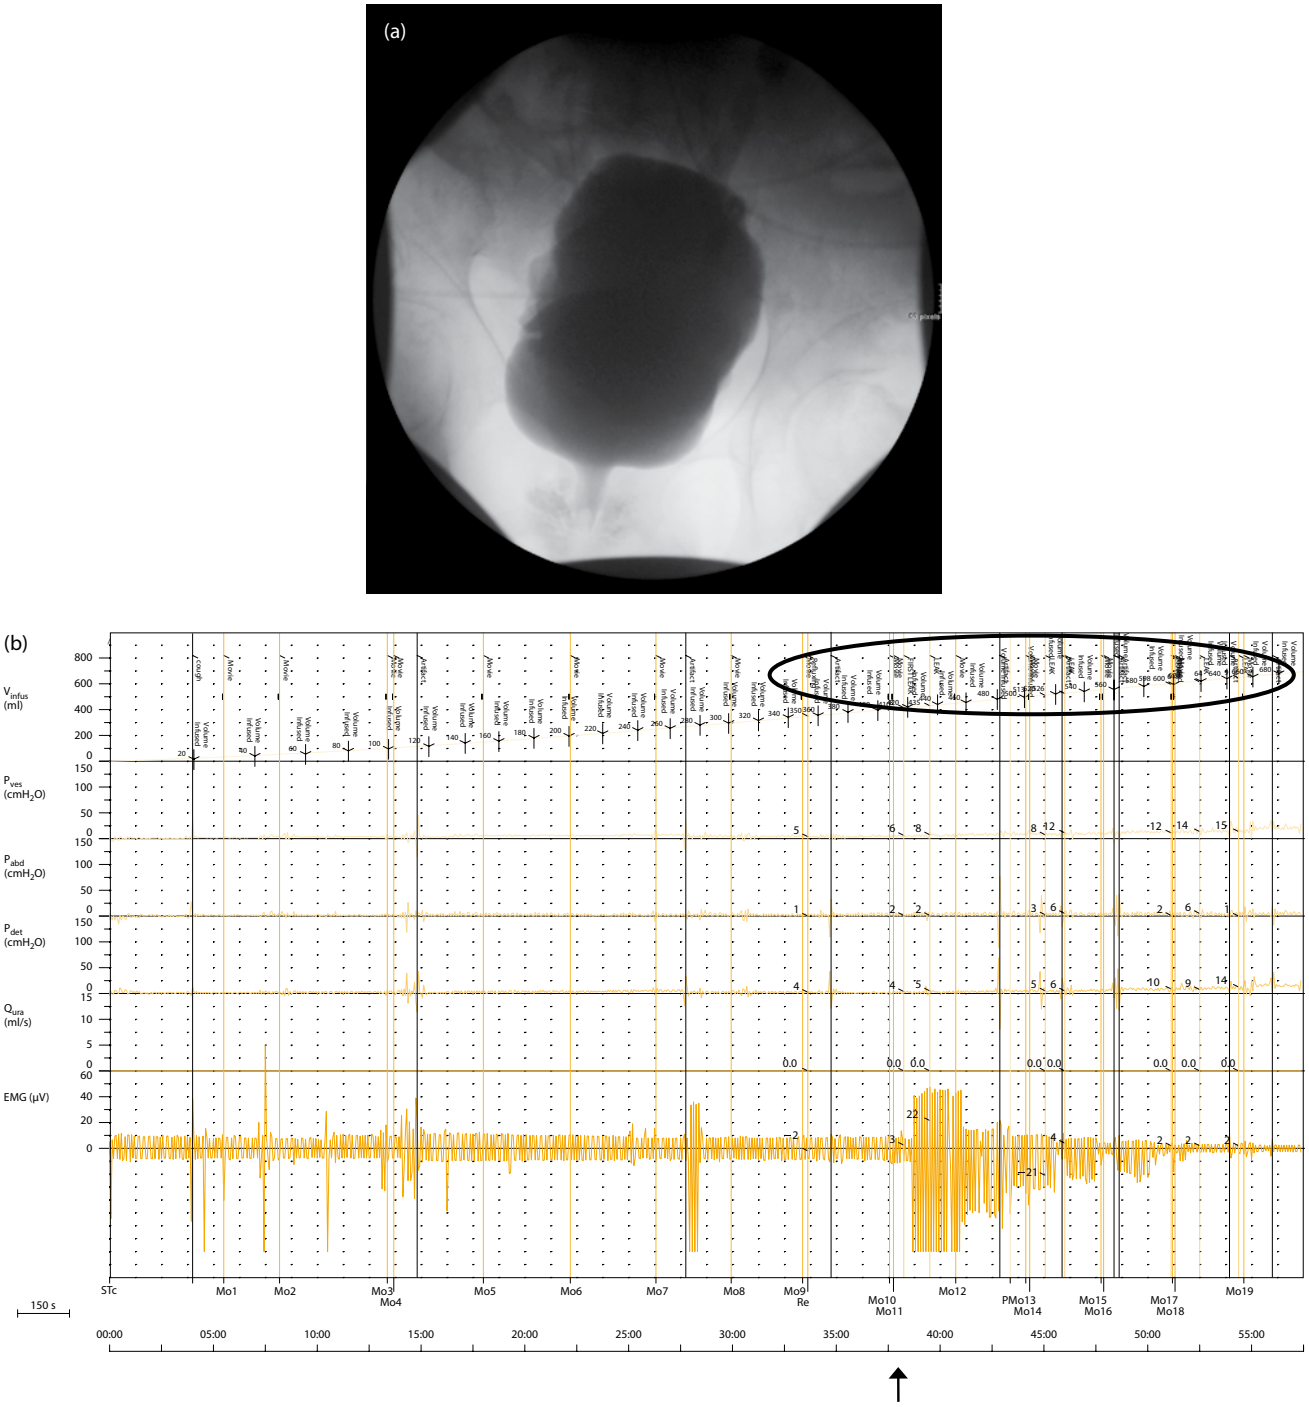

FIGURE 51.14 A 16-year-old male with L3–4 myelomeningocele had previous augmentation cystoplasty, Mitrofanoff and MACE procedure. He presented with continued incontinence, despite adequate anticholinergic therapy and clean intermittent catheterization (CIC) every 3–4 hours. His videourodynamic study revealed a bladder capacity of 810 mL. Radiographically, reflux occurred at 353 mL, (arrow) and the urethra was visible at his first leak point of 4 cmH_2O at 418 mL. His therapy included a sling procedure and a suburetric injection of Deflux paste. V_{infus} = volume of infusete; P_{ves} = intravesical pressure; P_{abd} = abdominal pressure; P_{det} = detrusor pressure; Q_{ura} = urinary flow.

CHAPTER 52

Neurological Control of Storage and Voiding

Julian Wan and Kate H. Kraft

INTRODUCTION

The storage and emptying of urine is controlled by a series of neurological pathways. These pathways are analogous to electrical circuits that help control the activities of a complex machine. They allow the lower urinary tract to shift rapidly between two different modes of function: storage and emptying. In infants, the transition between these two functions is subject to reflex control to produce involuntary voiding. In older children, urine storage and emptying are under voluntary control. This degree of control is unique in the body. Other visceral structures, such as the heart, bowels, and lungs, are controlled almost exclusively by autonomic or involuntary reflex mechanisms. They react to volitional activity but are not under a person's direct control. Yogis have been able to consciously slow their heart rate and rhythm, and elite athletes, such as Olympic target shooters, can delay the onset of their QRS complex, as seen on electrocardiogram (EKG), to allow them to fire between ventricular contractions. However, neither of these groups exhibit the degree of volitional control exerted over an autonomic system as experienced routinely by children over their bladder and urethra.[1–3] In more than a century of research, the physiology and neurology of the bladder and urethra have been fruitful areas of investigation, with better understanding acquired from clinical observation of patients, laboratory studies of human tissue, and animal models. For pediatric urologists, comprehension of the normal process of urine storage and drainage provides the foundation for our evaluation and treatment of congenital and acquired abnormalities of storage and emptying. This chapter reviews what is currently understood about these neurological pathways, their interaction with the target organs, and their clinical relevance to pediatric urology. Specific disease entities may be touched on by way of discussion, but these conditions (e.g., neurogenic bladder dysfunction) are discussed elsewhere in greater detail. The various components are first discussed, followed by the reflex pathways they help comprise. Finally, the role of higher centers and the plasticity of neurologic control are covered.

OVERVIEW SUMMARY

The lower urinary tract is composed of the bladder, urethra, and urinary sphincter. It has two principal functions: storage and emptying of urine. These actions are governed by a complex neural control system involving the brain, spinal cord, and autonomic and somatic nerves. This system performs as a series of circuits that overlay each other. At the most basic level, they serve as a simple switch to maintain a reciprocal relationship between the reservoir (bladder) and the outlet (urethra and urinary sphincter). They can also interconnect and create a complex sequence of coordinated selective excitation and inhibition of the bladder, urethra, and sphincter (Figure 52.1). A variety of neurotransmitters have been identified as playing significant roles in these pathways and may provide opportunities for pharmacological intervention. The urothelium also plays an important role in modulating bladder contractility. The lining of the bladder can be thought of as a sensory organ that tranduces physical and chemical signals to the afferent nerves and underlying smooth muscles.

During bladder filling, the viscoelastic properties of the bladder wall and an absence of an excitatory input from the parasympathetic ganglia to the bladder smooth wall musculature allow the bladder to accommodate more urine while keeping pressures low. This is unlike a balloon or other fixed container that cannot dynamically adjust and accommodate; its wall tension and storage pressure vary directly with infused volume. As the bladder continues to fill, an increase in outlet resistance occurs by means of a rhabdosphincter somatic reflex called the guarding reflex. In humans and many mammalian species, a sympathetic reflex also aids this process by increasing outlet resistance by increasing tension on the smooth muscle component of the sphincter and by inhibiting bladder contractility through an inhibitory effect on the parasympathetic ganglia. Finally, the sympathetic output also decreases the tension of bladder smooth muscle. Continence is maintained during increases in intra-abdominal pressure by the intrinsic competence of the bladder outlet with some reflex help from the rhabdosphincter.

Bladder emptying can be volitional or involuntary and involves an inhibition of the spinal somatic and sympathetic reflexes and activation of the parasympathetic pathways leading to the bladder. The coordinating center lies in the pons region of the brainstem and is otherwise known as the pontine micturition center (PMC). Initially, there is relaxation of the bladder neck and sphincter muscle, which is controlled by the cessation of somatic and sympathetic spinal reflexes, as well as local factors, such as nitric oxide (NO) that is released by parasympathetic stimulation.

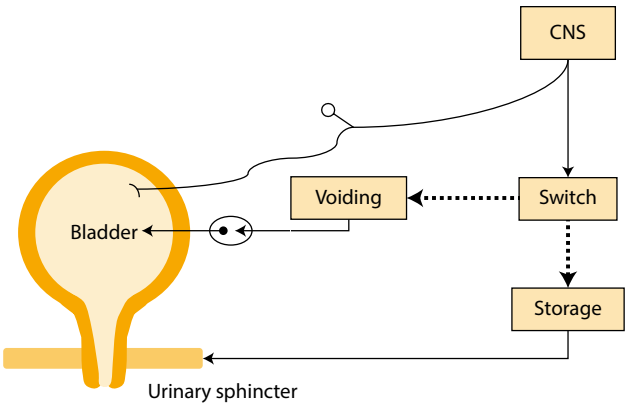

FIGURE 52.1 Schematic diagram illustrating the relationship between the anatomy of the lower urinary tract and the switch function of the micturition pathways. During urine storage, a low level of afferent activity activates efferent input to the urethral sphincter. A high level of afferent activity caused by bladder filling activates the switch in the CNS. This causes inhibition of the efferent pathway to the urinary sphincter, leading to relaxation, and excitation of the efferent pathway to the bladder, causing contraction and emptying.

After this has occurred, a coordinated, synchronized contraction of the bladder smooth muscle occurs. The bladder neck or outlet develops a funnel shape, which is due in part to the continuity of the bladder base and proximal urethra. There is modulation of this process from other peripheral reflexes and from supraspinal sources. The bladder then empties and normally drains to completion.

The ability to control and modulate between these two states develops with maturation. In neonates, the switch between the two modes of storage and emptying occurs reflexively once a threshold volume is reached. With maturation, the ability to modulate this action volitionally develops. This change occurs not because this early primitive set of pathways has been replaced by another. Instead, a layer of modulating and inhibitory controls that originate above the sacral spine are overlaid and mediated from the cerebral cortex and other higher centers. Once established, these pathways are not fixed but remain malleable throughout life. Injury and disease can cause these suprasacral inhibitory and modulating pathways to become lost or diminished. Earlier reflex pathways are then unmasked and can reemerge. Plasticity and resurfacing of earlier, more primitive pathways may help to explain the nature of many conditions due to neurogenic dysfunction. Even in adulthood, it appears that a significant degree of plasticity may be possible. This phenomenon offers potential in rehabilitating severe neurologic injuries and damage and may be of great research and practical importance in the near future.

TARGET ORGANS: BLADDER, URETHRA, AND URINARY SPHINCTER

The bladder and urethra are wrapped in a multilayer weave of smooth muscle. They are one anatomic unit but have two distinct functional regions: the body (or fundus) and the base and proximal urethra. The demarcation between these two areas roughly coincides with the division between the bladder body and the trigone.[4–6] They receive different types of autonomic innervation. Muscarinic cholinergic receptors are found throughout the smooth muscle but are most numerous in the fundus. Preganglionic cholinergic receptors in the sympathetic and parasympathetic ganglia are nicotinic, as are the cholinergic receptors of the striated muscle component of the urinary rhabdosphincter. Alpha-adrenergic receptors are more numerous in the smooth muscle of the posterior urethra and bladder base.[4–8] This cluster of alpha-adrenergic receptors is more concentrated in boys than in girls and is believed to explain the tight bladder neck closure seen during ejaculation.[9] Beta-adrenergic receptors are found in the fundus and act to help relax the bladder during filling.[10] Human fetal studies have shown that beta-adrenergic and cholinergic receptors are present as early as 3 months' gestation.[11] Alpha-adrenergic receptors appear in the trigone and urethra after 6 months' gestation.[6] These observations suggest that even very early in infancy, a complex system is already at work. The differences in receptor distribution have been exploited pharmacologically to create more precise acting drugs. This distribution is not static and can change due to injury or disease.

The organization of the bladder smooth muscle affects its normal function. Smooth muscles are organized into fascicles of 4–12 cells. Each fascicle is enveloped by extracellular matrix (ECM) consisting of collagen, elastin, and rare fibroblasts.[12] These bundles are arranged into circumferential and longitudinal patterns around the bladder and proximal urethra. The bundles are interwoven with no distinct layers. In males, the smooth muscle forms part of the prostatic capsule. The rhabdosphincter consists of circumferential fibers of striated muscle that surround the smooth muscle from the bladder base to the urogenital diaphragm.[13] It appears that the rhabdosphincter is distinct and separate from the urogenital diaphragm and pelvic-supporting striated muscles in both males and females.[14,15] The striated muscles are both fast and slow twitch. The fast-twitch, more easily fatigued fibers are used during voluntary attempts to stop micturition or during acts of active suppression of voiding, such as Vincent's curtsy. The slow-twitch, fatigue-resistant fibers contract during bladder filling as part of the guarding reflex. The rhabdosphincter initially behaves in a reflex fashion but later comes under volitional control from the higher cortical centers with maturation. In addition to somatic and sensory connections, the urinary sphincter also receives parasympathetic and sympathetic fibers from the pelvic plexus, making it "triple innervated."[16] Clinically, this concept is important, as alpha-blockers have been shown to be useful in treating urinary obstruction and dysfunctional voiding. This combination of sympathetic, parasympathetic, and somatic innervation has been clearly demonstrated in the cat and has been corroborated in humans with regard to the adrenergic sympathetic component. The full functional significance of the autonomic innervation of the striated sphincter in humans is not yet defined. Autonomic dysfunction of the sphincter has been found in patients with lower motor neuron lesions but is not seen in patients with functional issues, such as detrusor sphincter dyssynergia (DSD), suggesting that the degree of autonomic

innervation can change as a response to injury or disease in a manner not seen in normal individuals.[4,17]

Nerve endings do not innervate each individual smooth muscle cell of the human bladder. Electron microscopy shows that normal muscle cells are about 0.2 nm apart without intercellular links.[4] Direct cell-to-cell excitation has not been shown. Efficient coordinated detrusor contractions are propagated by electromechanical coupling and not by direct neuronal excitation. A few muscle cells are directly triggered, which in turn contract and pull on their neighboring cells, thereby triggering further excitation. Myogenic changes may be responsible for urge and urge incontinence seen with overactive bladder.[18,19] These changes could occur directly or as a reaction to stimuli or alterations to the overlying urothelium.

The normal bladder exhibits excellent compliance and viscoelasticity. These properties are influenced by the properties of the ECM, which is a mixture of collagen, elastin, and occasional fibroblasts. In many pathological states, there are changes in the ECM that affect the mechanical function of the bladder. The type of collagen that is laid down appears to play an important role.[20] Types I and III predominate in the ECM. Type I is thicker and stiffer. Type III is thinner and more pliable. As the human fetus ages, the ratio between types I and III decreases with an associated rise in bladder compliance and increase in elastin. A normal fetal bladder becomes more compliant as gestation progresses. Fibroblasts in the interstitium are the source of most of the connective tissue, and normally in the bladder there is little fibroblast activity. Denervation experiments show that increases in ECM may be in part due to a slowing of collagen degradation and decrease of activity of local proteases. Increases in ECM come not only from the fibroblasts but also from the smooth muscles themselves.[21] Dedifferentiation of smooth muscle cells under repetitive stress leads to more elaboration of collagen and elastin in the interstitium. This resembles the process seen in stressed walls of vasculature, wherein an injury or disease can initiate a spiraling cascade of pathology. A neurogenic bladder, for example, may lose the neurologic modulation that maintains compliance, which in turn leads to higher storage pressure that causes higher stress, which then promotes dedifferentiation of smooth muscles and greater deposits of elastin and collagen. This creates a vicious cycle of deteriorating elasticity and compliance. Removal or alteration of normal innervation may therefore result in lasting changes to the histology of the bladder.

NEUROTRANSMITTERS AND THE UROTHELIUM

The basic autonomic neurotransmitters are well known. The sympathetic nerves are adrenergic and use norepinephrine as a neurotransmitter in postganglionic synapses. Preganglionic sympathetic and all parasympathetic nerves are cholinergic and use acetylcholine (ACh). Less well known is a third system, the purinergic or peptidonergic system. Found in animals and humans, it comprises a wide variety of molecules, including vasoactive intestinal peptide (VIP), neuropeptide Y, adenosine triphosphate (ATP), substance P, somatostatin, and calcitonin gene-related peptide (CGRP).[4,22,23] This third pathway is believed to act as a modulator of overall autonomic activity. Neuropeptides have been found throughout the smooth and striated muscle of the lower urinary tract. In addition, from observations in some pathological states of autonomic denervation, the effects of these neurotransmitters are thought to be clinically more significant. The existence of this third pathway of the autonomic system was inferred when muscarinic blockade with atropine did not completely ablate in vitro bladder muscle contraction.[7] Atropine also seemed to be less effective in blocking bladder muscle contractions from specimens taken from neurogenic bladders, suggesting that there was an enhanced purinergic factor in these pathologic bladders.

Complicating the discussion is the role that the urothelium may play in how these neurotransmitters are released and modulated. The urothelium is not just a barrier between the urine and the underlying tissues of the bladder. It also acts as a sensory organ by transducing physical and chemical signals to the attendant afferent nervous system and underlying smooth musculature (Figure 52.2). The urothelium influences the detrusor smooth muscle by modifying its contractility and the extent of spontaneous activity. The urothelium responds to different forms of stress and stimuli. Urothelial cells have receptors that respond to mechanical changes: norepinephrine, ACh, purines, and many transient receptor potential vanilloid channels (TRPV). Stimulation of any of these urothelial sensory structures can lead to the release of active agents, such as ATP, ACh, and NO, which have both excitatory and inhibitory effects on the afferent nerves located in or near the urothelium. For example, mechanical stress results from changes in transmural bladder pressure, storage pressure, and increased lateral tension. These mechanical stresses become transduced to afferent signals using several different pathways that may play a pathological role in both overactive and underactive bladder syndromes.[24–28] Several purinergic transmitters are inhibitory: opioid peptides (enkephalins), inhibitory amino acids (glycine and gamma-aminobutyric acid [GABA]), serotonin, dopamine, and nonopioid peptides, such as neuropeptide Y and corticotrophin-releasing factor. All these can inhibit the micturition reflex when applied to the central nervous system (CNS). Excitatory purinergic transmitters include glutamic acid, neuropeptides such as substance P and VIP, NO, and norepinephrine.[29,30] These neurotransmitters also affect the vascular smooth muscle, may alter local blood flow, and can appear in increased concentration in obstructed or neurogenic bladders. VIP has been found to be lower in concentration in biopsy specimens of hypercontractile bladders.[31] A compensatory role for VIP and neuropeptide Y in the urethras of patients with spinal cord injury has been suspected because of their elevated levels.[32] ATP plays a well-known and important role as the basic molecule for energy transfer in the human body. Abundant in the cytoplasm, ATP is released into the extracellular space by several mechanisms: vesicular exocytosis or by selective channels. The level of ATP rises in response to distention and acts on P2X2 and P2X3 receptors on the afferent neural plexus.[33–35]

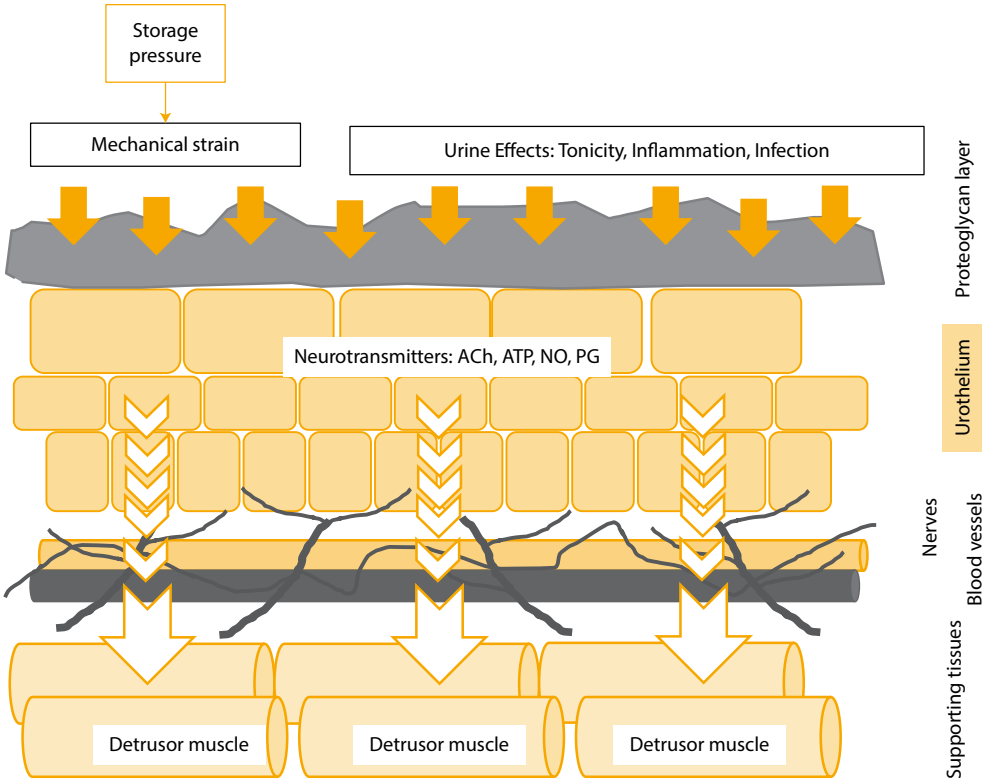

FIGURE 52.2 Schematic diagram illustrating the role of the urothelium in transducing and modulating the effects of neurotransmitters.

ATP levels have been found to be higher than normal in the bladder muscle of spina bifida patients and interact with two families of receptors, P2X and the G protein coupled on P2Y.[6] Therefore, it has been speculated that hyperactivity observed in neurogenic and obstructed bladders may be the result of abnormal purinergic influences mediated by these neurotransmitters.[36]

Cholinergic receptors are found throughout the smooth muscle of the lower urinary tract and are numerous in the body of the bladder but have subtle variations.[8] At least five subtypes of muscarinic receptors exist (M1–M5). Types M1, M2, and M3 are found in the human bladder.[37] Types M2 and M3 may act synergistically, with M2 enhancing the effect of M3-mediated contractions. Stretch and strain have also been shown to induce ATP release by alpha-adrenergic 1 receptors (using NE), TRPV1 agonists, and antimuscarinic agents via M2/M3 receptors. The M2 type may also modulate smooth muscle relaxation. Types M2 and M4 together may play a role in the prejunctional inhibition of ACh release.[38] The identification of subtypes makes possible the development of receptor-specific agents, which act not just to crudely block the postjunctional receptor but also to possibly modulate prejunctional release. The preganglionic cholinergic receptors in the sympathetic and parasympathetic ganglia in contrast are nicotinic, as are the cholinergic receptors in the rhabdosphincter. Pancuronium, an anesthetic, and botulinum toxin, both nicotinic-blocking agents, may be used to paralyze the rhabdosphincter, but total incontinence does not result because the smooth muscle component of the sphincter and bladder neck remains unaffected.[39]

Botulinum neurotoxin type A (Botox A), along with beta-3 adrenergic receptor agonists and phosphodiesterase type 5 (PDE-5) inhibitors, offers new ways of interacting with the cholinergic system. It may be an alternative to the classic antimuscarinic agents in the treatment of conditions such as overactive bladder.

At the neuromuscular junction, Botox A inhibits release of ACh from efferent cholinergic nerves at the neuroeffector junction and ganglion. In the epithelium, it may inhibit stretch-induced ATP release, as seen in spinal cord injury and cystitis patients.[40–42] Recent findings suggest that botulinum toxin A, beta-3 adrenergic receptor agonists, and PDE-5 inhibitors at lower concentrations can directly inhibit afferent excitation without decreasing detrusor contractility. The clinical impact is that these drugs alone or in combination may help treat the sensory component of lower urinary tract dysfunction without affecting contractility. Normally, Botox A inhibits the parasympathetic nerves, but in some pathologic disease states, it may be preferentially taken up by the afferents because of their increased activity. Beta-3 adrenergic agonists can indirectly decrease afferent excitability by inhibiting intrinsic activity through smooth muscle relaxation without affecting contractility. PDE-5 inhibitors appear to have little effect on contractility because guanylyl cyclase concentrations are very low in detrusor smooth muscle. Beta-3 agonist receptors are stimulated by endogenous NE released during the filling phase to promote bladder relaxation and facilitate bladder storage (Figure 52.3).

As noted earlier, alpha-adrenergic receptors are concentrated in the trigone, bladder neck, and posterior urethra

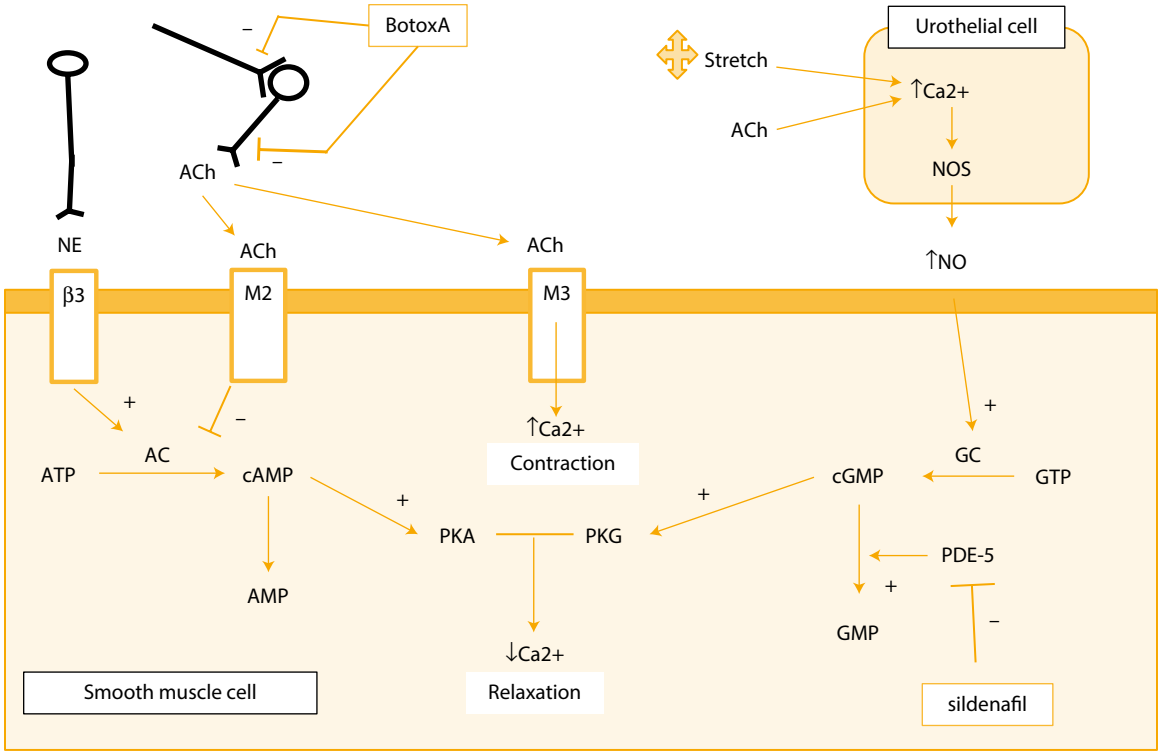

FIGURE 52.3 Schematic diagram showing the relationship between the different receptors (β3, M2, M3) and the effect of agents such as Botox A and sildenafil. Ca^{2+} = calcium, NOS = nitric oxide synthase, AC = adenylyl cyclase, PKA = protein kinase A, PKG = protein kinase G, GC = guanylyl cyclase, cAMP = cyclic adenosine monophosphate, cGMP = cyclic guanosine monophosphate.

and are more numerous in boys than girls.[8] Stimulation of beta-adrenergic receptors in the detrusor leads to relaxation of the smooth muscle. The effect is mediated via adenylyl cyclase, which leads to accumulation of cyclic adenosine monophosphate (cAMP). This observation led to speculation that beta-blockers could be used directly or that PDE inhibitors, which slow the breakdown of cAMP, could be adapted as drugs for treating bladder instability.[43] Hypogastric nerve stimulation and alpha-adrenergic agonists produce a rise in intraurethral pressure that is blocked by alpha-antagonists.[44] This supports the role for alpha-agonist agents in treating some forms of incontinence and alpha-blockers in relaxing the bladder neck and urethra. NO has been identified as a major inhibitory transmitter mediating relaxation of the urethral smooth muscle during micturition.[45] Parasympathetic postganglionic nerves release NO. Relaxation is blocked by inhibitors of NO synthase. NO is also involved with bladder afferent modulation. In situations of bladder irritation, NOS inhibitors can help decrease or eliminate bladder instability. NO-mediated smooth muscle relaxation is due to increased intracellular accumulation of cyclic guanosine monophosphate (cGMP). Like cAMP, it is inactivated by PDE and may be a target for PDE inhibitor drugs. Originally developed to treat hypertension and later erectile dysfunction, PDE-5 inhibitors have been shown recently to have a beneficial effect on lower urinary tract dysfunction.[46–49] The sites of action in the bladder remain unclear. PDE enzymes break down cyclic nucleotides, and PDE-5 inhibitors prevent the breakdown of cGMP, which increases the activity of protein kinase G (PKG), which in turn may inhibit contractility. Current studies of selective inhibitors of PDE-5 have shown their beneficial effects for lower urinary tract symptoms, including bladder overactivity.[47,50] Neuropeptides, such as substance P, neurokinin A, CGRP, VIP, pituitary adenylate cyclase-activating peptide (PACAP), and enkephalins, play a role in modulating afferent sensory nerves. The actions of these purinergic transmitters have led to the recognition that the bladder urothelium can be viewed in totality as a large sensory organ, and to the regarding of the urothelium as an integral part of the afferent pathway in much the same way that the detrusor and rhabdosphincter are considered distinct components.[51,52] Their actions help shape and form the type of afferent signal that enters the micturition reflex. This concept has led to novel approaches in treating conditions such as overactive bladder and interstitial cystitis. Rather than focusing on the efferent pathways, new treatments and therapies aim to dampen or alter the afferent signals from the urothelium.[51–53] For example, neuropeptides have been found to be active in capsaicin-sensitive C-fiber bladder afferents. These afferents are of particular interest because they seem to be normally quiescent but become very sensitive when faced with major bladder inflammation or other noxious intravesical events.[54–56] They can be desensitized by agents directed against vanilloid receptors. Capsaicin and its analogue resiniferatoxin have attracted recent interest because of their potent ability to affect the vanilloid receptors and desensitize these C-fibers.[57]

An intact urothelium is associated with increased spontaneous contractile activity in the bladder. It causes

high-frequency, low-amplitude contractions to convert into larger, more prolonged, and less frequent contractions. Two proposed theories have developed from observations seen in whole bladder preparation in vitro. First, the epithelium itself may be triggering the spontaneous contractions. Second, the epithelium through either cell-to-cell interaction or release of some diffusible agents is affecting detrusor function. Practically, this may explain why overactivity is often seen symptomatically when any inflammatory or infectious process results in denuding of the urothelium; it may be a fundamental effect related to changes in the urothelium and not wholly due to the inflammation alone.

As noted above, the urothelium releases substances that have an inhibitory or dampening effect on smooth muscle contractility, including NO, prostaglandins, and adenine nucleotides. However, there is no clear understanding of the role that these substances play in the normal physiological or pathophysiological control of bladder contractility. The bladder epithelium is theorized to metabolize or otherwise inactivate the excitatory agonist, to act as a barrier to the diffusion and penetration of these agonists to the detrusor muscle, or to respond to the agonists by releasing substances that reduce the contraction of the underlying muscle. Experimental bladder preparations have suggested these possible mechanisms, but to date the exact inhibitory pathway is not known to be mediated by any of these pathways.[55–57]

Treatments that affect the urothelium can lead to either dysfunction or benefit. Removal of the damaged or diseased urothelium (such as the use of laser therapy for forms of ulcerative interstitial cystitis) may help decrease bladder and pelvic pain. The formation of fresh urothelium after treatment has been associated with symptom-free periods of as long as 6–12 months. The turnover time of urothelial cells is about 200 days, which may explain the mechanism of relief. It remains unclear how much, if any, benefit can be associated with the barrier function of the urothelium. The surface proteoglycans and tight junctions of the urothelial membrane and uroplakins may play a key role.[56–57]

Intravesical administration of drugs may allow maximal dosing while minimizing associated side effects. There is a long history of using intravesical oxybutynin in the treatment of neurogenic bladder.[58,59] The low permeability of the urothelium, the dilution of the drug, and the later washout remain limiting factors. Permeability enhancement agents that improve transport across the bladder urothelial wall or mucoadhesive drug delivery systems that strongly adhere to the urothelium and ensure drug persistence near the site of action may be potential therapeutic mechanisms. Strategies that have been investigated include polymeric hydrogels and the use of electromotive force, drugs that temporarily disrupt the urothelial integrity, and nanocarriers such as liposomes. Electromotive drug administration uses electric field stimulation to enhance the transport of hydrophilic drugs. Agents that have been administered in this manner include protamine sulfate, which temporarily disrupts urothelial integrity, and dimethyl sulfoxide, which can penetrate without leaving significant damage.[60–62]

PERIPHERAL INNERVATION

The peripheral innervation of the lower urinary tract includes components of the sympathetic, parasympathetic, and somatic nervous systems. They connect to the target organs of the bladder, urethra, and urinary sphincter by the pelvic, hypogastric, and pudendal nerves. There are also modulating influences from the sympathetic ganglia chain and intramural ganglia.

The pelvic nerves are parasympathetic and originate from the sacral spinal cord. They excite the bladder and relax the urethra and urinary sphincter. The efferent nerves originate from the upper and middle sacral spinal cord segments S2 to S4 and course outward as the pelvic nerves. Parasympathetic preganglionic neurons (PGNs) are located in the lateral part of the sacral intermediate gray matter in the region termed the sacral parasympathetic nucleus (SPN), and the axons exit the ventral roots to reach the peripheral ganglia. In humans, parasympathetic postganglionic neurons are located in the detrusor wall layer, as well as in the pelvic plexus. Patients with cauda equina or pelvic plexus injury may be neurologically decentralized but are not completely denervated. Afferent and efferent neuron interconnections at the level of the intramural ganglia are still possible.[55]

The hypogastric nerves are sympathetic and arise from the lumbar spinal cord. They excite the bladder base, urethra, and urinary sphincter. The efferent sympathetic nerves originate from spinal cord segments T11 to L2. These nerves pass from the cord to the lumbar chain ganglia and then to the superior hypogastric plexus. Nerves from the plexus coalesce to form the right and left hypogastric nerves. Sympathetic pathways arise from the rostral lumbar spinal cord and provide noradrenergic excitatory and inhibitory activity to the bladder and urethra.[53] Activation of the sympathetic nerves causes relaxation of the bladder body and contraction of the bladder outlet and urethra, which facilitates storage of urine.

The pelvic and hypogastric nerves meet to form the inferior hypogastric plexus. Nerves from this plexus then travel to the lower ureter, bladder, urethra, and urinary sphincter. The preganglionic nerves of the hypogastric plexi are closely associated with the ganglia close to or within these target organs. Intramural ganglia have been identified in the adventitia, muscle, and suburothelium of the bladder and urethra. Postganglionic nerves from the intramural ganglion then travel the final distance to directly innervate the smooth muscle lining these organs. This last group of ganglia and nerves comprises the so-called "urogenital short-neuron system."[5,39]

The pudendal nerves excite the rhabdosphincter. They are somatic and arise from the sacral cord segments S1 to S4. The nucleus of these nerves resides in the lateral border of the ventral horn of the sacral cord, called Onuf's nucleus after Wladislaus Onufrowicz, Swiss anatomist, 1836–1900. Found in cats, dogs, and humans, it also innervates the bulbocavernosus and ischiocavernosus muscles. The rhabdosphincter initially behaves reflexively and later comes under voluntary control from the higher cortical centers with maturation. The sphincter motor neurons have dendrites that project laterally to the lateral

funiculus, dorsally to the intermediate gray matter, and dorsomedially to the central canal. These connections with interneurons allow for a complex pattern of reflexes to be created. In addition to somatic and sensory connections, the urinary sphincter also receives parasympathetic and sympathetic fibers from the pelvic plexus, making it "triple innervated." This combination of sympathetic, parasympathetic, and somatic innervation is modeled well in the cat and has been corroborated in humans, particularly the adrenergic sympathetic component.[16]

The ability to sense fullness is important to both the storage and emptying of urine. Afferent activity that occurs during bladder contraction has an important reflex function and appears to reinforce the central drive that maintains the detrusor contractions. All these named nerves also carry afferent sensory information back to the spinal cord.[55] Afferent nerves travel along the hypogastric and pelvic nerves to link the urogenital smooth muscle to the hypogastric plexus and further upward to the lumbar and sacral dorsal root ganglia. Afferent sensory nerves also travel along the pudendal nerve to the sacral spinal cord. These nerves conduct information from the bladder suburothelium and muscle, including the sense of fullness, urgency, and pain. The primary afferent nuclei of the pelvic and pudendal nerves are contained in the sacral dorsal ganglion (DRG), while the afferent innervation of the hypogastric nerves comes from the rostral lumbar DRG. The central axons of these DRG neurons carry the sensory information to the second-order neurons within the spinal cord.[55,63] Visceral afferent fibers of the pelvic nerve and pudendal nerve enter the cord and move within the portion of the dorsal cord called Lissauer's tract, named for Heinrich Lissauer, German neurologist, 1861–1891.[63,64] This is a longitudinal bundle of thin, unmyelinated, and poorly myelinated fibers capping the apex of the posterior horn of the spinal gray matter, composed of posterior root fibers and short association fibers that interconnect neighboring segments of the posterior horn. Pelvic nerve afferents monitoring bladder volume and degree of contraction are carried on both myelinated and unmyelinated axons. The myelinated axons are alpha-delta fibers, and the unmyelinated are C-fibers. Neuropathic conditions and possibly inflammatory conditions can lead to recruitment of C-fibers, which can form new functional afferent pathways that are believed to cause urge incontinence and possibly increased bladder pain. Alpha-delta fibers carry information from smooth muscle and sense wall tension. When inflamed, there is increased discharge at a lower threshold pressure. The C-fibers carry stretch and bladder fullness sensation from the urothelium and smooth muscle and act as nociceptors for overdistention. Usually quiet when irritated, they can discharge at lower threshold and unmask a new afferent pathway during inflammation. This has formed the basis for several lines of treatment that act against the sensory end (e.g., capsaicin and resiniferatoxin). Current theory holds that several different types of afferents are present: stretch, volume, tension, and silent (nociceptors). Irritation intravesically can lower the pressure threshold. Most C-fibers are insensitive to normal distention but can become mechanosensitive and active when irritated or inflamed. As noted earlier, afferent signaling is subject to multiple layers of modulation and a variety of stimulatory and inhibitory agents.

REFLEX PATHWAYS

Several reflex pathways help mediate urinary storage and emptying. The standard model describes the central pathways that control the lower urinary tract function as being organized as simple on–off switching circuits. Some reflexes promote urine storage and others facilitate voiding. These reflexes do not act in isolation but are interlinked to create complex feedback mechanisms. The guarding reflex that links bladder distention to external sphincter activity during filling can activate, in turn, sphincter afferents that inhibit the parasympathetic excitatory inputs to the bladder. This explains how bladder-to-rhabdosphincter activity could lead to decreased bladder activity during storage. The disruption or discoordination of these interactions may be the underlying cause in forms of neurogenic bladder dysfunction (Figures 52.4 and 52.5).

There are four types of pathways in the spinal cord that link together to form the reflex pathways: (1) spinal efferent nerves, which include autonomic PGNs and somatic motor neurons; (2) spinal interneurons, which are located between the dorsal and ventral horns; (3) primary afferent neurons; and (4) central neurons from the brain and brainstem that modulate spinal reflexes.[56] These pathways were elucidated using intracellular labeling, pseudorabies virus tracing, and measurement of gene product expression.[65]

Urine Storage, Guarding, and Sphincter-to-Bladder Reflex

During the storage of urine, distention of the bladder causes afferent nerves to be stimulated. These in turn trigger sympathetic excitatory outflow to the bladder trigone and urethra and pudendal outflow to the rhabdosphincter. These responses together have been collectively labeled the guarding reflex. Sympathetic stimulation also inhibits detrusor muscle and bladder ganglia transmission. The guarding reflex in turn becomes inhibited during the start of micturition.[55,66] This sequence of reflex activity is demonstrable clinically. During bladder filling, there is an involuntary increase in the activity of the rhabdosphincter detected on urodynamics, which is measurable by either an intraluminal pressure transducer placed at the highest pressure zone of urethral pressure or by perineal electromyography (EMG) (Figure 52.6). During bladder filling, the EMG of the urinary sphincter will show increased activity, reflecting the increase in the efferent firing in the pudendal nerve and an increase in outlet resistance that contributes to the maintenance of continence. The intraluminal pressure will drift upward. This variation is not accidental or random and is related to bladder activity. The external urethral sphincter activity reaches a peak just before the onset of micturition. At low bladder volume, the reflex is involuntary, but as the volume continues and the sensory threshold of fullness of the bladder is reached, the external urethral sphincter activity increases and becomes

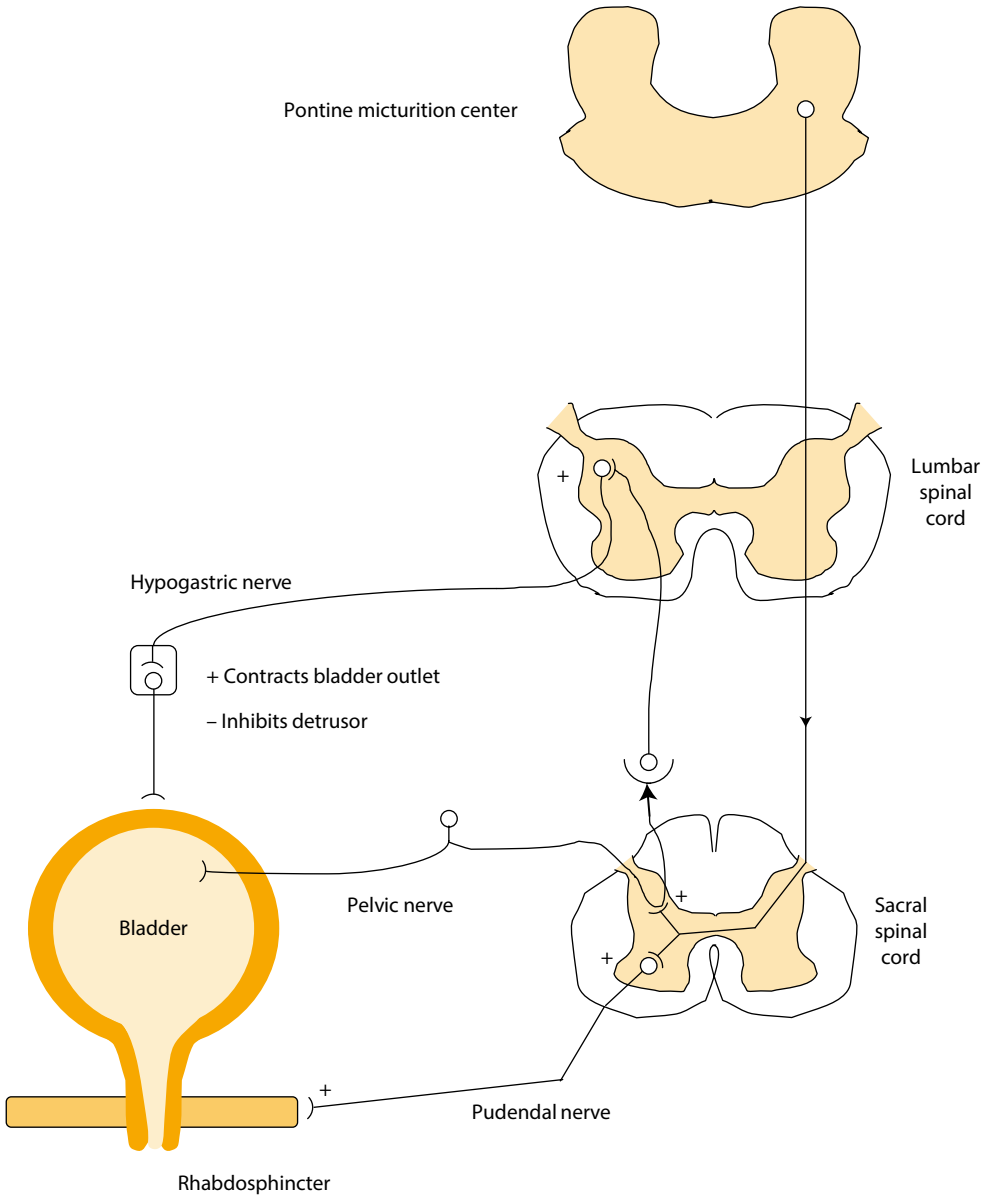

FIGURE 52.4 During storage, distention of the bladder causes low-level bladder afferent activity. This in turn activates the sympathetic outflow to the bladder and urethra and increases pudendal nerve activity to the rhabdosphincter. These constitute the guarding reflex. Sympathetic activity also inhibits detrusor activity and transmission in the bladder ganglia.

a conscious and voluntary phenomenon. While bladder afferent stimulation is the primary activation of pudendal motor neuron activity, urethral and perineal afferents may also contribute.[66,67] This part of the guarding reflex links proprioceptive afferents from the pelvic floor to induce closure of the urethral outlet.

It was originally theorized that this reflex increase may be a mechanism that protects against stress incontinence.[68] For clinicians, it is probably more relevant as a way of explaining signs and symptoms in patients who are infrequent voiders or who are trying to ward off urgency. This mechanism explains how certain avoidance maneuvers, such as vigorously crossing the legs repeatedly and "squirming" (doing the "potty dance") or tucking the heel into the perineum (Vincent's curtsy), are used by children who are infrequent voiders to dampen feelings of urgency, thereby allowing them to prolong holding of urine. This observation is further supported by data that stimulation of the somatic afferent pathways of the pudendal nerve to the caudal lumbosacral spinal cord can inhibit voiding. Afferent input can come from a variety of sites, such as the penis, vagina, rectum, perineum, urethral sphincter, and anal sphincter. This aspect has been termed the sphincter-to-bladder reflex pathway. Studies in cats suggest that this is mediated by suppression of the interneuronal pathways in the sacral spinal cord and also by direct inhibition of the parasympathetic PGNs.[69] Sympathetic firing is initiated at least in part by a sacrolumbar intersegmental spinal reflex pathway that is triggered by vesical afferent activity in the pelvic nerves. The vesicosympathetic reflex represents a negative feedback mechanism whereby an increase in bladder pressure triggers an increase in inhibitory input to the

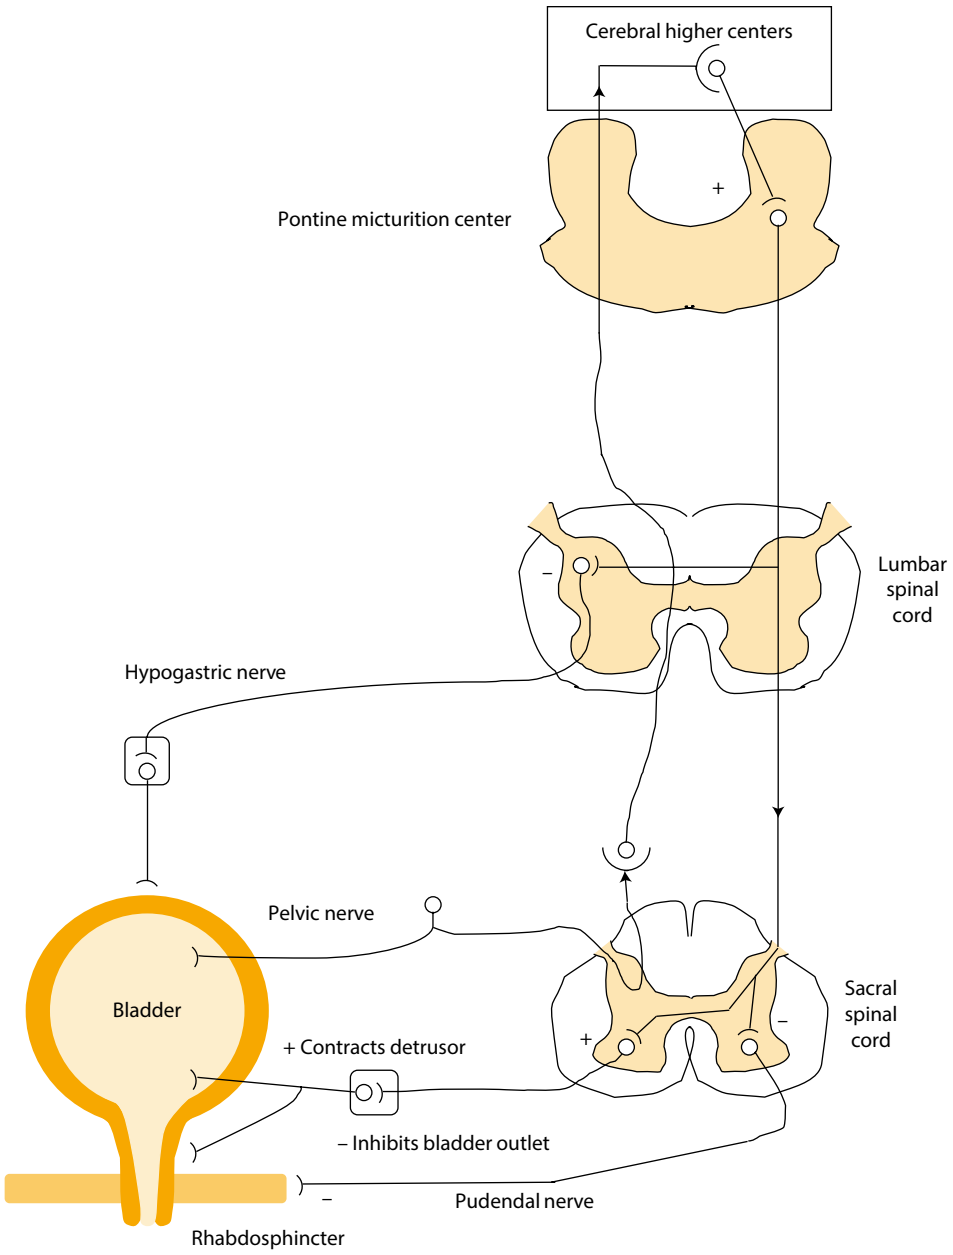

FIGURE 52.5 At the initiation of voiding, bladder afferent activity increases, which activates the PMC. This inhibits the spinal guarding reflexes, which are conducted via the pudendal nerve. It also stimulates the parasympathetic outflow to the bladder and bladder neck. Ascending afferents complete the reflex loop by bringing feedback input to the cerebral cortex and higher centers.

bladder, thus allowing the bladder to accommodate larger volumes of urine. The reflex pathway is inhibited during voiding, and this inhibition is in turn abolished by transection of the spinal cord at the thoracic level, suggesting that it originates at a supraspinal site, probably the PMC.

Voiding or Micturition Reflex

The switch from storage to the voiding phase can occur voluntarily or reflexively. Infants and patients with neuropathic bladder demonstrate the former when the volume of urine exceeds the threshold volume beyond which micturition occurs (Figures 52.5 and 52.6). At that point, increased afferent firing from the tension receptors in the bladder leads to a shift in the efferent activity. Sympathetic and somatic pathways are inhibited, and sacral parasympathetic activity increases. There is an initial relaxation of the urethral sphincter, followed a few seconds later by the contraction of the bladder, an increase in bladder pressure, and a flow of urine. Relaxation of the urethral smooth muscle during micturition is mediated by parasympathetic stimulation to the urethra that triggers the release of NO, which acts as an inhibitory transmitter, and by removal of excitatory inputs to the urethra. The parasympathetic outflow to the detrusor and urethra has a more complicated central organization involving spinal and spinobulbospinal pathways passing through the PMC. When this coordination is disrupted as a result of

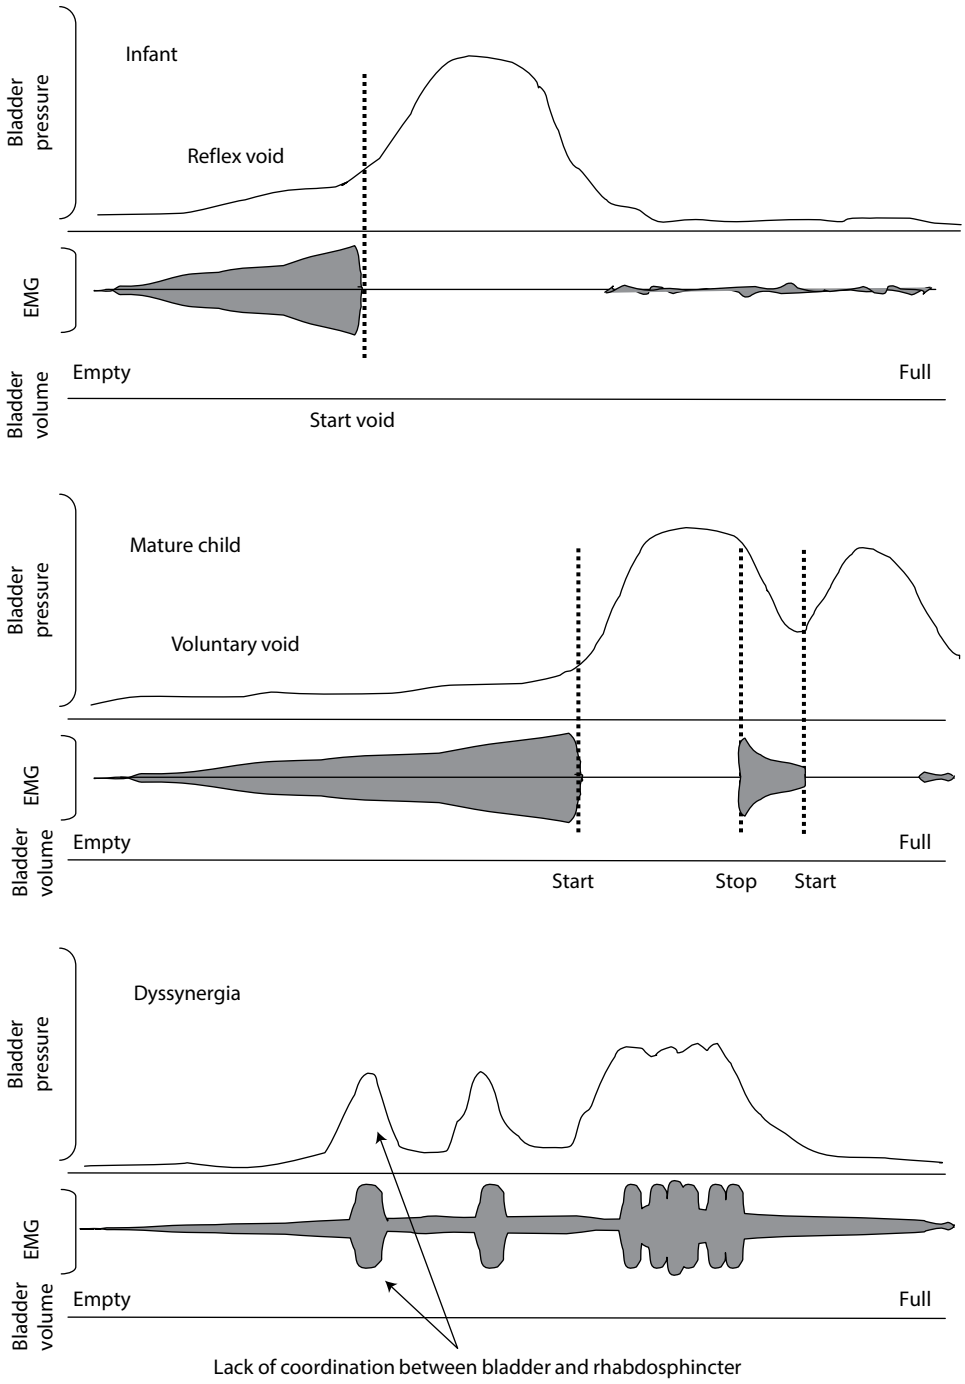

FIGURE 52.6 Schematic diagram showing the differences between infantile, mature child, and dyssynergic voiding, where there is a loss of coordination between the bladder and sphincter. The latter condition is often seen as a result of injury or disease to the CNS. Note that in both the infantile and mature child, there is coordination between the bladder and sphincter, so that the sphincter relaxes before the onset of bladder contraction, and the EMG becomes quiet. In the mature child and adult, there also exists the ability to interrupt voiding volitionally. When this happens, note that the sphincter activity precedes the cessation of bladder contractions, and when voiding is restarted, relaxation of the sphincter occurs before voiding is resumed. In contrast, in dyssynergia the detrusor and sphincter contract out of sequence, thereby working against each other.

injury or disease, simultaneous contraction of the bladder and rhabdosphincter can occur, leading clinically to DSD (Figure 52.6).[70]

Voiding is mediated by activation of the sacral parasympathetic efferent pathway to the bladder and the urethra along with reciprocal inhibition of the somatic pathway to the urinary sphincter. Cat studies reveal that the neurons in the brainstem have an essential role in the control of the parasympathetic component of voiding. Removal of the areas of the brain above the pons usually facilitates voiding by removing inhibitory inputs from higher centers. Transection at any point below abolishes micturition.

The region thereby isolated is the PMC. The PMC has been shown by physiologic and anatomic experiments to be the key switch in the voiding pathway. Chemical and electrical stimulation of the PMC in cats and dogs causes suppression of the urethral sphincter EMG activity, firing of the sacral PGNs, bladder contractions, and release of urine. These regions play a regulatory role, as shown by injections of the inhibitory transmitter, GABA, into the PMC of cats, which can increase the volume threshold for inducing micturition and, in high enough doses, completely block reflex voiding. In contrast, administration of a GABA inhibitor, such as bicuculline, can lower micturition volume threshold. Injuries above the lumbosacral area but beneath the PMC lead initially to an areflexic bladder and complete retention (similar to the spinal shock seen in human spinal cord injury patients) and later automatic micturition, but with bladder hyperactivity and DSD.[55,71]

The voiding reflex analogy to the guarding reflex is the urethra-to-bladder reflex.

Barrington first noted that flow of urine or mechanical stimulation of the urethra with a catheter would excite afferent nerves that can lead to bladder contractions in anesthetized cats.[72,73] It was hypothesized that the urethral-to-bladder reflex helps promote emptying. Two pathways have been identified. One is activated by somatic afferents in the pudendal nerve and needs facilitation from the PMC. The other uses afferents in the pelvic nerves to facilitate other spinal reflex mechanisms. Desensitizing the urethral afferents by capsaicin decreases this reflex. It is thought that this pathway may explain why stress and urge incontinence can occur together. The leakage of urine into the urethra triggers the reflex leading to urgency. Similarly, correction of stress incontinence has been observed to paradoxically improve detrusor instability.[65,74]

SPINAL AND SUPRASPINAL PATHWAYS

In the spinal cord, afferent pathways terminate and connect with second-order interneurons that relay information to the brain and to other regions of the spinal cord, including the preganglionic and motor nuclei at other levels. These are polysynaptic processes that interlink the various bladder, urethral, and sphincter reflexes. These interneuronal mechanisms play an important role in modulating lower urinary tract function.[75] The lower tract interneurons also receive afferent inputs from the bladder. Glutamic acid is the excitatory transmitter of these pathways.[74] About 15% of interneurons located medial to the SPN have inhibitory connections to the parasympathetic preganglionic nuclei. These inhibitory neurons use GABA and glycine.[74] Reflex pathways that control the external sphincter muscles also use glutamic excitatory and GABA or glycine inhibitory interneurons. The micturition reflex can be modulated at the spinal cord level by afferents from the cutaneous and striated muscle sources. Stimulation of afferent fibers can inhibit the firing of sacral interneurons evoked by bladder distention, which occurs as a result of presynaptic inhibition of primary afferents or due to direct postsynaptic inhibition of second-order neurons. Direct postsynaptic inhibition of bladder PGNs can occur by somatic afferent stimulation in the pudendal nerves. Suppression of bladder hyperactivity in patients with sacral root stimulation may reflect in part activation of the afferent limb of these inhibitory reflexes. This concept has been used to artificially modulate bladder behavior by sacral nerve stimulation.[76]

Control of bladder function starts in the higher cortical centers through the brainstem pons regions in the PMC and is mediated through the spinal cord nuclei to the efferent and afferent peripheral pathways. The micturition reflex is normally controlled and mediated by the pathway linking the brain with the reflexes described above. This pathway is termed the spinobulbospinal reflex pathway. Animal brain lesion studies show that the neurons in the brainstem at the level of the inferior colliculus have an essential role in the control of the parasympathetic component of micturition.[55] Decerebration above the colliculus facilitates micturition by eliminating inhibitory inputs from more cephalad centers. Transections below the colliculi abolish micturition. The essential control center thus isolated was found in the dorsal pontine tegmentum. First described in 1921, it is commonly referred to as the PMC or medial location.[77] The medial and lateral region of the pons is responsible for the micturition reflex. The medial region controls detrusor contraction via the reticulospinal tracts, which synapse with the preganglionic parasympathetic neurons in the sacral micturition center. Electrical stimulation of the medial region causes relaxation and opening of the urethral sphincter, followed within milliseconds by a contraction of the detrusor muscles.[78] The lateral regions of the PMC are connected via the corticospinal tracts to Onuf's nucleus. Electrical stimulation of this area leads to contraction of the rhabdosphincter. Voluntary control is via a link with the frontal cortex.[79,80] Neurons from the PMC project to the periaqueductal gray matter, thalamic nuclei, and limbic system. Neurons from the PMC communicate with supraspinal neuronal clusters that coordinate micturition with other functions. The location is of note because of two interesting neural topographic findings. First, the facial nerve nucleus is very near the PMC. Patients with Ochoa syndrome (urofacial syndrome) exhibit a combination of voiding dysfunction and a characteristic inversion of facial expression. No obvious structural lesion has ever been shown on imaging studies, but speculation suggests that there could be subtle synaptic or interneuron abnormalities.[81] Second, the nucleus locus ceruleus within the brainstem is a close neighbor of the PMC. The locus ceruleus in animals is activated by colonic stimulation. The PMC has been shown to affect the afferent signals from the pelvic viscera that reach the locus ceruleus. This has led to speculation that there may be bilateral interaction. Clinically, it has been observed that constipation and bowel dysfunction are associated with bladder dysfunction. It has been theorized that a local phenomenon, such as rectal distention impinging on the trigone or the pelvic nerves, may be responsible. This concept, however, fails to explain why women seem to be equally affected yet have the uterus and vagina "shielding" the bladder from the rectum. Perhaps the problem is at the central level due to interaction between the PMC and the locus ceruleus.[82,83]

The PMC has important direct synaptic inputs to the sacral PGNs and to the GABA-nergic neurons. The former carry excitatory outflow to the detrusor, whereas the latter act as an inhibitor on rhabdosphincter motor neurons. These reciprocal connections result in promoting bladder urethral sphincter synergy. Studies in rats indicate that activation of bladder PGNs from the PMC can be blocked by inotropic glutamate receptor antagonists, suggesting that neurons in the PMC utilize glutamate as a neurotransmitter.[70,84–86]

CENTRAL CEREBRAL PATHWAYS

Voluntary control of voiding is dependent on the connections between the frontal cortex and the septal or preoptic region of the hypothalamus, as well as connections between the paracentral lobule and the brainstem.[55] Lesions to those areas of cortex appear to directly increase bladder activity by removing cortical inhibitory control. Brain imaging by positron emission tomography (PET) has implicated the frontal cortex and anterior cingulate gyrus in the control of micturition, which is predominantly a right-sided function.[87,88] Since sacral parasympathetic pathways to the bladder form a predominantly positive feedback system, further inhibitory modulation is required to store urine and prevent early voiding. Higher centers, such as the cerebral cortex, cerebellum, basal ganglia, thalamus, and hypothalamus, thus play an inhibitory role in modulating the activity of the PMC.[89]

Studies in human beings indicate that voluntary control of micturition is dependent on connections between the frontal cortex and septal preoptic region of the hypothalamus and the paracentral lobule, brainstem, and spinal cord. Lesions in these areas due to trauma, tumors, or cerebrovascular disease appear to indirectly increase bladder activity by removing cortical inhibitory control. In cats, removal of the cortex lowers the functional bladder capacity. If the rest of the neuraxis is intact, removal of the cerebrum lowers the inhibitory input from the cortex. The hypothalamus plays a role in activating the sacral parasympathetic excitatory pathways, thereby inducing bladder contraction and voiding. It is thought to act either through direct inputs to the PMC and sacral micturition center or indirectly. This is not a unidirectional process. Modulating afferent inputs from the bladder are received by the hypothalamus. The gene *c-fos* has been identified as a marker for subsets of second-order neurons, as expression of *c-fos* has been found to increase in these neurons.[90,91]

PLASTICITY, MATURATION, AND REEMERGENCE

The neonatal bladder is not a fully functional storage organ. At birth, there is little cerebral input, and the bladder reflexively empties. In modern urodynamic parlance, a newborn through infancy and early toddler years has bladder overactivity. This is also seen in neonatal animals whose bladders show early spontaneous repetitive contractions. These early pathways do not disappear but rather become incorporated into more mature pathways by active inhibition from increasing cerebral maturation. Inhibition rather than cessation of these infantile reflexes is the important observation. Much as a layer of inhibition from the cerebrum modulates the spinal reflexes, a layer of inhibitory control is overlaid atop the neonatal reflexes. In newborn kittens and rats, a primitive reflex, the exteroceptive perineal-to-bladder reflex, is the principal voiding reflex until the mature spinobulbar or PMC-based reflex begins functioning at several weeks of life.[92] During the subsequent weeks, the adult-type voiding mediated by the micturition center and spinobulbospinal pathway becomes active, and the perineal-to-bladder reflex becomes progressively weaker and ultimately vanishes. Studies using pseudorabies virus tracing, cellular labeling, and CNS transection preparations in animals demonstrate that there is prominent reorganization of synaptic connections in the bladder reflex pathways.[93] At this time, the bulbospinal pathways that connect to the PMC are fewer and weaker. However, as the neonate matures, there is pruning of the interneuron to preganglionic synapses from the afferents and increased synapses from the bulbospinal pathways (Figure 52.7).[93,94] Interestingly, the higher pathways seem to be present and organized but inactive at birth. In animal studies, decerebration unmasks reflex bladder activity, which responds to bladder distention and is mediated by a supraspinal pathway. This indicates that supraspinal bladder-to-bladder reflexes are organized early after birth but are suppressed by inhibitory mechanisms within the brain. Postnatal development is associated with a marked reorganization of the circuitry of the CNS affecting micturition. The mechanism underlying the developmental suppression of the perineal-to-bladder reflex and the later reemergence after spinal cord injury appears to be similar to that of the maturation process. Downregulation occurs in the interneuronal to PGN excitatory synapses, possibly by synapse elimination due to competition for synaptic space between the boutons of the interneurons and the descending axons. Injury that causes degeneration of the descending axons, such as transection of the spinal cord, blocks this reorganization and maintains the primitive neonatal reflex. A similar degeneration of the descending axons in mature animals could stimulate axonal sprouting in interneuronal pathways and cause reemergence of the neonatal perineal-to-bladder reflex. While the details are not completely known, it is certain that remodeling of the interneuron to preganglionic synapses in the SPN has a prominent role. This synaptic plasticity and rearrangement lead to the downregulation of primitive spinal reflexes and the appearance of mature supraspinal control of voiding.[93]

Plasticity is therefore not a one-way process. Where inhibitory controls can be overlaid, they can also be removed. Disease processes can decrease or eliminate inhibitory influences, thereby unmasking the primitive neonatal reflexes. The urological sequelae of injury and disease, therefore, may not be a "new" change as much as an old reflex pathway that has reemerged. The classic example is the chilled water bladder test. Infants will develop involuntary bladder contractions when saline cooled to 4°C is instilled rapidly into the bladder. Mature children and adults can sense the cold but are able to maintain

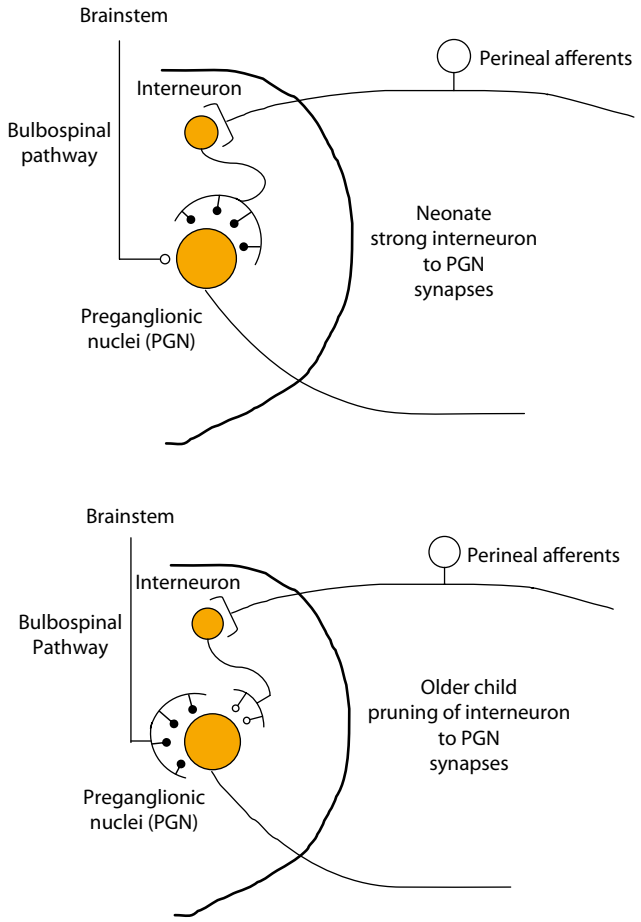

FIGURE 52.7 Schematic diagram showing possible anatomic changes at the synapses of the preganglionic nuclei in the sacral spinal cord of neonatal rats and kittens, which explain the changes during the first few weeks of life. Early in life, the interneurons bring greater active input (•) from the perineal afferents, but with maturation, these connections become pruned and downregulated (○). Input from the bulbospinal pathways then predominates.

control. Patients with neuropathic bladders are not able to do so. The cold receptors are mediated by C-fibers, and the chilled fluid response reflects unmasking of the neuropathology. It is positive until about age 4.[95,96] Further studies have shown that unmasking of reflexes can lead to structural changes that are not limited to the CNS and can occur in the periphery as well. In chronic spinal cord–transected cats, the afferent limb of the micturition reflex consists primarily of C-fiber afferents, whereas in intact cats, the pathways are myelinated alpha-delta afferents.[97]

Prior to maturation of the nervous system in the human fetus, urine is presumably eliminated by nonneural mechanisms. Later, voiding is initially regulated by a primitive reflex pathway organized in the spinal cord. As the CNS matures, this reflex voiding is eventually brought under voluntary control, which originates in the higher centers of the brain. As in animal models, a hierarchical control system overlays the more primitive components that are intrinsic to the target organs and spinal cord, as well as more complex components of the cerebral cortex. In adults, injuries and diseases of the CNS can lead to the reemergence of primitive functions that were suppressed during maturation.[98]

How do these observations correlate with the development of micturition control in humans? It appears that the process in humans does not occur suddenly. The process of maturation is not a simple switch from a primitive voiding reflex to the mature model but rather a gradual transition. Several observations support this viewpoint. First, small infants wake up to void when asleep.[99] By age 6 months, 90% of infants show signs of waking or arousal with voiding.[100] Another observation is that if an infant is disturbed while voiding, micturition halts or becomes interrupted. Longitudinal studies show increasing percentages of infants who arouse when voiding at night. This correlates with the degree of activation of cortical areas of the voiding reflex and to the degree of maturation.[99,100] Variable bladder volumes have also been noted, which causes doubt that threshold volume alone triggers voiding.[99–101] Interrupted voiding has been noted. This is defined as being two voids within 10 minutes. Seen in two-thirds of preterm and only one-third of full-term infants, it decreases over the first year and is not seen at all in the fully toilet-trained child. It is believed to be due to a form of DSD. Studies suggest that this dyssynergia may be a normal part of development.[102,103] There seem to be more interrupted voids in patients with posterior urethral valves (PUVs) and high-grade vesicoureteral reflux (VUR). Whether there is a more severe form of dyssynergia compared with the normal physiological form or an increase in hyperactivity of the neonatal detrusor is unclear. It also remains unknown if this observation has any relationship to bladder problems that can be associated with these conditions later in life (e.g., detrusor instability with VUR and myogenic detrusor failure with PUVs).[103,104] Increasing bladder capacity with age has been observed and leads to speculation that the stimulus for increasing bladder capacity is when the child begins to hold more urine at night, contrary to the conventional notion that daytime continence is a prerequisite for nighttime dryness.[101,102] Finally, increased hyperactivity is seen on cystometry during the first months of life and is felt to be a response to filling that is faster than normal and/or stimulus by the catheter. This fades as the neonate matures.[103] Increased reactivity of the detrusor may also be responsible for high voiding pressures. Voiding pressures of up to 100 cm H_2O have been measured in infants, which decreases to 70 cm H_2O by age 3 and continues to drop thereafter.[105]

These observations together suggest that the first few years of life mark an important transition period for infants and toddlers as they begin to shift over from a more primitive to a more mature micturition process. This transition seems to progress through a period where neither reflex pathway is clearly preeminent, thus explaining the higher voiding pressure, the hyperactive detrusor, and the period of physiologically normal DSD. The transition, therefore, in infants is not as abrupt and rapid as seen in animals. These findings and the earlier observation of the plastic nature of the micturition pathways and the reemergence of primitive pathways suggest that perhaps voiding dysfunction seen in childhood may have its roots in an incomplete transition to a more mature micturition pathway or the reemergence of the more primitive pathway.

Recent observations in the treatment of amblyopia ("lazy eye") suggest that plasticity may be dormant in adults and can be enhanced, trained, and perhaps induced pharmacologically. Originally, it was believed that if treatment (eye patching) were done too late (older than age 10 years), it would be ineffective because the brain would no longer be plastic enough to make the needed changes.[106] Reports of plasticity in adults with amblyopia challenged this long-held belief. Adults could experience spontaneous improvement of visual acuity in the amblyopic eye.[107,108] These studies are consistent with the notion that connections made early in life may be suppressed or inhibited and not destroyed. Brain plasticity in older children and adults may be more restricted because of physical and physiological "brakes" or limiters. Physical constraints from the myelin sheath restrict dendrite growth. Functional limiters may alter the balance between the excitatory and inhibitory stimuli to local neural circuits. The release of neurotransmitters like dopamine, serotonin, and norepinephrine could tilt the excitatory and inhibitory balance in favor of plasticity and overcome these limiters.[109,110] These observations lead to speculation that noninvasive induction or restoration of brain plasticity is possible even late in life by altering the balance of these excitatory and inhibitory neuromodulators. The treatment of amblyopia suggests two practical approaches to achieve this effect. First, rather than just depending on patching alone, systematic repeated eye exercises known as perceptual learning (PL) are prescribed. The use of PL has been shown to lead to improvement of overall acuity. Regular play of commercial off-the-shelf action video games can be more effective than the usual PL exercises.[111–113] Adults with amblyopia showed improvements of 13%–44% in visual acuity after regular play with their contralateral unaffected eye patched. There might be parallels to be drawn with the efforts to make biofeedback more effective by incorporating video games (see Chapter 55, Constipation and Lower Urinary Tract Symptoms).[114,115] The fundamental exercises (Kegel and others) of relaxing and contracting the pelvic muscles and urinary and anal sphincters are linked to visual goals and cues of a video game. This makes the process more fun for the patient but may promote this same plasticity effect. Second, it may be possible to reset plasticity by changing the excitatory and inhibitory balance pharmacologically. Chronic use of fluoxetine (Prozac™) has been shown to have an effect in adult rats with the murine equivalent of amblyopia.[116,117] This effect is believed to act on the Lynx1 mechanism. Lynx1 is a murine protein that appears to prevent plasticity in the primary visual cortex. Removing this molecular brake enhanced nicotinic ACh receptor signaling. Lynx1 expression is normally a positive factor by maintaining mature cortical networks in the presence of cholinergic innervation. Modulating the excitatory and inhibitory balance reactivates visual plasticity and may present a therapeutic target.[110]

CONCLUSIONS

Our understanding of the neurologic control of the storage and emptying of urine continues to deepen and broaden. Where once we only knew of a few neurotransmitters and a few basic reflex pathways, we now know of a dozen, along with their complex interplay. These pathways change with maturity but may never be completely lost. They may reemerge due to the plasticity of the nervous system. This plasticity may be a crucial target for future treatments and interventions for neurourologic conditions.

CHAPTER
53

Neurogenic Voiding Dysfunction and Functional Voiding Disorders: Evaluation and Nonsurgical Management

Emilie K. Johnson and Stuart B. Bauer

INTRODUCTION

Neurologic lesions that affect lower urinary tract (LUT) function cause at least 25% of the more severe clinical problems in pediatric urology. The advent of clean intermittent catheterization (CIC), introduced in the early 1970s by Lapides et al.,[1] and the refinements in techniques of urodynamic studies in children[2–4] dramatically changed the way these children were managed.[5] As a result, a greater understanding of the pathophysiology of the many diseases that primarily affect children, coupled with improved functional assessment of the LUT, has changed the treatment paradigm.[6,7] Now that it has been established that urodynamic studies can define children at risk for urinary tract deterioration, early aggressive and even proactive therapy have become the mainstay of management. Urodynamic testing is discussed in Chapter 51.

ASSESSMENT

All children with overt or suspected neuropathic bladder dysfunction (NBD) should undergo a thorough evaluation:

1. History
   a. Prenatal health
   b. Birth and development
   c. Perinatal complications
   d. Bowel and bladder habits
   e. Pattern of incontinence
   f. Bowel-emptying regimen
      i. Frequency, soiling
2. Physical examination
   a. Spine
   b. Lower extremities
      i. Deep tendon reflexes
      ii. Muscle mass and strength sensation
      iii. Gait
      iv. Perineal sensation, tone, reflexes
   c. Central nervous system (CNS)
      i. Handedness
      ii. Fine and gross motor coordination
3. Laboratory
   a. Urine analysis and culture
   b. Urine specific gravity
   c. Serum creatinine level
4. Radiography
   a. Renal and bladder sonography
   b. Voiding cystourethrography (VCUG)
   c. Spine radiograph—ultrasound, <3 months of age; magnetic resonance imaging (MRI), >3 months
5. Urodynamics
   a. Flow rate
   b. Residual urine (ultrasound or catheterized)
   c. Cystometrogram
   d. External urethral sphincter (EUS) electromyography (EMG)
   e. Static, filling, voiding urethral pressure profile

The history and physical examination are of paramount importance in the workup of children with NBD. The child's voiding habits prior to any injury and the current pattern of bladder emptying should be delineated. It is imperative to note whether the child voids voluntarily, spontaneously, or only with a Credé maneuver. Does the child have periods of dryness, or is there constant urinary leakage? Is the incontinence characterized by urgency and an inability to reach the toilet on time? Does the urine flow with a steady or intermittent stream or only dribble out during emptying? Does leakage occur with crying or laughing? Has the child had a urinary tract infection (UTI)? How much urine is produced each day? What is the pattern of bowel emptying? Is there fecal soiling?

Important components of the physical examination include an assessment of perianal and perineal sensation, anal sphincter tone, and the presence of bulbocavernosus and anocutaneous reflexes. Placing one's finger just at or slightly inside the external anal sphincter and briskly squeezing the glans penis or compressing the clitoris elicits the bulbocavernosus reflex. If the reflex is present, the external anal sphincter should contract. The anocutaneous reflex is elicited by scratching the pigmented skin directly adjacent to the anal opening, resulting in contraction of the perianal muscle. In children with

suspected NBD, complete evaluation of the back, including looking for agenesis of the sacrum, an abnormality of the gluteal cleft, or a cutaneous manifestation of an underlying occult spinal dysraphism, is important.[8–12] Examination of the lower extremities, comparing the muscle mass and strength of each leg, eliciting deep tendon reflexes, pinpointing sensory losses, and observing the gait may provide clues to the presence of an occult spinal dysraphism affecting not only the sacral but also the lumbar cord. Left-handedness in a family in which all members are right-handed, learning disabilities at school, poor fine and/or gross motor coordination, and attention deficit disorders all suggest the possibility of a central nervous disorder that might adversely affect LUT function.

CLASSIFICATION OF NEUROPATHIC BLADDER

The classification of NBD used in this chapter is that which has been adopted by the Urology Section of the American Academy of Pediatrics (AAP) in conjunction with the Urodynamic Society's classification, the International Continence Society (ICS),[13,14] and most recently, the International Children's Continence Society (ICCS).[15]

Under normal conditions, all portions of the LUT (detrusor, bladder neck, and EUS mechanism) function as a coordinated unit for adequate storage and efficient evacuation of urine. When a neurourologic lesion exists, these components usually fail to act in unison. A further refinement of the classification has been adopted based on dysfunction of a specific area of the vesicourethral unit and timing during the storage and/or voiding phase, rather than on a specific etiology:

1. Storage phase
   a. Detrusor tone
      i. Normal
      ii. Increased
         A. Detrusor overactivity (DO)
         B. Poor compliance
      iii. Diminished
         A. Good compliance
   b. Urethral closing mechanism
      i. Incompetent
         A. Bladder neck
         B. EUS
2. Voiding phase
   a. Detrusor contraction
      i. Normoactive
      ii. Underactive
         A. Unsustained
         B. Completely nonreactive
      iii. Overactive (highly contractile)
   b. Urethral closing mechanism
      i. Nonsynchronous (dyssynergic)
         A. Bladder neck
         B. EUS
      ii. Delayed opening
         A. Increased EMG lag time

Improper storage may be related to an alteration in detrusor function or an inadequate urethral closure mechanism. The bladder may have increased tone secondary to loss of muscle elasticity, and DO from excessive or unopposed sympathetic discharges, or due to a central lesion that prevents the normal inhibitory centers from influencing the sacral reflex arc. Incontinence may occur with any of these conditions despite a normal level of resistance in the bladder neck and urethra. Alternatively, incontinence may occur when the bladder neck and EUS areas do not provide adequate resistance during filling of the bladder or do not generate a reciprocal increase in outflow resistance as the bladder fills or abdominal pressure is raised. An injury to the spinal cord or nerve roots affecting the sympathetic, parasympathetic, or sacral somatic nervous system may alter both bladder neck and urethral sphincter tone. Periodic relaxation of the EUS during filling of the bladder, the result of loss of CNS inhibition, may also lead to urinary incontinence.

Incomplete evacuation of the bladder during the voiding phase may be due to an underactive detrusor muscle. A CNS lesion affecting the parasympathetic efferents may be responsible. However, nonsynchronous relaxation of the bladder neck or EUS area mechanisms (detrusor sphincter dyssynergia [DSD]) (Figure 53.1)[16] resulting from a lesion above the sacral cord, i.e., the pontine mesencephalic center or the cerebral cortex, can produce a similar effect. Myogenic failure occurs as the detrusor muscle hypertrophies, leading to DO, and then decompensates owing to persistent bladder outflow resistance. Eventually, this mechanism may produce overflow incontinence. Poor emptying can also occur as a result of delayed opening of the urethral sphincter. This abnormality manifests as an abnormally long lag time between voluntary detrusor contraction and pelvic floor relaxation, as seen on EMG.[17]

CONDITIONS: OVERVIEW

Congenital neurospinal dysraphisms (myelomeningocele, lipomeningocele, sacral agenesis, and other occult lesions) are the most common causes of NBD in children. However, a range of conditions can lead to pediatric NBD:

1. Neuropathic
   a. Spinal cord
      i. Congenital
         A. Neurospinal dysraphism
         B. Other anatomic
      ii. Acquired
         A. Trauma
         B. Tumor
         C. Infection
         D. Vascular
         E. Miscellaneous
   b. Supraspinal cord
      i. Anatomic or congenital
      ii. Trauma
      iii. Tumor
      iv. Infection
      v. Vascular

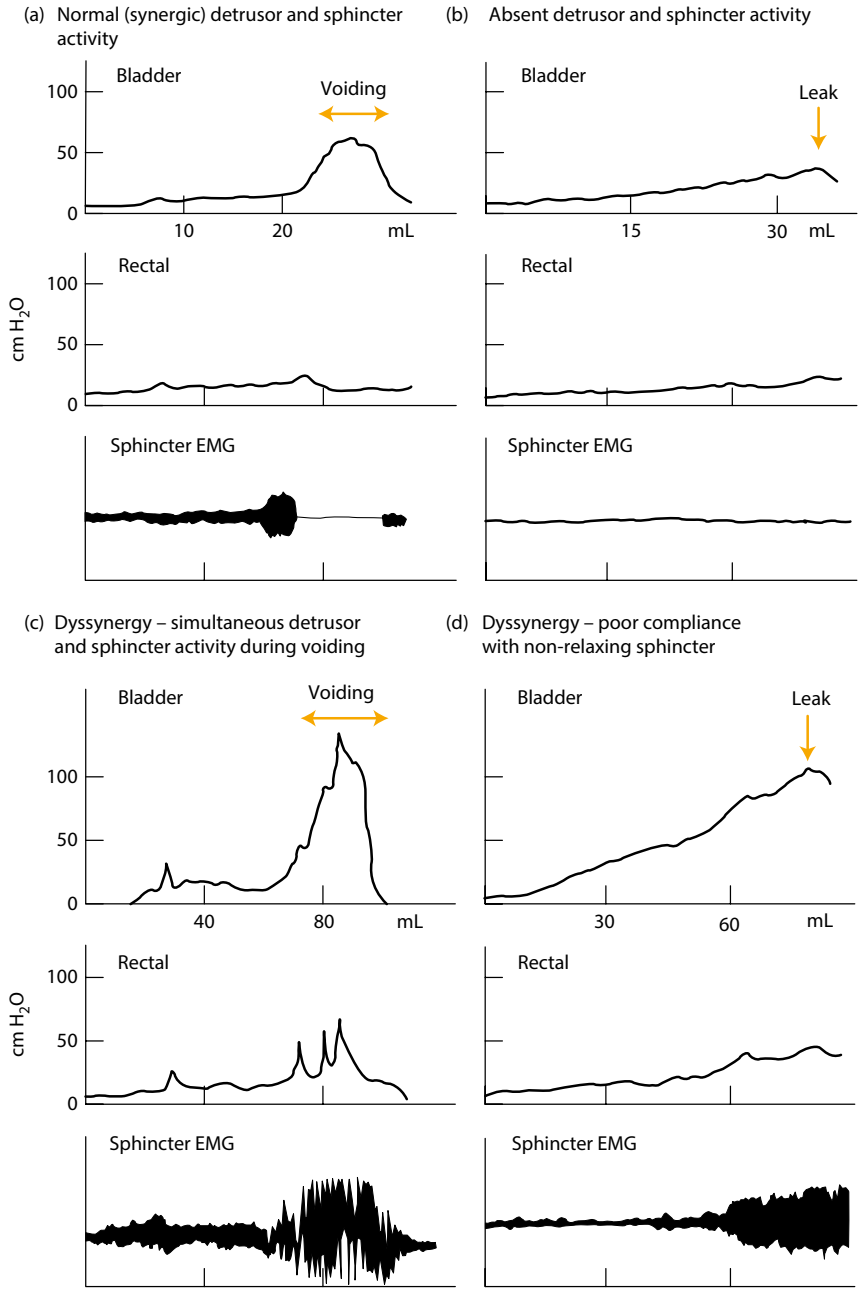

FIGURE 53.1 (a–d) Various patterns of urodynamic findings in newborns with myelodysplasia. Note that a hypertonic detrusor with a nonrelaxing sphincter (b) is also labeled dyssynergy. (Adapted from Bauer SB. Early evaluation and management of children with spina bifida. In King LR, ed., *Urologic Surgery in Neonates & Young Infants*. Philadelphia: Saunders, 1988, 252.)

vi. Degenerative
vii. Miscellaneous
viii. Temporary

c. Peripheral
i. Trauma
ii. Tumor
iii. Degenerative
iv. Guillain–Barré syndrome

2. Nonneuropathic
a. Anatomic
b. Myopathic
c. Psychological
d. Endocrinologic
e. Toxic

GENERAL TREATMENT STRATEGIES

Medical management of NBD regardless of etiology is based on the functional impairment produced by the specific neurologic defect:

1. DO or poor compliance
a. Oral anticholinergics—block detrusor cholinergic receptor sites

   b. Direct smooth muscle relaxants—relax detrusor
   c. Intradetrusor botulinum A toxin—inhibits acetylcholine release at the presynaptic cholinergic neuromuscular junction
   d. Urotherapy
2. Inadequate urethral resistance
   a. α-Sympathomimetics—stimulate bladder neck α_1 receptors to increase tone
   b. Dextronamer/hyaluronic acid injection—bladder neck bulking agent
   c. Urotherapy
3. Incomplete bladder emptying
   a. Cholinergic agonists—enhance detrusor contraction
   b. α-Sympatholytic agents—relax bladder neck
   c. Skeletal muscle relaxants—relax EUS
   d. EUS botulinum A toxin injection—relaxes EUS
   e. Urotherapy

Specific agents and typical doses are detailed in Table 53.1.

Lowering detrusor tone or abolishing overactive contractions with anticholinergics or direct smooth muscle relaxants aims to enhance inadequate storage capacity and decrease intravesical pressure. For patients refractory to oral agents, endoscopically injected botulinum A toxin (Botox™; Allergan, Inc.) may also be used. The effects of botulinum A are generally temporary, lasting approximately 6 months before repeat injection is necessary.[18,19] Our technique of Botox injection into the bladder is detailed in Video 53.1. Failure of conservative therapy to increase bladder capacity and lower detrusor tone results in the need for augmentation cystoplasty.

If inadequate urethral resistance is the primary reason for impaired storage of urine, the bladder neck mechanism, the EUS, or both, may be responsible. α-Sympathomimetics stimulate bladder neck α_1 receptors to enhance the tone of the muscles in this region. No drugs are commercially available that will increase the tone of denervated skeletal muscle in the EUS. The use of endoscopic bladder neck bulking agents, including dextronamer/hyaluronic acid (Deflux™; Salix Pharmaceuticals, Inc.), has also been described,[20–24] although results are mixed and incontinence due to low outlet resistance often ultimately requires surgical management.[25]

Incomplete emptying of the bladder may be due to an underactive bladder, unsustained detrusor contractions, or uncoordinated activity at the bladder neck and/or EUS. α-Sympatholytic agents or skeletal muscle relaxants may facilitate emptying. Although conflicting reports have been published regarding the efficacy of bethanechol, it does seem to improve emptying of the bladder in most instances.[26,27] Bethanechol (Urecholine™; Teva Pharmaceuticals) should be administered with α-sympatholytic agents because it also increases urethral resistance at the bladder neck. For patients who fail α-sympatholytic therapy, injection of botulinum A toxin into the EUS has been reported, with promising results.[28]

For children with functional causes of DO and/or incomplete emptying, urotherapy is the mainstay of treatment and pharmacologic therapies are largely adjunctive. The functional voiding disorders and their treatments are discussed in detail toward the end of the chapter.

NEUROSPINAL DYSRAPHISMS

Myelodysplasia

The most common etiology of NBD in children is abnormal spinal column development. During normal fetal maturation, the spinal canal closes cranially to caudally, completing the process by 35 days' gestation. Although the exact mechanism causing dysraphism is unknown, numerous factors, including genetic influences,[29,30] have been implicated. The incidence is estimated at 1 in 1000 births in the United States,[31] but there has been a decrease in this occurrence.[32] Two explanations are possible: first, with the advent of prenatal screening, many families are electing to terminate their pregnancies when they have affected fetuses,[33] and second, *the addition of folic acid supplements to the diet of women of childbearing age has reduced the incidence of spina bifida by more than 50%*.[34,35] If spina bifida is already present in one member of a family, there is a 2%–5% chance of a second sibling being born with the same condition.[36] The incidence doubles when more than one family member has a neurospinal dysraphism (Table 53.2).

Pathogenesis

Myelodysplasia is an all-inclusive term used to describe several abnormalities of the vertebral column. More specific labels regarding each abnormality include

- *Meningocele*: Just the meninges extend beyond the confines of the vertebral canal without any neural elements within it.
- *Myelomeningocele*: Neural tissue (nerve roots and/or portions of the spinal cord) has evaginated with the meningocele.
- *Lipomyelomeningocele*: Fatty tissue has developed with the cord structures, and both are protruding into the sac.

Myelomeningocele accounts for >90% of all the open spinal dysraphic states.[37] Most spinal defects occur at the level of the lumbar vertebrae, with the sacral, thoracic, and cervical areas being affected in decreasing order of frequency (Table 53.3).[38] In 85% of affected children, an associated Arnold–Chiari malformation is present; in such cases, the cerebellar tonsils have herniated to a variable degree down through the foramen magnum, obstructing the fourth ventricle, thus preventing cerebral spinal fluid from entering the subarachnoid space surrounding the brain and spinal cord.

The neurologic lesion produced by this condition is variable depending on which neural elements have protruded with the meningocele sac. The bony vertebral level often gives little or no clue as to the level of neurologic deficits. The height of the bony level and the highest extent of the neurologic lesion may vary from one to three vertebrae in each direction.[39] There may be differences in function from one side of the body to the other at the same neurologic level, and from one neurologic level to the next, as a result of asymmetry of affected neural elements. Children with thoracic and upper lumbar meningoceles often have complete reconstitution of their spine in the sacral area

TABLE 53.1 Oral (a) and endoscopic (b) therapy for neuropathic bladder dysfunction

(a) Type	Minimum dosage	Maximum dosage
Cholinergic		
Bethanechol (Urecholine; Teva Pharmaceuticals)	0.7 mg/kg tid	0.8 mg/kg qid
Anticholinergic		
Propantheline (Pro-Banthine; RPG Life)	0.5 mg/kg bid	0.5 mg/kg qid
Oxybutynin (Ditropan; Janssen Pharmaceuticals)	0.2 mg/kg bid	0.2 mg/kg qid
Glycopyrrolate (Robinul; Shionogi)	0.01 mg/kg bid	0.03 mg/kg tid
Hyoscyamine (Levsin; Alaven Pharmaceutical, LLC)	0.003 mg/kg bid	0.01 mg/kg qid
Tolteridine (Detrol; Pfizer)	0.03 mg/kg bid	0.1 mg/kg bid
Trospium (Sanctura; Allergan)	0.1 mg/kg bid	0.5 mg/kg bid
Darifenacin (Enablex; Novartis Pharmaceuticals Corp.)	0.1 mg/kg qd	0.5 mg/kg qd
Fesoterodine (Toviaz; Pfizer)	0.03 mg/kg qd	0.1 mg/kg qd
Solifenacin (Vesicare; Astellas Pharmaceuticals, Inc.)	0.05 mg/kg qd	0.3 mg/kg qd
Sympathomimetic		
Phenylpropanolamine (alpha) (Ornade; GlaxoSmithKline Pharmaceuticals, Inc.)	2.5 mg/kg bid	2.5 mg/kg tid
Ephedrine (alpha)	0.5 mg/kg bid	1.0 mg/kg tid
Pseudoephedrine (alpha) (Sudafed; Johnson & Johnson)	0.4 mg/kg bid	0.9 mg/kg tid
Sympatholytic		
Prazosin (alpha) (Minipress; Pfizer)	0.05 mg/kg bid	0.1 mg/kg tid
Phenoxybenzamine (alpha)	0.3 mg/kg bid	0.5 mg/kg tid
Propranolol (beta)	0.25 mg/kg bid	0.5 mg/kg bid
Doxazosin (alpha) (Cardura; Pfizer)	0.01 mg/kg qd	0.02 mg/kg qd
Smooth muscle relaxant		
Flavoxate (Urispas; GlaxoSmithKline Pharmaceuticals, Inc.)	3.0 mg/kg bid	3.0 mg/kg tid
Dicyclomine (Bentyl; Aptalys Pharmaceutical Technologies)	0.1 mg/kg tid	0.3 mg/kg tid
Other		
Imipramine (Tofranil; Covidien)	0.7 mg/kg bid	1.2 mg/kg tid
(b) Type	**Typical dosage**	
Anticholinergic—detrusor		
Botulinum toxin A (Botox; Allergan, Inc.)	10–12 IU/kg, up to a maximum of 300 IU	
Anticholinergic—sphincter		
Botulinum toxin A (Botox; Allergan, Inc.)	50–100 IU	
Bladder neck bulking agent		
Dextronamer/hyaluronic acid (Deflux; Salix Pharmaceuticals, Inc.)	1–10 mL	
Subureteric injection for reflux		
Dextronamer/hyaluronic acid (Deflux; Salix Pharmaceuticals, Inc.)	1–2 mL/ureter	

and will frequently have intact sacral reflex arc function. In fact, it is more likely for children with upper thoracic or cervical lesions to have just a meningocele and no myelocele, with no demonstrable loss of function. Finally, the differential growth rates between the vertebral bodies and the elongating spinal cord add a factor of dynamicism in the developing fetus that further complicates the picture.[40] Superimposed on all this is the Arnold–Chiari malformation, which may have a profound effect on the brainstem and pontine center involved in the control over LUT function.

Given this complicated anatomic relationship, LUT function is affected in a variety of ways and cannot be predicted just by looking at the spinal abnormality or the neurologic function of the lower extremities. This wide spectrum of dysfunction is evident when examining babies with sacral-level lesions.[41] Even careful assessment of the sacral area may not provide sufficient information to make

TABLE 53.2 Familial risk of myelodysplasia in the United States per 1000 live births

Relationship	Incidence
General population	0.7–1.0
Mother with one affected child	30–50
Mother with two affected children	100
Patient with myelodysplasia	40
Mother older than 35 years	30
Sister of mother with affected child	10
Sister of father with affected child	3
Nephew who is affected	2

a concrete inference. Therefore, urodynamic evaluation in the neonatal period is now standard. Urodynamics provide a clear picture of the function of the sacral spinal cord and LUT that helps predict risk for future urinary tract deterioration.[6,7,41–44]

Newborn Assessment

Ideally, urodynamic testing would occur immediately after the baby is born, but the risk of spinal infection and the urgency for closure have not made this a viable option. A 1990 study showed that fewer than 5% of children experience a change in their neurologic status as a result of the spinal canal closure.[45] Therefore, renal ultrasonography and a measurement of residual urine are performed as early as possible postnatally, with urodynamics delayed until it is safe to transport children and place them on their backs or sides for the test. For infants who cannot empty completely, CIC is begun, even before urodynamic testing. The normal bladder capacity in the newborn period is between 10 and 15 mL; thus, an acceptable residue of urine is <5 mL. Urine analysis and culture and serum creatinine should also be evaluated in the newborn.[46] Once the spinal closure has healed sufficiently, renal scintigraphy is performed to assess upper urinary tract function and drainage. VCUG is conducted if there is hydronephrosis and/or the urodynamic study demonstrates risk factors for upper urinary tract deterioration. Thus, urodynamics fulfill multiple objectives:[6,7,43,47]

1. They provide baseline information about the radiologic appearance of the upper and lower urinary tract, as well as the condition of the sacral spinal cord and the CNS.
2. They can be compared with later assessments, so that early signs of urinary tract deterioration or of progressive neurologic denervation can be detected.
3. They help to identify babies at risk for urinary tract deterioration as a result of poor compliance or outflow obstruction from DSD, which then allows prophylactic measures to be initiated before the changes actually take place.
4. They help the physician to counsel parents with regard to their child's future bladder and sexual function.

Findings

Ten to fifteen percent of newborns have an abnormal radiographic appearance to their urinary tract when first evaluated;[48] 3% have hydroureteronephrosis secondary to spinal shock, probably from the closure procedure,[49] whereas 10% have abnormalities that developed in utero as a result of abnormal LUT function in the form of bladder outlet obstruction (BOO).

Urodynamic studies in newborns have shown that 57% of infants with myelomeningocele have bladder contractions. This is especially true in children with upper lumbar or thoracic lesions who have sparing of the sacral spinal cord, 83% of whom have detrusor contractions.[50] Forty-three percent have an underactive bladder, and compliance during bladder filling is either good (25%) or poor (18%) in this subgroup.[7] EMG assessment of the EUS demonstrates an intact sacral reflex arc with no evidence of lower motor neuron (LMN) denervation in 47% of newborns, whereas partial denervation is seen in 24% and complete loss of sacral cord function is noted in 29%.[51] One recent study suggested that a higher degree of cerebellar herniation on MRI was associated with more severe postnatal bladder function.[52]

Combining bladder contractility and EUS activity results in three categories of LUT dynamics: synergic; dyssynergic, with and without poor compliance; and complete denervation (Figure 53.1).[7,43] Synergy is characterized by complete silencing of the sphincter during a detrusor contraction or when capacity is reached at the end of filling. Voiding pressures are usually within the normal range. Dyssynergy occurs when the EUS fails to decrease, or increases its activity during a detrusor contraction or a sustained increase in intravesical pressure, during bladder filling.[53] Frequently, a poorly compliant bladder with high intravesical pressure is seen in conjunction with DSD, resulting in a bladder that empties only at high intravesical pressure.[42,43] Complete denervation is noted when no bioelectric potentials are detectable in the region of the EUS at any time during the micturition cycle or in response to a Credé maneuver or sacral reflex stimulation.

Categorizing LUT function in this way is useful because it defines which children are at risk for urinary

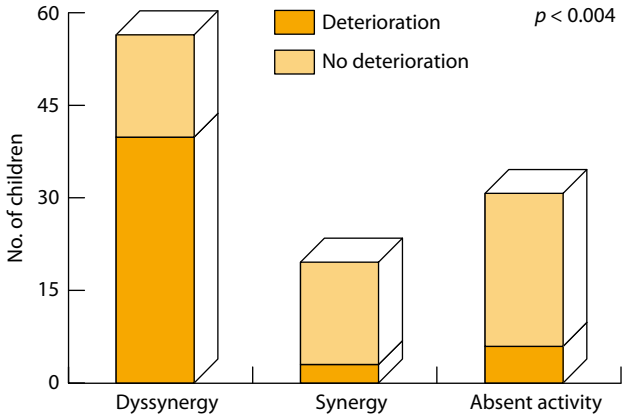

FIGURE 53.2 Urinary tract deterioration is related to outflow obstruction and most often associated with dyssynergy. Children with synergy converted to dyssynergy and patients with complete bladder denervation developed fibrosis with a fixed high-outlet resistance in the external sphincter, before any changes occurred in the urinary tract. (Adapted from Bauer SB. Early evaluation and management of children with spina bifida. In King LR, ed., *Urologic Surgery in Neonates & Young Infants*. Philadelphia: Saunders, 1988, 252.)

tract changes, which should be treated prophylactically, which need close surveillance, and which can be followed at greater intervals without fear of deterioration. On initial assessment or subsequent studies, 71% of newborns with DSD had urinary tract deterioration within the first 3 years of life, whereas only 17% of synergic voiders and 23% with a completely denervated sphincter developed similar changes (Figure 53.2). When the upper urinary tract of the infants in the synergic group deteriorated, it did so only after the infants converted to a dyssynergic pattern. Among the infants with complete denervation, the only babies with hydronephrosis were those who had elevated levels of urethral resistance, presumably due to fibrosis of the skeletal muscle component of the EUS. Thus, it appears that BOO is a major contributor to the development of urinary tract deterioration in these children (Figure 53.3). Bladder tonicity plays an important but somewhat less critical role in this regard,[6] although detrusor compliance seems to be worse in children with high levels of outlet resistance.[54] This combination of parameters (poor compliance and high outlet resistance) is very provocative for the development of hydroureteronephrosis,[55,56] whereas DSD is a significant factor in the onset of vesicoureteral reflux (VUR) (Figure 53.3).[57] First Bloom and associates[58] and then Park and associates[59] noted an improvement in compliance when outlet resistance was lowered following gentle urethral dilation in these children; however, the reasons for this are unclear and the long-term effect of this maneuver on ultimate continence and upper urinary tract function remains uncertain.

Specific Recommendations

Because expectant treatment has revealed that infants with BOO due to DSD or denervation fibrosis are at considerable risk for urinary tract deterioration, the idea of prophylactically treating the children has emerged as an important alternative to expectant therapy. When CIC is initiated in newborns, it becomes easy for parents to master, even in uncircumcised boys, and for children to accept as they grow older.[60] Complications of meatitis, epididymitis, or urethral injury are rare, and symptomatic UTI occurs in fewer than 30%,[61] although asymptomatic bacteriuria can be seen in almost 70%.[62]

CIC alone or in combination with anticholinergic agents, when detrusor filling pressures are >40 cm H_2O and voiding pressures reach levels of >80–100 cm H_2O, has resulted in only an 8%–10% incidence of urinary tract deterioration (Figure 53.4).[61,63,64] This represents a significant

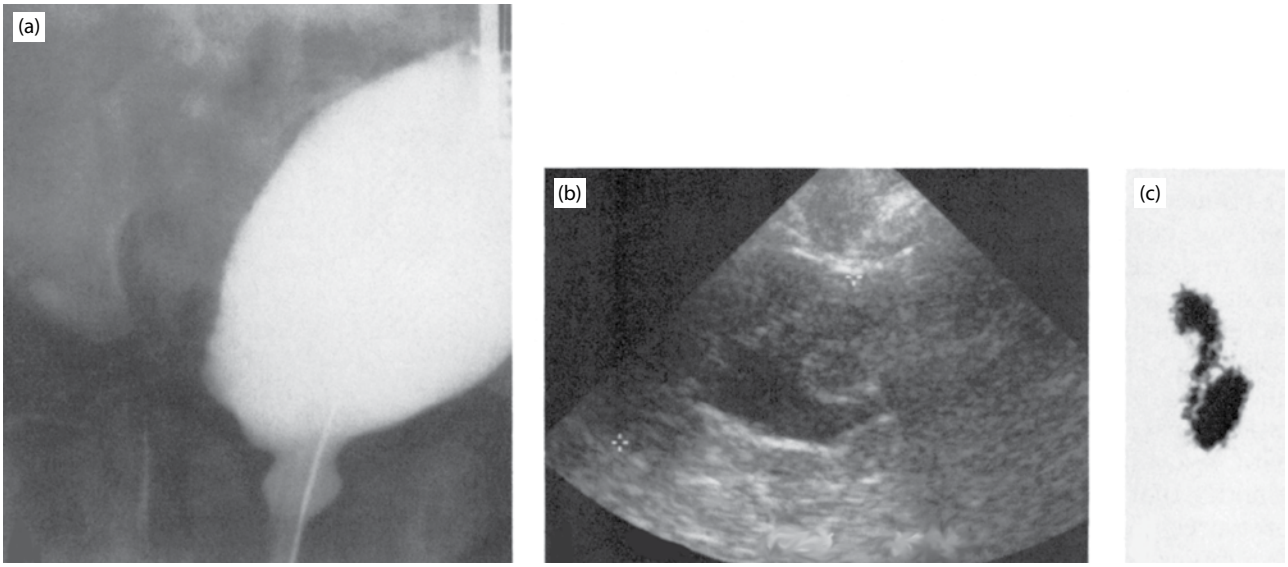

FIGURE 53.3 (a) VCUG in a newborn girl with dyssynergy and elevated voiding pressures demonstrated no reflux and a smooth-walled bladder. Her initial renal echogram was normal. She was started on CIC and oxybutynin (Ditropan) but did not respond. Within 1 year, she had right hydronephrosis (b) and severe reflux on a radionuclide cytogram (c).

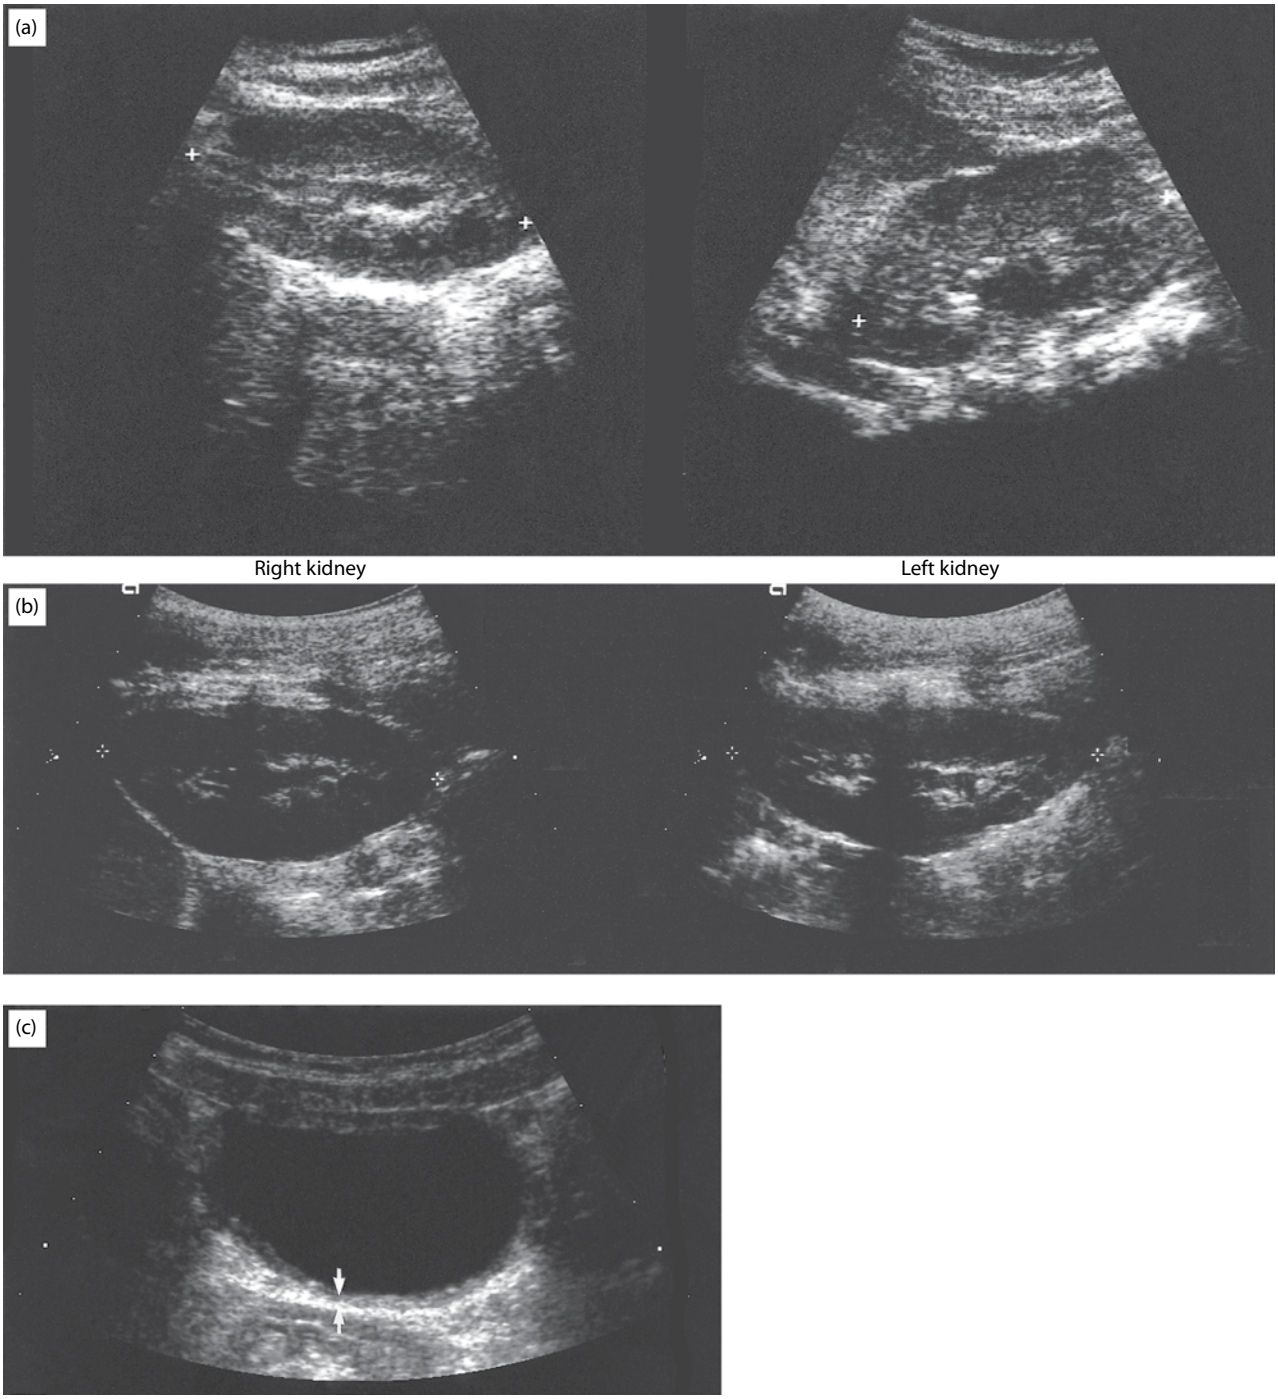

FIGURE 53.4 A newborn boy with DSD was successfully treated with CIC and oxybutynin. Over a 14-year period, his kidneys have remained normal by renal ultrasound (a and b) and his bladder wall has not increased its thickness (c).

drop in the occurrence of detrimental changes compared with children followed expectantly.[6,7,43] For infants, oxybutynin is administered in a dose of 1.0 mg/year of age, every 12 hours, in order to help lower detrusor filling pressure. In neonates or children younger than 1 year of age, the dose is lowered to below 1.0 mg in relation to the child's age at the time and increased proportionately as the child approaches 1 year. Subsequent management should be guided by the pattern of NBD, as detailed earlier in the chapter.

Follow-Up

The neurourologic lesion in myelodysplasia is dynamic with changes taking place throughout childhood,[65–67] especially in early infancy,[51] and then at puberty,[68] when the linear growth rate accelerates again. When a change is noted on neurologic, orthopedic, or urodynamic assessment, radiologic investigation of the CNS often reveals (1) tethering of the spinal cord, (2) a syrinx or hydromyelia of the cord, (3) increased intracranial pressure due to a shunt

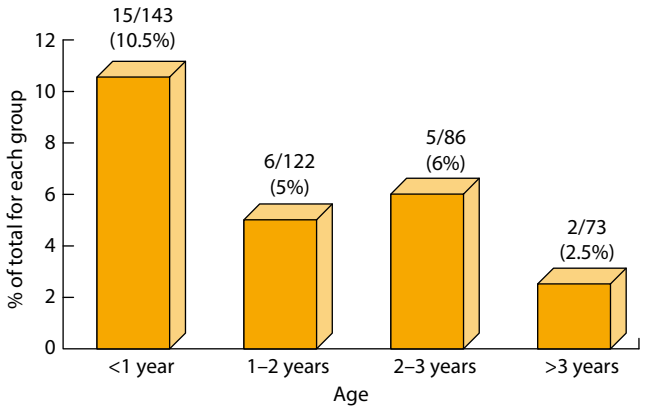

FIGURE 53.5 Propensity for deterioration in EUS innervation is greatest in the first year of life, with a decreasing incidence noted subsequently. (Adapted from Bauer SB. Early evaluation and management of children with spina bifida. In King LR, ed., *Urologic Surgery in Neonates & Young Infants*. Philadelphia: Saunders, 1988, 252.)

malfunction, or (4) partial herniation of the brainstem and cerebellum. Children with completely intact or only partially denervated sacral cord function are particularly vulnerable to progressive changes.

Most children who change tend to do so in the first 3 years of life (Figure 53.5). Thus, yearly urodynamics from birth to 5 years of age provide the means for carefully following children to detect signs of change, offering the hope that early detection and neurosurgical intervention may help to arrest or reverse a progressive pathologic process. All babies with myelodysplasia should be observed according to the guidelines set forth in Table 53.4. Urodynamics should also be repeated when the upper urinary tract dilates secondary to impaired drainage from a hypertonic detrusor, recurrent UTIs develop, or incontinence occurs after a prolonged period of dryness.

TABLE 53.4 Surveillance in infants with myelodysplasia[a]

Sphincter activity	Recommended tests	Frequency
Intact—synergic	Postvoiding residual	Every 4 months
	Renal ultrasound	Every 12 months
	UDS	Every 12 months
Intact—dyssynergic[b]	Renal ultrasound	Every 12 months
	UDS	Every 12 months
	VCUG or RNC[c]	Every 12 months
Partial denervation	Postvoiding residual	Every 4 months
	Renal ultrasound	Every 12 months
	UDS[d]	Every 12 months
	VCUG or RNC[c]	Every 12 months
Complete denervation	Postvoiding residual	Every 6 months
	Renal ultrasound	Every 12 months

Abbreviations: UDS, urodynamic study; RNC, radionuclide cystography.
[a] Until the age of 5 years.
[b] Patients on intermittent catheterization and anticholinergic agents.
[c] If detrusor hypertonicity or reflux already present.
[d] Depending on degree of denervation.

Management of Reflux

VUR occurs in 3%–5% of newborns with myelodysplasia, usually in association with poor compliance and/or dyssynergia.[63,69] If left untreated, the incidence of reflux in these at-risk infants increases with time until 30%–40% are afflicted by 5 years of age,[69] with even higher levels noted in older children.[57]

In children with mild to moderate reflux (I–III), who void spontaneously, or who have complete lesions with little or no outlet resistance and empty their bladder completely, management consists of antibiotic prophylaxis to prevent recurrent infection. Children with high-grade reflux (grade IV or V) and/or who cannot empty their bladders spontaneously, regardless of the grade of reflux, undergo CIC to ensure complete emptying. Children with DO, with or without hydroureteronephrosis, are also treated with anticholinergics to lower intravesical pressure and ensure upper urinary tract decompression. This strategy results in reflux resolution in 30%–55% and preserved renal function.[60,69–73] Although bacteriuria can be seen in as many as 56% of children on CIC, generally it is not harmful except in the presence of high-grade reflux because symptomatic UTI and renal scarring rarely occur with low-grade VUR.[70,74]

Credé voiding is to be avoided in children with reflux and a reactive EUS. Under these conditions, Credé results in a reflex response of the EUS that increases urethral resistance and raises the pressure needed to expel urine from the bladder (Figure 53.6).[75] This aggravates the degree of reflux and increases upper urinary tract dilation. Vesicostomy drainage[8,76] is reserved for children (1) who have such severe reflux that CIC and anticholinergic medication fail to improve upper urinary tract drainage, or (2) whose parents cannot adapt to the catheterization program.

The indications for antireflux surgery are similar to those for children with normal bladder function and include recurrent symptomatic UTI while on adequate antibiotic therapy and appropriate catheterization techniques, persistent hydroureteronephrosis despite effective emptying of the bladder and lowering of intravesical pressure, severe reflux with an anatomic abnormality at the ureterovesical junction, and reflux persisting into puberty. In addition, children with any grade of reflux who are being considered for implantation of an artificial urinary sphincter or another procedure designed to increase bladder outlet resistance should have the reflux corrected at the time of or prior to the anti-incontinence surgery.

Jeffs et al.[77] noted that antireflux surgery could be very successful in children with NBD as long as it is combined with measures to ensure complete bladder emptying. Since the advent of CIC, success rates for antireflux surgery have approached 95%.[70,78–80] Unilateral reflux does not warrant bilateral reimplantation, because the incidence of contralateral reflux postoperatively is insignificant.[79] The endoscopic injection of dextronamer/hyaluronic acid has altered the management of reflux in children with myelomeningocele, but long-term salutary effects are yet to be appreciated.[81,82]

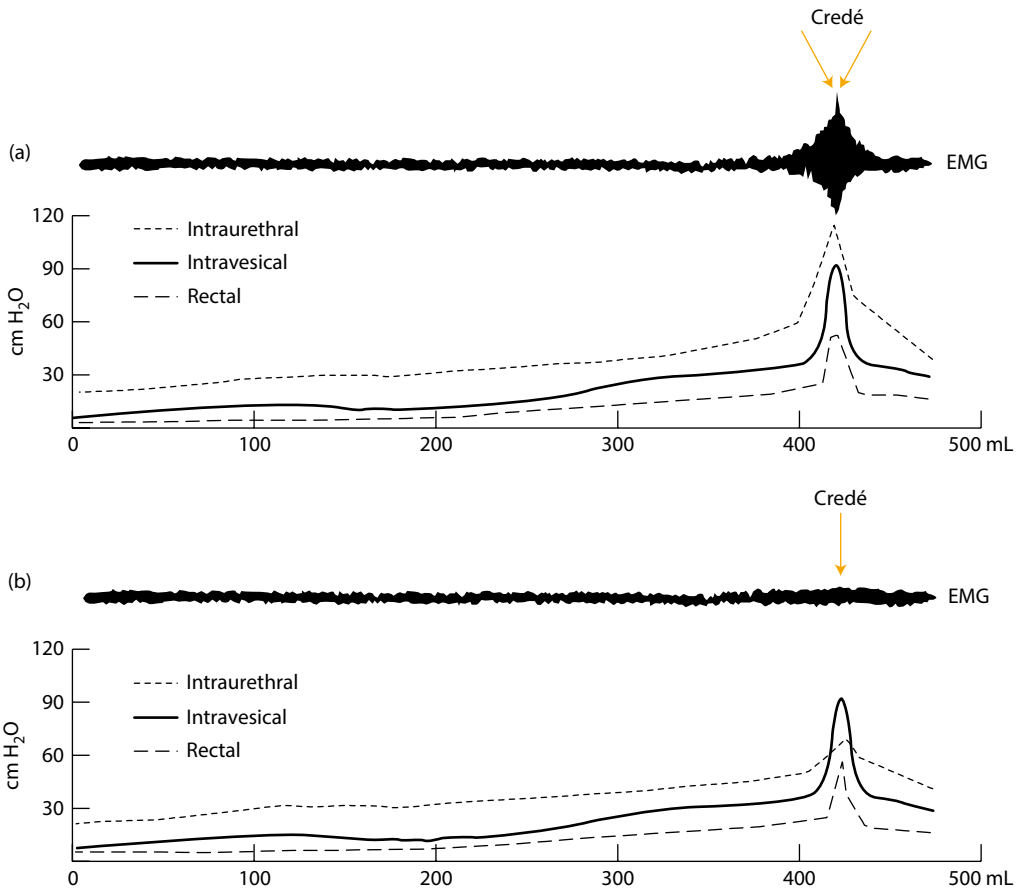

FIGURE 53.6 (a) When the external sphincter is reactive, a Credé maneuver produces a reflex increase in EMG activity of the sphincter and a concomitant rise in urethral resistance, resulting in high voiding pressure. (b) A child whose sphincter is denervated and nonreactive will not have a corresponding rise in EMG activity, urethral resistance, or voiding pressure. A Credé maneuver here will not be detrimental. (Adapted from Bauer SB. Early evaluation and management of children with spina bifida. In King LR, ed., *Urologic Surgery in Neonates & Young Infants*. Philadelphia: Saunders, 1988, 252.)

Continence

Urinary and fecal continence are becoming increasingly important issues to address at an early age as we strive to help children with myelodysplasia adapt socially. Initial attempts at achieving urinary continence include CIC and drug therapy designed to maintain low intravesical pressure and a reasonable level of urethral resistance. Although this approach can be administered on an empiric basis, it is more efficient to determine treatment protocols based on urodynamic findings. As a result, urodynamic testing is performed if initial attempts with CIC and oxybutynin fail to achieve continence.

Urodynamic findings guide further therapy, as detailed in the "General Treatment Strategies" section earlier in this chapter.

Fecal continence is also an important social issue for children with myelomeningocele, especially as they reach adolescence.[83] In addition to dietary maneuvers, intravesical bladder stimulation has helped with fecal continence,[84] but the most impressive results have come from the Malone antegrade continence enema (MACE) procedure. A continent catheterizable conduit is created from the colon to the anterior abdominal wall using the appendix or a narrowed reconfigured segment of bowel. The cecal end of the conduit is implanted in such a manner as to prevent leakage. An enema solution consisting of either GoLYTELY™, saline, or tap water is instilled nightly or every other night, cleansing the distal bowel within a short time, and resulting in fecal continence for up to 2–3 days at a time. Although equal continence rates have been observed with antegrade and retrograde enemas,[85] the MACE allows older children to become independent in managing their bowel function, which leads to improved self-esteem and social functioning.[86,87] Despite the advantages and promise of the MACE procedure, stomal complications and reoperations are common, a risk that patients and families should understand from the outset.[88,89]

Sexuality

Sexuality in this population has become an increasingly important issue to address as more individuals reach adulthood and desire marriage or other meaningful long-term romantic relationships.[90] Few studies are available, however, that critically evaluate sexual function in these patients.

In one study, researchers interviewed a group of affected teenagers and reported that at least 28% of them had one or more sexual encounters, and almost all had a desire to marry and ultimately bear children.[90] In another study,[91]

57 men were questioned regarding their sexual history: 41 (72%) had erections and 27 of them (66%) had ejaculations. Twenty men said they had had sexual intercourse, but only 11 attempted to father children, of whom 8 were successful. Overall, 12 men (21%) were married. Another study revealed that 70% of myelodysplastic women were able to become pregnant and have an uneventful pregnancy and delivery, although urinary incontinence in the latter stages of gestation and cesarean section were common.[92] In the same study, 17% of males claimed that they were able to father children. It is more likely for males to have problems with erectile and ejaculatory function because of the frequent neurologic involvement of the sacral spinal cord, whereas reproductive function in the female, which is under hormonal control, is not affected. However, the level of the neurologic lesion is not completely predictive of ultimate sexual function in men.[91]

In addition to understanding what the precise anatomical sexual function is in an individual, understanding the individual's sexuality as the ability to interact with a partner in a fulfilling and lasting way is just as important. Sexual identity, education, and social mores are issues that have been taken out of the realm of secrecy and are now openly discussed with and taught to patients with myelodysplasia,[93–96] although relatively few patients receive sex education specific to individuals with their condition.[97] Boys reach puberty at an age similar to that for normal males, whereas breast development and menarche tend to start as much as 2 years earlier than usual in myelodysplastic females. The etiology of this early hormonal surge is uncertain, but it may be related to pituitary function changes in girls secondary to their hydrocephalus.[98] The degree of sexuality attained by most is inversely proportional to the level of neurologic function; a lower lesion level has been correlated with a greater likelihood of sexual activity.[99] Note that the level of lesion does not correlate with the degree of sexual satisfaction in patients with myelodysplasia.[100]

Lipomeningocele and Other Spinal Dysraphisms

Diagnosis

A group of congenital defects that affects formation of the spinal column but does not result in an open vertebral canal has been labeled occult spinal dysraphisms[101] and includes

- Lipomeningocele
- Intradural lipoma
- Split cord syndrome (diastematomyelia)
- Tight filum terminale
- Dermoid cyst or sinus
- Aberrant nerve roots
- Anterior sacral meningocele (when occurring in conjunction with sacral agenesis—Currarino syndrome)
- Cauda equina tumor

These lesions may exist with no obvious signs, but 78%–90% of the children manifest a cutaneous abnormality overlying the lower spine.[11,102] The abnormalities include a small dimple or skin tag or a tuft of hair, a dermal vascular malformation, asymmetry of the gluteal cleft, and/or a very noticeable subcutaneous lipoma (Figure 53.7). On careful inspection of the legs, one may note a high-arched foot or alterations in the configuration of the toes, with hammer or claw digits. Other signs include a discrepancy in muscle size and strength between the legs, with weakness at the ankle, and/or a gait abnormality, especially in older children, as a result of shortness of one leg.[103–105] Absent perineal sensation and back pain are not uncommon symptoms in older children or young adults.[104,106,107] LUT function is abnormal in 40% of affected individuals.[108] The child may experience difficulty with urinary control (especially during the pubertal growth spurt), urinary retention, recurrent UTI, and/or fecal soiling after an initial period of continence.

Findings

The majority of children evaluated in the newborn or early infancy period have a normal neurologic examination. Urodynamic testing, however, will reveal abnormal LUT function in about one-third of <18-month-old babies (Figure 53.8).[10,109] These studies may provide the only evidence for a neurologic injury involving the lower spinal cord.[109–111] When present, the most likely abnormality is an upper motor neuron (UMN) lesion characterized by DO and/or hyperactive sacral reflexes, with mild forms of DSD being noted less often. LMN signs with denervation potentials in the sphincter, or detrusor underactivity, occur in only 10% of very young children.

In contrast, practically all individuals in the group of >3 years of age who have not been operated on or have been belatedly diagnosed as having an occult dysraphism will have either a UMN and/or LMN lesion on urodynamic testing (92%) (Figure 53.8), or neurologic signs of lower extremity dysfunction.[106,109,111–113] There does not seem to be preponderance for one type of lesion over another (UMN vs. LMN), and often the child manifests signs of both.[112,114]

Pathogenesis

The neurologic findings of occult dysraphism may be related to (1) compression on the cauda equina or sacral nerve roots by an expanding lipoma or lipomeningocele,[115] or (2) tension on the cord from tethering secondary to differential growth rates between the bony and neural elements.[103] The stretching that occurs when there is forcible flexion and/or extension of the spinal cord leads to changes in oxidation–reduction of cytochrome oxidase, most notably in the lumbosacral spinal neurons.[116] *Under normal circumstances, the conus medullaris terminates just below the L-2 vertebra at birth and recedes upwards to T-12 by adulthood.*[117] When the cord does not "rise" secondary to one of these lesions, ischemic injury may ensue.[116,118] Correction of the lesion in infancy has resulted in not only stabilization but also improvement in the neurologic picture in some instances (Figure 53.9). Sixty percent of the babies with abnormal urodynamic findings preoperatively reverted to normal postoperatively, with improvement noted in 30%, whereas 10% worsened with time. In the older child, there is a less dramatic change following surgery, with only 27% becoming normal, 27% improving,

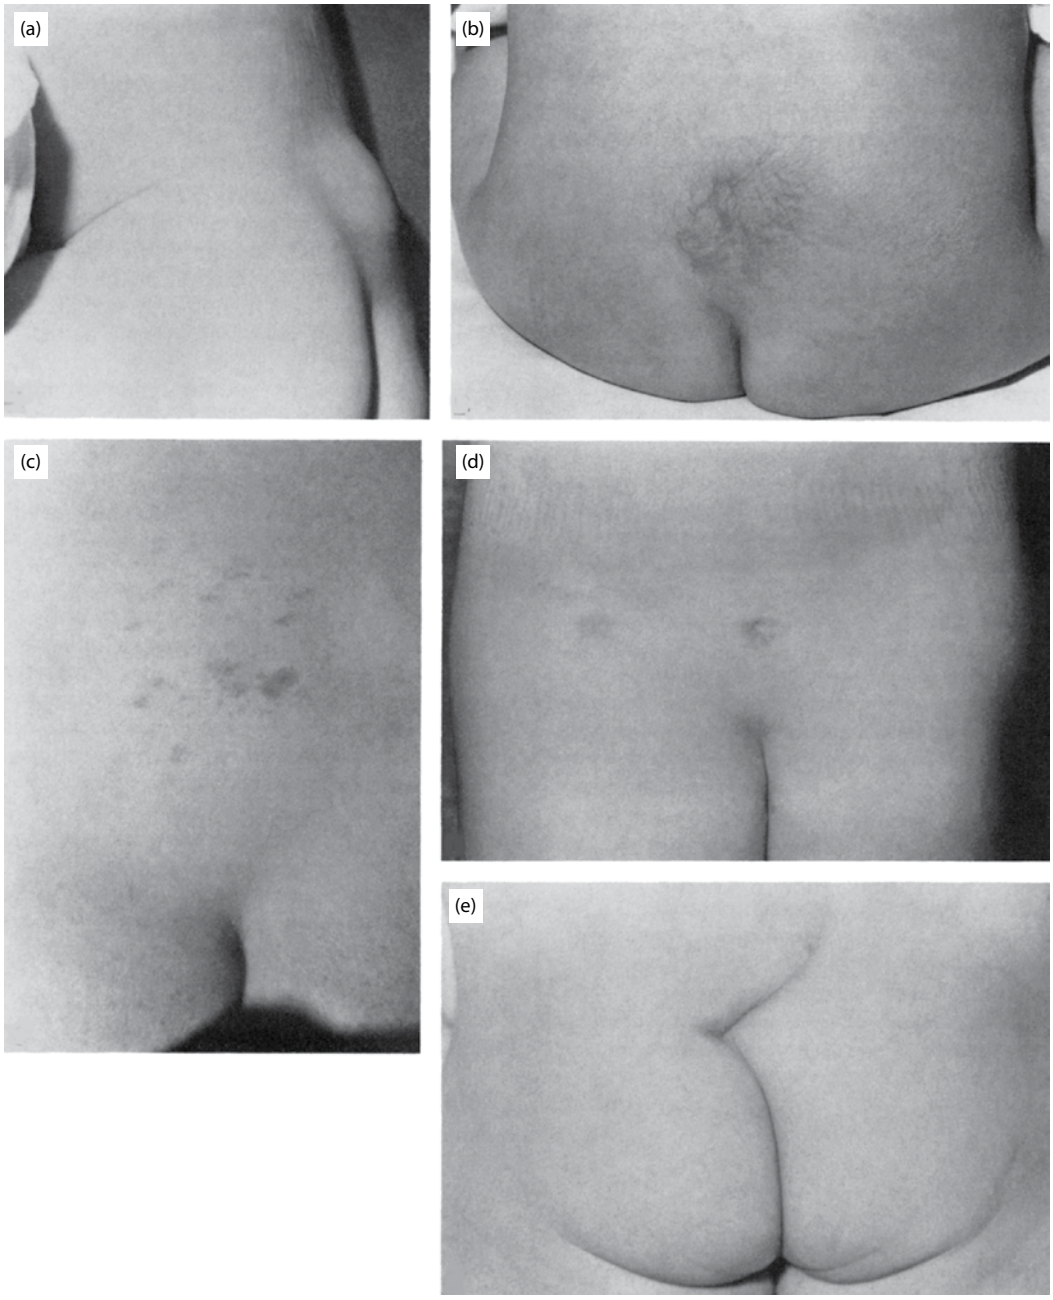

FIGURE 53.7 Cutaneous lesions occur in 90% of children with various occult dysraphic states. These lesions may vary from a small lipomeningocele (a) to a hair patch (b), a dermal vascular malformation (c), a dimple (d), or an abnormal gluteal cleft (e).

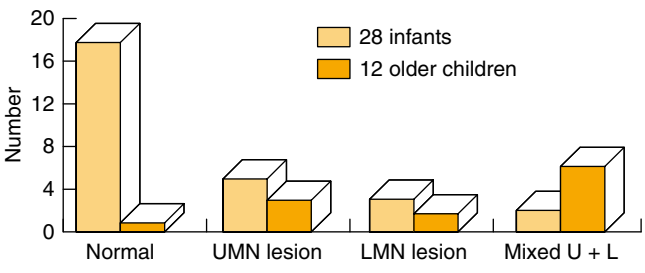

FIGURE 53.8 Most newborns with a covered spinal dysraphism have normal LUT function, whereas older children tend to have both UMN and LMN lesions. U + L = upper and lower motor neurons.

27% stabilizing, and 19% worsening (Figure 53.9).[109] The response to surgical untethering seems to be age related, with infants being more likely to improve than older children.[111] Older individuals with DO tend to improve, whereas those with an underactive bladder do not.[112,114,119] Finally, fewer than 5% of the children operated on in early childhood develop secondary tethering when observed for several years, suggesting that early surgery has both a beneficial and sustaining effect.

From these observations, it appears that urodynamic testing is the best method to determine whether an occult spinal dysraphism is affecting lower spinal cord function.[109,120] Some investigators have shown that posterior tibial somatosensory evoked potentials are an even more

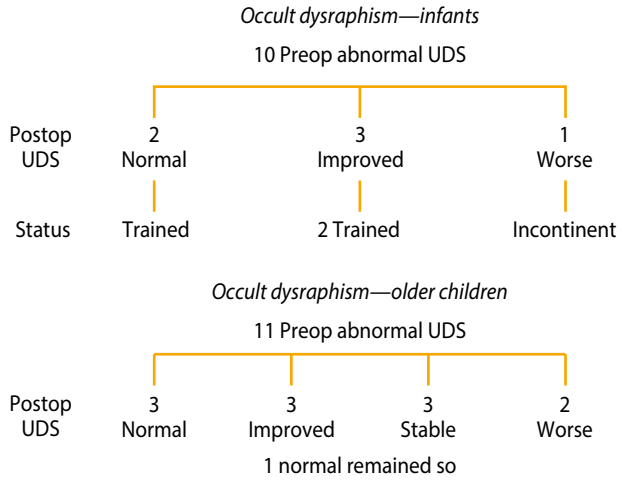

FIGURE 53.9 Potential for recoverable function is greatest in infants (6/10 [60%]) and less in older children (3/11 [27%]). The risk of damage to neural tissue at the time of exploration to those with normal function is small (2/19 [11%], not shown). UDS = urodynamic study.

sensitive indicator of tethering and should be an integral part of the urodynamic evaluation.[121] The implication is that early detection and intervention are both associated with reversibility of the lesion that is lost in the older child[115,118,122,123] and a degree of protection from subsequent tethering, which seems to be a frequent occurrence when the lesion is not treated expeditiously in infancy.[124]

Recommendations

Both MRI and urodynamics should be conducted in everyone who has a questionable skin or bony abnormality of the lower spine.[125–129] It is the most reliable way to detect a neurologic deficit involving the lumbosacral spinal cord initially, following surgical correction and as a means of predicting and identifying subsequent tethering, which can occur in 10%–20% of children.[129]

If the child is younger than 4 months of age, ultrasonography may be useful to image the spinal canal before the vertebral bones have ossified.[130,131] At this age, there is good correlation between the ultrasound and MRI findings, but the latter gives better definition of the lesion affecting the spinal cord.[132] Thus, ultrasound provides a screening modality, but spinal MRI is definitive.

In the past, removal of the superficial skin lesions without dissecting further into the spinal canal to remove or repair the entire abnormality was the standard treatment. Today, most neurosurgeons advocate laminectomy and removal of the intraspinal process as completely as possible without injuring the nerve roots or cord as soon as feasible after the diagnosis is made in order to release the tethering and prevent further injury that might ensue with subsequent growth.[105,107,110–112,123]

Sacral Agenesis

Sacral agenesis has been defined as the absence of part or all of two or more lower vertebral bodies. Although the etiology of this condition is still uncertain, a number of factors have been implicated. Teratogenic factors may play a role; *insulin-dependent mothers have a 1% chance of giving birth to an affected child. Conversely, 16% of children with sacral agenesis have a diabetic mother.*[133,134] Maternal drug exposure to minoxidil has also been reported as a cause.[135] In cases of sacral agenesis associated with the Currarino syndrome (presacral mass, sacral agenesis, and anorectal malformation), deletions have been identified in chromosome 7q, resulting in mutations of HLXB9, which appears to be responsible for neural plate infolding.[136,137] Thus, sacral agenesis may represent one point on a spectrum of abnormalities that encompasses sacral meningoceles and anorectal malformations.[138]

Diagnosis

The diagnosis is often delayed until failed attempts at toilet training bring the child to medical attention.[134] Sensation, including perianal dermatomes, is usually intact, and lower extremity motor function is normal.[139–141] Sacral vertebral bony ossification begins at 15 weeks, so it is possible to detect the abnormality after 18 weeks of gestation by prenatal ultrasonography and confirm by fetal MRI.[142] The lesion is often overlooked because these children have normal sensation and little or no orthopedic deformity involving the lower extremities (although high-arched feet and/or claw or hammer toes may be present). The only clue, requiring a high index of suspicion, is flattened buttocks and a low or short gluteal cleft (Figure 53.10).[143] Palpation of the coccyx will detect the absent vertebrae.[144] *The diagnosis is confirmed with a lateral film of the lower spine, because this area is often obscured by overlying*

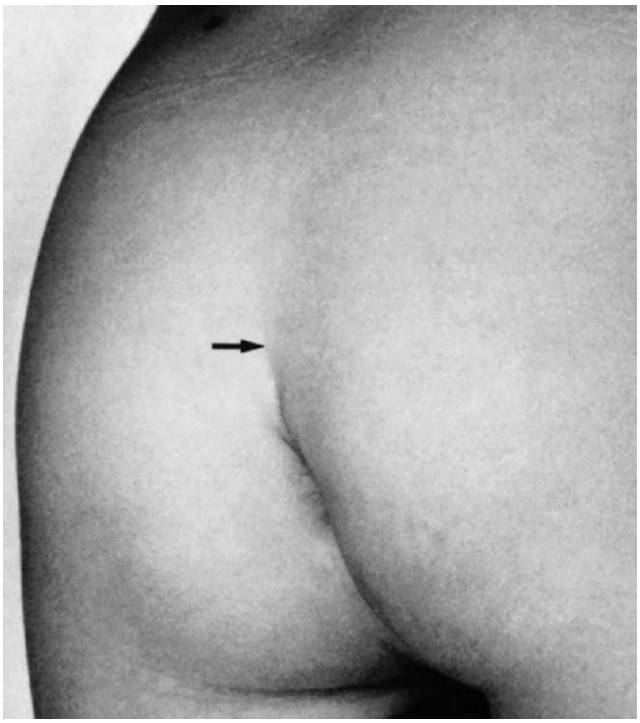

FIGURE 53.10 Characteristically, the gluteal crease is short and seen only inferiorly (below arrow) as a result of the flattened buttocks in sacral agenesis.

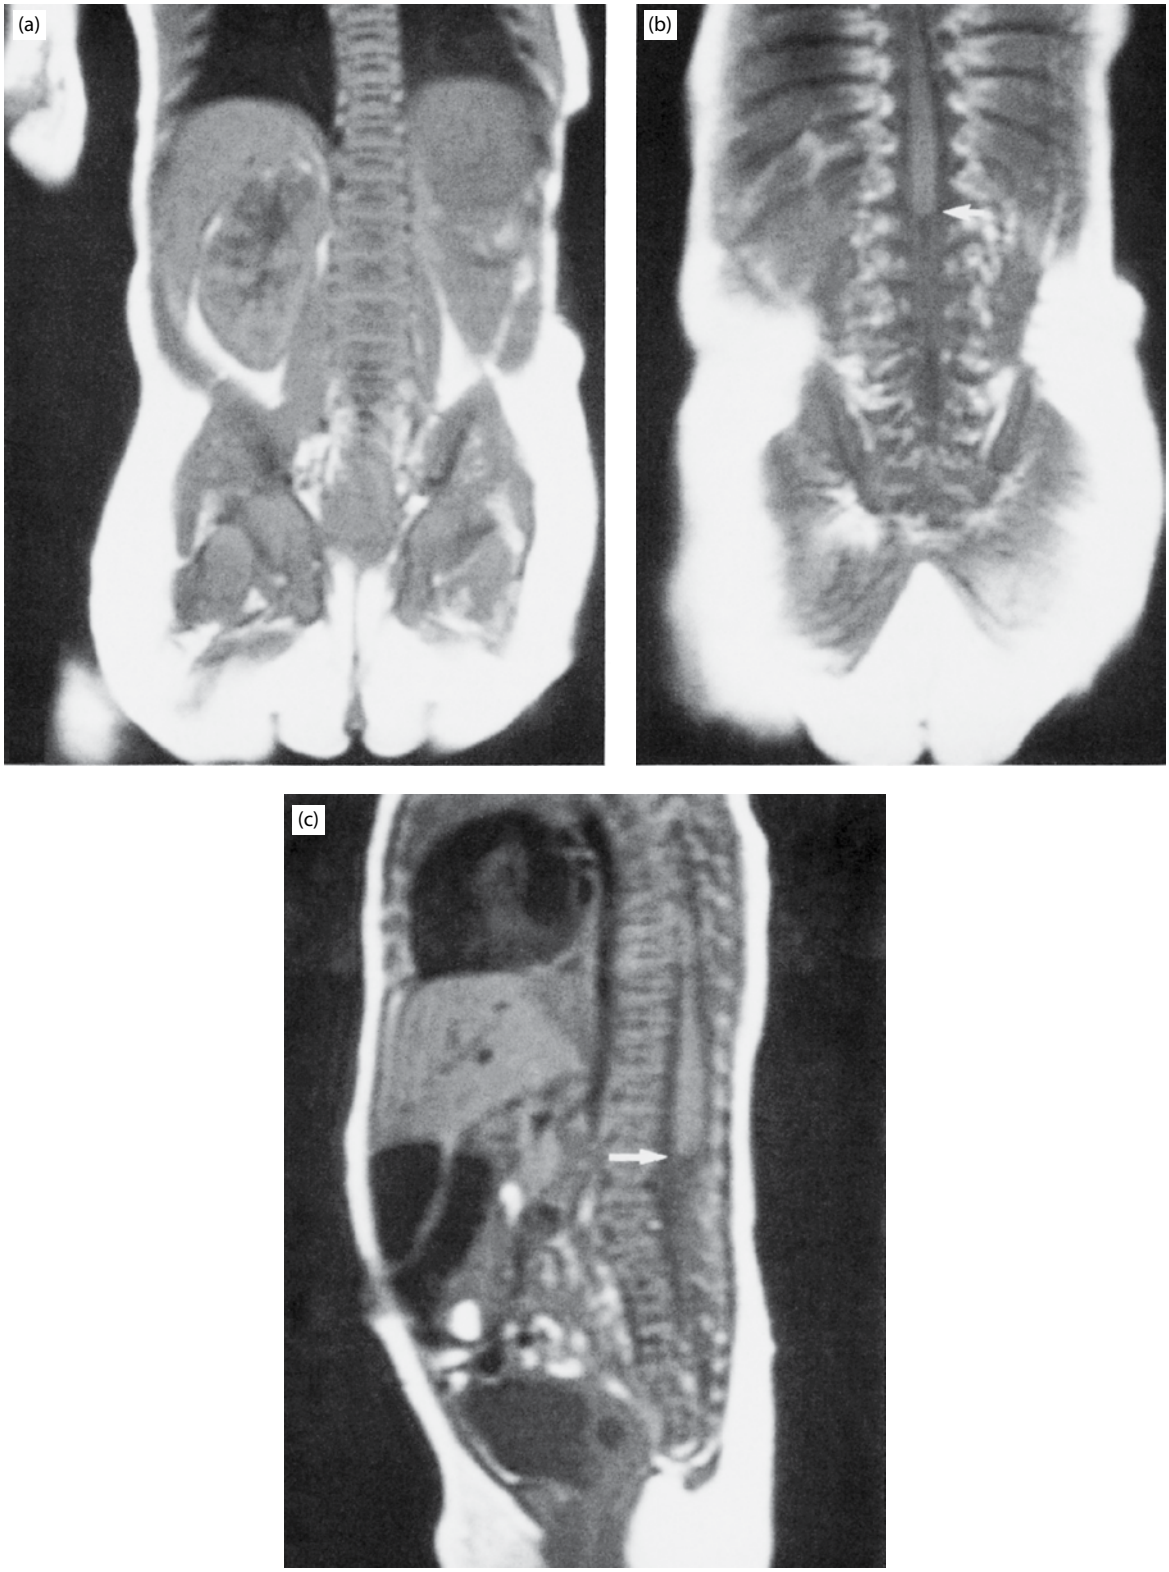

FIGURE 53.11 Coronal (a, left and right) and sagittal (b) magnetic resonance images in a 6-month-old girl with sacral agenesis at S-1 reveal a squared lower limit of the cord adjacent to T-12 (arrow). Note a solitary right kidney (a, left).

gas on an anteroposterior projection.[134,144] MRI has been used to visualize the spinal cord in these cases; a sharp cutoff of the conus opposite the T-12 vertebra seems to be a consistent finding (Figure 53.11).[145]

Urodynamic Findings

Urinary incontinence and recurrent UTIs are common in patients with sacral agenesis, occurring in 85% and 74% of patients, respectively.[12] When urodynamic studies are

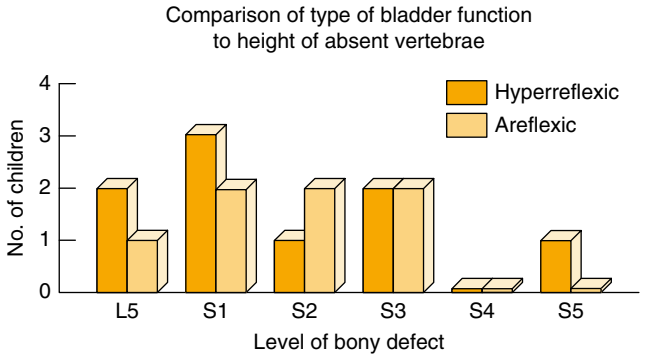

FIGURE 53.12 Bladder contractility is unrelated to the number of absent vertebrae. (Adapted from Bauer SB. Early evaluation and management of children with spina bifida. In King LR, ed., *Urologic Surgery in Neonates & Young Infants*. Philadelphia: Saunders, 1988, 252.)

undertaken, almost an equal number will manifest a UMN or LMN lesion (35% vs. 40%, respectively), whereas 25% have no signs of denervation at all.[134] The lesion is characterized by DO, exaggerated sacral reflexes, the absence of voluntary control over sphincter function, DSD, and no electromyographic evidence of denervation potentials in the urethral sphincter.[134,139,141,144] VUR occurs almost exclusively in children with poor compliance with or without dyssynergy.[146] An LMN lesion is noted when detrusor underactivity and partial or complete denervation of the EUS with diminished or absent sacral reflexes are seen. The bladder is usually small and smooth walled, with an open bladder neck.[146] The number of affected vertebrae does not correlate with the type of motor neuron lesion present (Figure 53.12). The lesion rarely shows signs of progression. It is unclear whether spinal cord detethering improves urodynamic parameters postoperatively.[147]

Recommendations

Management depends on the specific type of neurourologic dysfunction seen on urodynamics, as detailed previously in this chapter. Anorectal manometry has identified abnormalities in the internal anal sphincter and in voluntary anal sphincter squeeze pressure, leading to weakness of the muscle and fecal incontinence.[148] It is important to identify these individuals as early as possible so that they can be rendered continent at an appropriate age, avoiding the social stigmata of fecal and/or urinary incontinence.

Associated Conditions

Imperforate Anus

Imperforate anus is a condition that occurs alone or as part of a constellation of anomalies that has been called the VATER or VACTERL syndrome.[134] This mnemonic stands for the organs that possibly can be affected (V = vertebral, A = anal, C = cardiac, TE = tracheoesophageal fistula, R = renal, L = limb). This may be part of a spectrum of hindgut abnormalities that includes sacral agenesis and Currarino syndrome (discussed above).[29,147] Urinary incontinence is relatively rare unless there is coexisting spinal cord pathology or the pelvic floor muscles and/or nerves have been injured during the imperforate anus repair.[149] An abdominal plain film and an ultrasound of the spine and kidneys are obtained in the neonatal period regardless of the level of the rectal atresia, once the child has either stabilized or has had a colostomy performed.[150–152] Vertebral bony anomalies often signify an underlying spinal cord abnormality. Any hint of an abnormality on these studies or the presence of a lower midline skin lesion overlying the spine warrants an MRI to evaluate for a potentially pathologic intraspinal process.[153] If radiographic images demonstrate an abnormality, urodynamic studies are recommended. Urodynamics are also indicated before repair in the child with high imperforate anus who has undergone an initial colostomy. Abnormal findings may provide a reason to explore and treat any intraspinal abnormality in order to improve the chances of fecal and urinary continence. In addition, they furnish a baseline for future comparison, particularly for those children needing extensive surgery for their imperforate anus.

EMG studies of the perianal musculature help to define the optimal location for the future anus. Before the Peña operation (a posterior midline approach) was developed to correct a high imperforate anus, rectal incontinence was thought to be due to an injury involving the pelvic nerves that innervate the levator ani muscles.[154–156] Because the Peña approach is confined to the midline area, this procedure has reduced the chance of traumatizing nerve fibers that course laterally and around the bony pelvis from the spine to the urethral and rectal sphincter muscles. Despite careful dissection techniques, 37% of patients still have long-term problems with fecal incontinence.[157] Urodynamic and perianal EMG studies are repeated after imperforate anus repair, if fecal and/or urinary continence has not been achieved by a reasonable age or if urinary incontinence develops secondarily.

Thirty to seventy percent of affected children have a spinal abnormality even though they may not have any associated anomalies.[158,159] The incidence of NBD is related to the presence (64%) or absence (31.5%) of a sacral bony defect. Similarly, the level of the anal atresia determines the incidence of NBD, with supralevator atresia having a higher risk (70%) than infralevator (35%) lesions.[152] Boemers et al.[160] found impaired LUT function in 24% of 90 children; all but one had a sacral bony abnormality, suggesting an even closer association of dysfunction with abnormal bony spinal development. The abnormality may range from tethering of the spinal cord secondary to an intraspinal dysraphism producing a UMN type of dysfunction, to an atrophic abnormality of the conus medullaris, which leads to a partial or complete LMN lesion involving the LUT.[161] In these circumstances, urinary and fecal incontinence might be the child's only complaints. Because lower extremity function may be totally normal, an examination of the legs alone can be misleading.[159]

CENTRAL NERVOUS SYSTEM INSULTS

Cerebral Palsy

Etiology

Cerebral palsy (CP) is a nonprogressive injury to the brain in the perinatal period that produces a neuromuscular

disability or a specific symptom complex of cerebral dysfunction. In 2006, the prevalence of CP in the United States was estimated at 3.3 per 1000 children.[162] It is usually due to a perinatal infection or period of anoxia (or hypoxia) that affects the CNS.[163,164] CP most commonly appears in babies who were premature and of low birth weight, but it may be seen following a seizure, infection, or intracranial hemorrhage in the neonatal period.

Diagnosis

Affected children have delayed gross motor development, abnormal fine motor performance, altered muscle tone, abnormal stress gait, and exaggerated deep tendon reflexes. The findings can vary substantially from being very obvious to exquisitely subtle. Among the more overtly affected individuals, spastic diplegia is the most common of the five types of dysfunction that characterize the disease, accounting for nearly two-thirds of the cases.

Findings

Most children with CP develop total urinary control. Incontinence is a feature in some, but the exact incidence has never been truly determined.[165,166] Bladder dysfunction appears to be more common in children with a greater degree of motor dysfunction.[167] A 2001 survey of more than 600 families with an affected child aged 4–18 years demonstrated that 23.5% had persistent urinary incontinence.[168] When urinary continence was achieved, its development was delayed when compared with that of normal children of similar age. With further analysis of the data, 80% of children with spastic diplegia, 54% with tetraplegia, and 38% with low intellectual capacity attained continence. The presence of incontinence was related in part to the extent of the physical impairment because this prevents the individuals from reaching the toilet expeditiously. If the children are cognitively delayed, they either do not recognize the need to void or do not relate this fact to caregivers early enough to be toileted.[168] Some children have such a severe degree of cognitive delay that toilet training is not feasible, but the majority are able to attain social control, albeit at a later than expected age. Daytime continence is attained first, and nocturnal continence ensues within the subsequent year.[168] Therefore, urodynamic evaluation is reserved for children who appear trainable and not hampered by their physical impairment, but who have not achieved continence by later childhood or early puberty.

Several studies have examined urodynamic parameters in children with CP.[166,169] One series found only 29% of patients with CP and urinary symptoms had normal urodynamic findings, with reduced bladder capacity seen in 54% and DO seen in 35%.[170] The most typical pattern includes UMN dysfunction with DO and/or DSD. However, some patients also exhibit an LMN lesion, most of whom experienced an episode of cyanosis in the perinatal period. In a meta-analysis of all published reports of urodynamic findings in children with CP, DO was seen in 80%, DSD in 5%, and normal function in only 12%.[166,169,171] These reports suggest that urodynamic studies can be revealing in all children with CP,[169] and are especially useful if frequent toileting or initial anticholinergic treatment fails to improve incontinence, the child develops UTI, or hydronephrosis develops.

Recommendations

Therapeutic goals include treating DO with anticholinergics, but residual urine volume must be monitored closely. CIC may be required for those who cannot empty. Selective dorsal sacral rhizotomy has helped with spasticity and incontinence, with <5% developing incontinence if careful mapping delineates the dorsal sacral nerve roots.[172,173]

Traumatic Injuries to the Spine

Traumatic spinal cord injury (SCI) is a rare entity in children; the incidence in Sweden is 2.6 cases per million children per year,[174] and SCI accounts for only 1.3% of pediatric traumas in the United States.[175] Motor vehicle accidents are the most common mechanism overall.[174,176–178] Within specific age groups, infants are more prone to an injury from a motor vehicle accident (71%), toddlers and children secondary to a fall (48% and 34%, respectively), and adolescents due to a sporting event (29%).[177] SCI has also occurred iatrogenically following spinal and vascular surgery.[176,179] Newborns are particularly prone to hyperextension injuries during a high forceps delivery.[180,181]

The LUT dysfunction due to SCI is usually associated with loss of sensation and paralysis of the lower limbs. Radiologic investigation of the spine may not reveal any bony abnormality, even though momentary subluxation of osseous structures due to the high elasticity of vertebral ligaments can result in a neurologic injury.[182] This has been labeled spinal cord injury without radiologic abnormality (SCIWORA), and it can account for up to 38% of pediatric SCIs.[178] Imaging will show swelling of the cord below the level of the lesion, central disk herniation, spinal stenosis, or contusion.[180,181,183] Often, what appears initially as a permanent lesion turns out instead to be a transient phenomenon. Although sensation and motor function in the lower extremities may be restored relatively soon, the dysfunction involving the bladder and rectum may persist for considerably longer.

If urinary retention occurs immediately following the injury, an indwelling Foley catheter is inserted and left in place for as short a time as possible until CIC can be started safely.[184,185] When the child resumes voiding, CIC is used to measure residual urine; residuals of <25 mL are considered safe enough to allow for weaning and cessation of CIC as long as voiding pressures are not excessive (i.e., >60–70 cm H_2O).[185] If there is no improvement in urinary tract function after 4–6 weeks, urodynamics are conducted to determine whether the condition is the result of spinal shock, nerve root injury, or SCI. Sustained detrusor underactivity is not uncommon under these circumstances.[186] An EMG recording of the sphincter often reveals normal motor units without fibrillation potentials, but absent sacral reflexes, and a nonrelaxing sphincter with bladder filling indicates transient spinal shock.[186] The outcome from this latter condition is guarded but favorable; most cases resolve completely as edema of the cord in response to the injury subsides, leaving no permanent damage.[186,187]

Most permanent traumatic SCIs involve the upper thoracic or cervical spinal cord, but some affect the cauda equina region. Sacral SCI usually produces an LMN deficit of the striated sphincter that leads to low-pressure bladder emptying with little risk of upper urinary tract deterioration. However, it often necessitates medical and/or surgical therapy to achieve continence. Conversely, upper SCIs can produce a lesion associated with DO and DSD. The potential danger from this outflow obstruction is obvious.[188] Substantial residual urine volumes, poor compliance, high voiding pressure, reflux, UTIs, and their sequelae are the leading cause of long-term morbidity and mortality in SCI patients. Urodynamics will identify those patients at risk.[185] *Even if the child is continent and voiding to completion or requires CIC to empty, it is imperative to perform urodynamics to assess for risk to the upper urinary tract.*[189] *Early identification and proper management may prevent the signs and effects of BOO before they become apparent on x-ray examination of the urinary tract.*[190–192]

FUNCTIONAL VOIDING DISORDERS

Children without obvious neurologic disease may have a voiding abnormality on a functional or maturational basis. Most children gain urinary control before 5 years of age. Persistent day and night incontinence without a prolonged period of dryness or the recurrence of nocturnal wetting lasting into puberty is an indication for urodynamic evaluation in neurologically normal children. Although many children have normal urodynamic findings, greater than 30% of patients may have a dysfunctional voiding state.[193]

ICCS Classification of LUT Symptoms

In order to understand these disorders, it is helpful to recall the ICCS classification of various LUT symptoms and the specifics regarding urinary incontinence in children:[15]

1. Storage symptoms
   a. Increased or decreased voiding frequency
   b. Incontinence
   c. Urgency
   d. Nocturia
2. Voiding symptoms
   a. Hesitancy
   b. Straining
   c. Weak stream
   d. Intermittency
3. Other symptoms
   a. Holding
   b. Feeling of incomplete emptying
   c. Postmicturition dribble
   d. Genital or LUT pain

Urinary incontinence is defined by the ICCS as the uncontrolled leakage of urine; it can be continuous or intermittent, occurring during the daytime or nighttime. Continuous incontinence means leakage of urine all the time that denotes the probability of an ectopic ureter. It is abnormal at any age because even infants have a degree of cortical control over bladder emptying, void at reasonably spaced intervals, and stay dry between urinations. Daytime (diurnal) incontinence may be on an urgent or sudden basis, associated with stress activity, such as coughing or running, or occur just after voiding (only in girls, resulting from the vaginal trapping of urine during voiding that drips out afterwards). Nocturnal incontinence (enuresis) means the leakage of urine while asleep at an age when urinary control is expected. It is difficult, however, to say when this should occur. Studies of large groups of children have provided some guidelines for expectations, but there are no absolute milestones for the individual child.[194,195] Girls tend to become trained before boys, and daytime continence is achieved before nighttime control. It is rare to achieve control before 18 months of age.[196] Thereafter, urinary control is gained by approximately 20% of children for each year of life up to 4.5 years. By the age of 10, about 5% of children still have some nocturnal wetting, diminishing to 2% after puberty.[197] Recently, evidence has come to light that there may be a genetic basis for the development of urinary control.[198–200]

Recommended Evaluation

The evaluation of a neurologically normal-appearing child with incontinence and/or other evidence of voiding dysfunction includes

- History and physical examination
- Voiding diary
- Radiologic evaluation
  - Renal and bladder ultrasound
  - Abdominal x-ray
  - ± VCUG
- Noninvasive urodynamic testing
  - Uroflowmetry
  - Flow EMG
- ± Invasive urodynamic testing

The assessment of the child with incontinence and/or other LUT symptoms begins with a comprehensive history. This includes detailing any family history of enuresis; the mother's pregnancy, including the presence of maternal insulin-dependent diabetes; the stage of gestation at the time of delivery; Apgar scores, difficulties occurring perinatally or early postnatally; and developmental milestones, including school performance. History of fine and gross motor incoordination, previous continence, social setting and sibling interaction, parental expectations, and characterization of the wetting episodes are also important. A voiding diary provides a representation of the child's typical patterns of urination and leakage, and creates a baseline for future comparison. One group of clinicians has developed a comprehensive questionnaire that accurately identifies and quantifies children with abnormal voiding patterns that has been used successfully in determining responses to therapy.[201]

If there is a suspicion of an ectopic ureter in a girl (normal voiding, but constant dampness), then renal and bladder ultrasonography is performed. Although not yet standard of care, bladder ultrasound has also been helpful in determining bladder wall thickness in

this population, which may be predictive of poor urodynamic parameters, such as high detrusor pressure.[202] In the future, this may be used as a basic screening study to triage patients to invasive urodynamic testing. Abdominal radiographs allow visualization of the colonic stool load, as well as the sacrum. Boys who have a question of bladder outflow obstruction (urgency or urge incontinence with enuresis beyond the age of 5 years despite basic urotherapy maneuvers) are evaluated by voiding cystography.

Noninvasive urodynamic testing (uroflowmetry or flow EMG) can help to differentiate the patient's specific type of voiding dysfunction through examination of the flow rate and pattern.

The indications for performing invasive urodynamic studies for patients with functional voiding disorders are as follows:

- Any suspicion of a neurologic condition
- Diurnal incontinence with no associated pathology
- Fecal and urinary incontinence at any age
- Persistent voiding difficulties long after a UTI has been treated
- Recurrent UTI despite continuous antibiotics
- Bladder trabeculation and/or "sphincter spasm" on VCUG (Figure 53.13)
- Persistent LUT symptoms while on anticholinergics
- Recurrence of symptoms after the cessation of successful medical therapy

FIGURE 53.13 This 10-year-old girl with recurrent UTIs has spasm of the sphincter during voiding, with narrowing in the distal urethra, demonstrated on this voiding cystourethrogram (arrow). Note the grade II/V right-sided reflux.

When urodynamic studies are performed on a group of children who have these findings without an obvious systemic neurologic disorder, a spectrum of abnormalities emerge that can be classified in accordance with the ICCS classification of LUT symptoms:[15]

1. Storage disorders
   a. Overactive bladder
   b. Urge incontinence
   c. Voiding postponement
   d. Underactive bladder
2. Voiding disorders
   a. Dysfunctional voiding
      i. Psychological nonneuropathic bladder

General Approach to Treatment

Urotherapy via a comprehensive, multimodal approach is the mainstay for functional voiding disorders. This strategy is effective for both DO and functional causes of incomplete emptying, such as incomplete relaxation of the pelvic floor muscles. The urotherapy approach focuses on behavioral management, and includes timed voiding, regulation of fluid intake, elimination of caffeine from the diet, instructions on proper toileting posture, biofeedback, and treatment of constipation (if necessary).[203–205] *Urotherapy benefits up to 90% of children with LUT symptoms due to voiding dysfunction, and results appear to be durable both in the short term*[205] *and into adulthood.*[204] Recently, biofeedback training using computer technology has been employed successfully to achieve continence and to reduce the need for medication in children refractory to anticholinergic medication.[206–209] In some centers, biofeedback therapy is employed initially. Pharmacologic treatment, as detailed in the beginning of the chapter, serves as an important adjunct for children with voiding dysfunction, but it is not generally the primary treatment strategy.

Overactive Bladder, Voiding Postponement, and Urge Incontinence

Children with long-standing symptoms of daytime frequency, urgency, or sudden incontinence and squatting, in addition to nocturia and/or enuresis, may have DO. Vincent's curtsy, a characteristic posturing by these children in an attempt to prevent leakage, is a commonly described behavior pattern.[210,211] When micturition is postponed, many of these children also manifest urge incontinence. One or more of the child's parents or siblings often have a history of delayed control over micturition and/or LUT symptoms into later childhood or puberty. These affected family members may compensate for their own abnormality by displaying continued daytime frequency and/or nocturia. Although the child's physical examination may be normal, hyperactive deep tendon reflexes in the lower and/or upper extremities, tight heel cords, ankle clonus, posturing with a stress gait, or difficulty with tandem walking, and mirror movements (similar motion in the contralateral hand when the individual is asked rapidly to pronate and supinate one hand) may be evident. Left-handedness, left-footedness, or left-eyedness in a family in which all other members

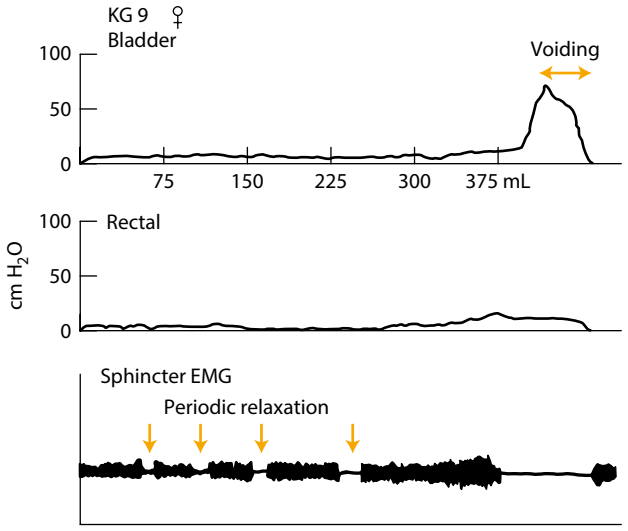

FIGURE 53.14 Some children only manifest periodic relaxation of the sphincter without a rise in detrusor pressure as an early phase of a hyperreflexic bladder producing urgency and incontinence.

are right-handed may signify crossed dominance from a previously unrecognized perinatal insult. Attention deficit disorders, poor writing ability and/or incoordination, and learning difficulties are also more commonly encountered in these children.[212,213] Carefully questioning parents about perinatal events or reviewing birth history records may uncover an insult that affected the CNS and caused these findings. The dysfunctional voiding symptom score devised by the group in Toronto has been successfully used to identify and treat children with subtle effects of such insults.[201]

Radiologic evaluation usually reveals no abnormality other than a mildly trabeculated or thick-walled bladder. Noninvasive urodynamics reveal a tower uroflow pattern with complete emptying and a total quieting of the sphincter on EMG measurements. Invasive urodynamics demonstrate premature bladder contractions during filling, which the child may or may not sense and/or abolish by increasing the activity of the EUS.[214,215] Alternatively, periodic relaxation of the sphincter, the initial phase of an overactive contraction that leads to a sense of urgency or to an episode of leaking, may be the only clue to an overactive bladder (Figure 53.14). Urethral instability can also occur along with DO, resulting in incontinence (Figure 53.15). During filling, capacity may be reached sooner than expected, at which time a normal detrusor contraction occurs with a sustained relaxation of the sphincter, resulting in complete emptying. Some children will not be able to suppress this contraction even though the bladder has not been filled to its intended capacity. Sometimes, DO may only be elicited following a cough or strain, or when the child assumes a change in posture.[211] The overactivity is thought to be responsible for the symptoms.[216]

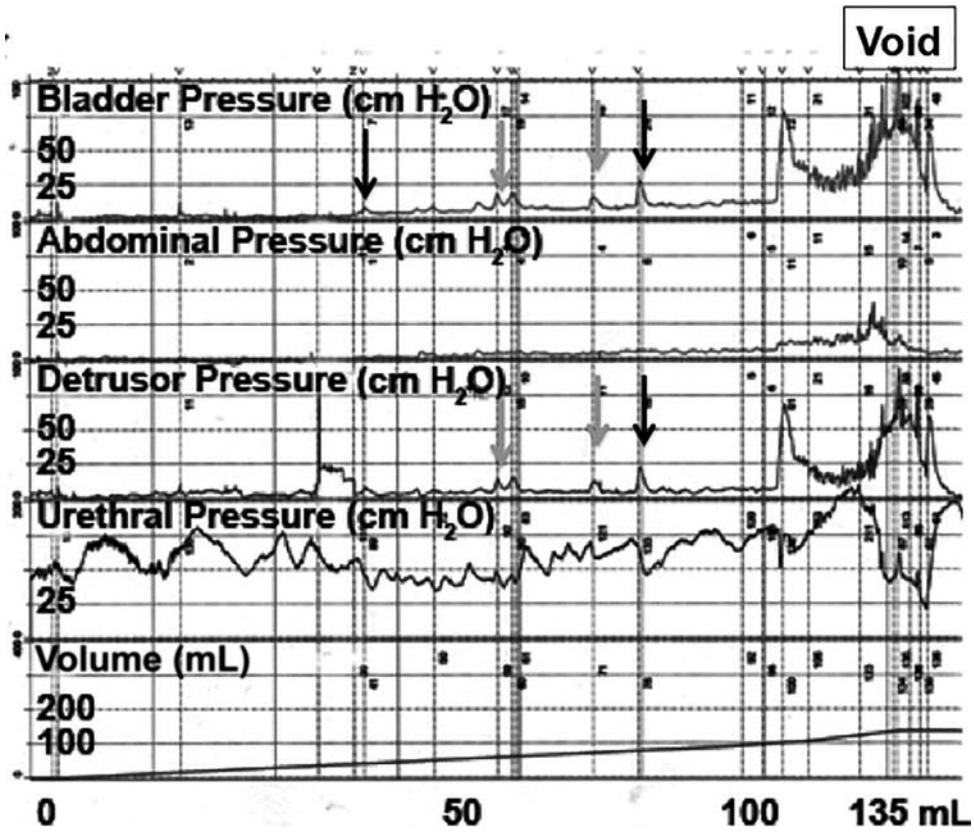

FIGURE 53.15 Urodynamic tracing demonstrating urethral instability. Some periods of overactivity are associated with drops in urethral pressure (black arrows) and some with an increase in urethral resistance (gray arrows). Detrusor instability during periods of low urethral resistance results in urge incontinence.

These findings may be the result of a cerebral insult, however mild, in the neonatal or prenatal period, but they are linked more commonly to delayed maturation of the reticulospinal pathways and the inhibitory centers in the midbrain and cerebral cortex. Thus, total control over vesicourethral function may be lacking.[196,197,217] Several investigators have found a similar urodynamic picture in a significant number of adults with nocturnal enuresis and/or daytime symptoms.[218] Parents who exhibit the same behavior pattern as their children may have a genetically determined delayed rate of CNS maturation.[199] A recent functional MRI study of adult patients with urge incontinence found that increasing activation of specific cortical regions (dorsal anterior cingulate gyrus, insula, and parietal lobe) occurs with increasing severity of incontinence;[219] the ability to target individual regions of the brain may provide greater understanding of functional voiding disorders and new targets for therapy in the future.

Children with profound constipation can also develop DO that leads to urinary incontinence.[220] The etiology of this condition is unclear, but treatment of the bowel distention has resulted in a dramatic improvement in the bladder dysfunction.[221]

Sometimes, repeated UTI may produce an identical urodynamic picture. DO occurs as a result of the inflammatory response in the bladder wall that irritates the receptors located in the submucosa and/or detrusor muscle layers.[222] Therefore, these children should be evaluated for infection. It has been postulated that DO may lead to inappropriate voiding. The child realizes what is happening, and tightens the sphincter to reverse this process, which shuts the distal urethra first and the bladder neck second, causing the "milk-back" phenomenon and the potential for UTI, as presented in the previous discussion, to occur.[222,223]

If biofeedback therapy and continuous antibiotics (if recurrent UTI is present)[214,224,225] fail to nullify the symptoms, anticholinergics alone or in combination with other therapies have been used successfully to manage this condition.[211] Oxybutynin has been highly successful,[226] with tolterodine somewhat less so, primarily due to underdosing, but the latter is better tolerated than the former and constipation is less of an issue.[227]

Underactive Bladder

Most children urinate between four and seven times per day, and defecate daily or at least every other day. Some children, primarily girls, may void only twice a day, once in the morning (either at home or after they are in school) and again at night.[228] These children exhibited normal voiding patterns as infants, but after toilet training, they learned to withhold micturition for extended periods. As a result, a few develop a fear of strange bathrooms or mimic their mother's pattern of infrequent urination and defecation.[214]

The infrequent voiding and incomplete emptying produce an ever-increasing bladder capacity and a diminished stimulus to urinate.[223] The chronically distended bladder is at risk for UTI and/or overflow or stress incontinence. Sometimes, these signs are the first manifestations of the abnormal voiding pattern. When the child is carefully questioned, the aberrant micturition is easily detected. If a comprehensive history has not been taken and/or a voiding diary not completed, the problem is sometimes diagnosed following a VCUG or radionuclide cystography performed for an assessment of UTI. Findings include a larger than normal bladder capacity and/or a high residual volume on initial catheterization, but the bladder is usually smooth walled without reflux. When the child is questioned about voiding habits, this infrequent pattern of elimination is detected (Figure 53.16).[223]

Noninvasive uroflow reveals an interrupted stream with a large residual; flow EMG shows a quiet sphincter during the voids that occur by straining or Valsalva. The urinary flow rate may be intermittent, with sudden peaks coinciding with straining, or it may be normal but short-lived, secondary to an unsustained detrusor contraction.[223] Invasive urodynamics demonstrate a very large, highly compliant bladder with either normal, unsustained, or absent detrusor contractions (Figure 53.17a).[214] Sphincter EMG reveals normal motor unit potentials at rest and normal responses to sacral reflexes, bladder filling, and attempts at emptying. Unless strongly encouraged, the child will not completely empty the bladder during voiding (Figure 53.17b).[214] This picture is consistent with myogenic failure from chronic distention.[229]

Changing the child's voiding habits is the first approach to therapy.[230] A structured timed voiding schedule and encouraging children to empty each time they void are mandatory.[231] Behavioral therapy techniques to encourage compliance are also helpful. Constipation is often an accompaniment of this scenario; treating it aggressively with cathartics or stool softeners is imperative. Rarely, CIC may be necessary to allow the detrusor muscle to regain its contractility and ability to empty.[232] Antibiotics are needed when UTI is present and are continued until the voiding pattern improves and residual urine is minimal.

Dysfunctional Voiding

Dysfunctional voiding *is a specific term that denotes a type of voiding dysfunction characterized by discoordination of the detrusor and EUS that occurs only during the voiding phase of the micturition cycle.*[15,233] When children attempt to withhold urination because it is either painful or inappropriate to void, they may actually tighten or only partially or intermittently relax the EUS muscle during voiding. Children with this condition have LUT symptomatology, including frequency, urgency, urge incontinence, staccato or intermittent voiding, nocturia and/or enuresis, and dysuria.

Persistence of these symptoms with their associated abnormal voiding dynamics can lead to repeated infections.[234] An inflammatory reaction in the bladder wall may produce an irritability that affects the sensory threshold and increases the need to void sooner than anticipated. If the detrusor muscle is affected as well, the increased irritability may lead to DO and eventually to poor compliance.[224] The discoordination between the bladder

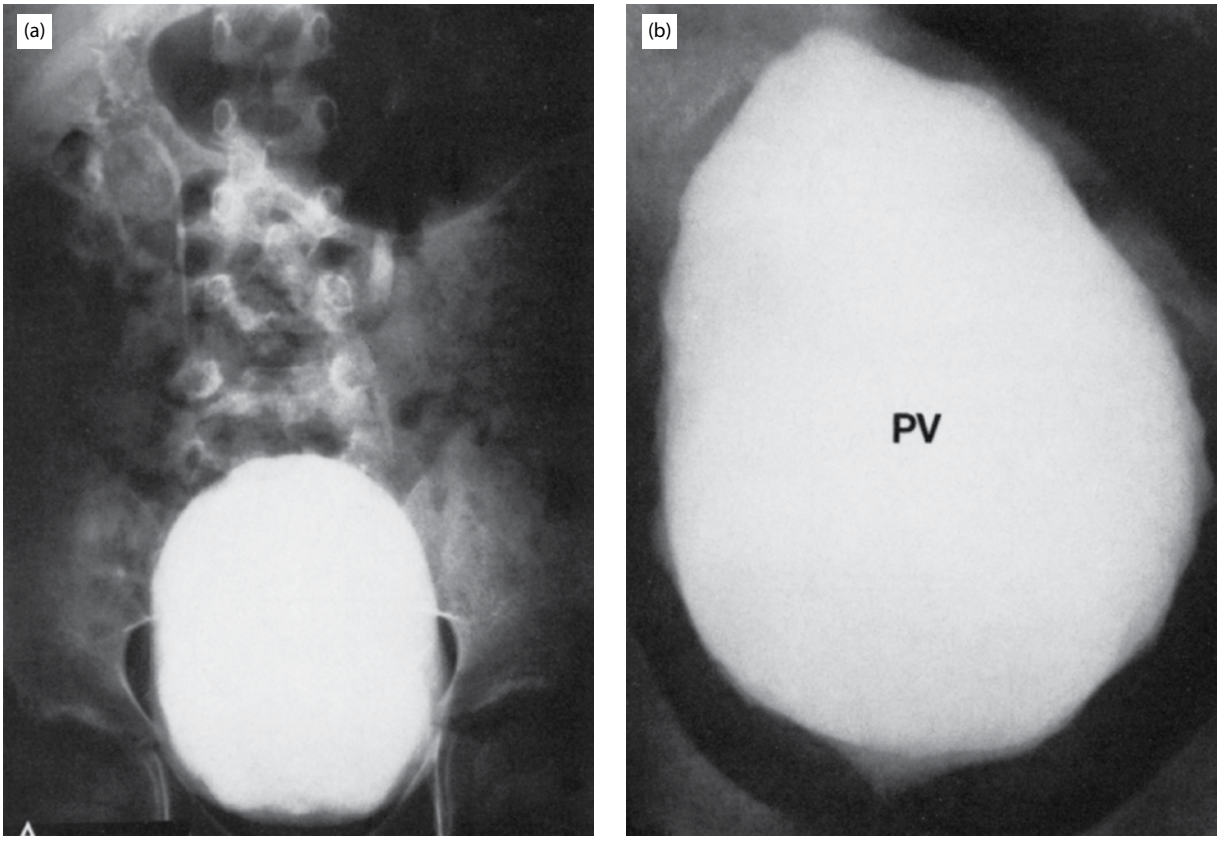

FIGURE 53.16 (a) Excretory urogram in a girl who urinates infrequently, demonstrating a large-capacity bladder with a normal upper urinary tract. (b) Her postvoiding (PV) residual is quite large.

and sphincter can also result in a functional BOO that disrupts the laminar flow pattern that normally exists (Figure 53.18).[234–236] This stop-and-start (staccato) voiding (Figure 53.19) is a prominent pattern of dysfunction in girls leading to recurrent infection,[237] because bacteria can be carried back up into the bladder from the meatus as a result of the milk-back phenomenon occurring within the urethra when urination is interrupted in this manner.[223] Theoretically, if unrecognized or left untreated in young girls, this may become the forerunner of interstitial cystitis seen in many adult females and may even be the precursor of prostatitis in males.

Radiologic investigation often reveals a normal upper urinary tract, but the bladder may be small and have varying degrees of trabeculation and/or a thickened wall.[214,238] During the voiding phase of cystourethrography, the posterior urethra may show signs of intermittent dilation at its upper end, with a uniform narrowing occurring toward the EUS region. In girls, this "spinning-top" deformity has raised the question of an obstructed meatus (Figure 53.13),[235,236] whereas in boys, it has often been mistaken for posterior urethral valves. This appearance is due to failure of complete relaxation of the EUS and persistence of a relative obstruction at the distal end of the posterior urethra as the child attempts to suppress voiding.[239]

Noninvasive uroflow reveals a staccato-type flow pattern with either complete emptying or a modest residual. During flow EMG, the sphincter may relax intermittently or even completely at first, but then contract in response to discomfort, preventing complete emptying (Figure 53.20).[234] Invasive urodynamic studies demonstrate a bladder of small capacity (when adjusted for age) and elevated detrusor pressure during filling (Figure 53.19).[214,236] At capacity, the child has an uncontrolled urge to void that may not be suppressed despite tightly contracting the EUS. The bladder contraction is usually sustained, with pressures reaching higher than normal values. Emptying may not always be complete despite these high pressures. The baseline sphincter EMG activity is normal at rest, but there may be complex repetitive discharges (pseudomyotonia)[240] or periodic relaxation of the muscle during filling, contributing to the sense of urgency or actual incontinent episodes.

Treatment goals include eliminating recurrent UTIs, minimizing environmental influences that predispose the individual to infection, and improving the child's voiding pattern and bathroom habits. Girls should learn to take showers instead of baths, or at least to bathe alone without other siblings; wipe from front to back; try to completely relax when they void so that a steady stream is produced; and take the time to empty completely each time they urinate.[234] Biofeedback training to teach these children to relax the sphincter when they void has been used, with 67%–80% of children benefiting.[206–208,231,241–243] In addition to antibiotics, antispasmodic and anticholinergic agents are administered for periods ranging from 6 to 9 months.

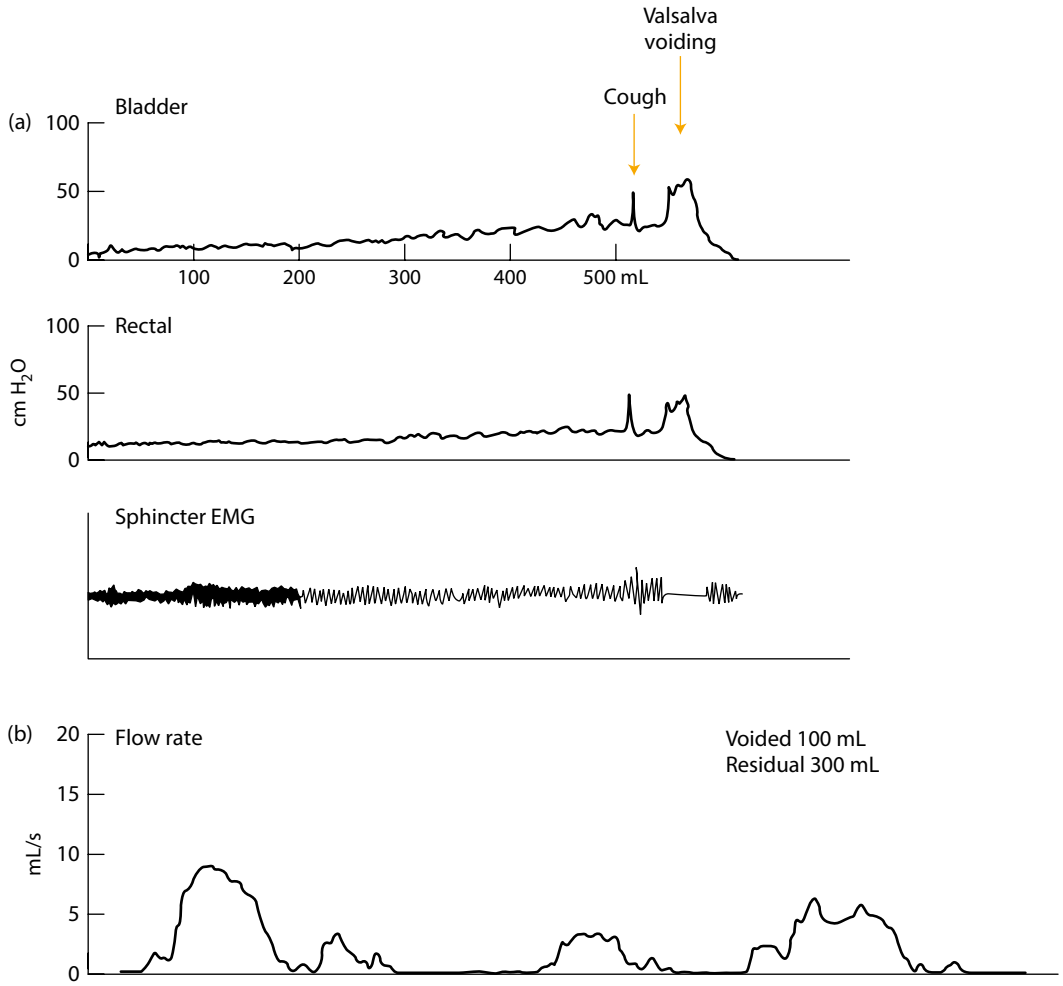

FIGURE 53.17 (a) Urodynamic evaluation reveals a very large-capacity, low-pressure bladder. The girl empties entirely by straining after relaxing the sphincter with no apparent detrusor contraction. (b) Her intermittent urinary flow rate is characteristic of this effort to empty and leads to a considerable volume of residual urine.

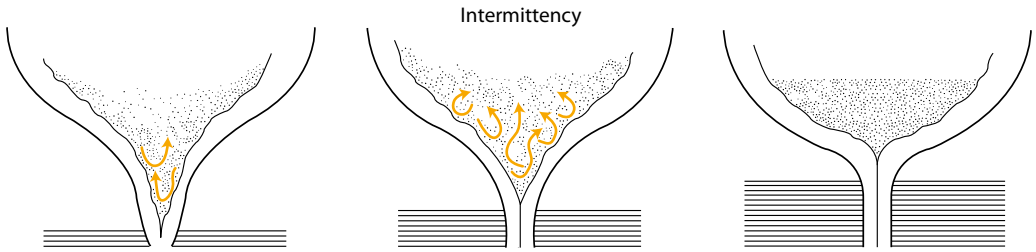

FIGURE 53.18 Nonlaminar flow secondary to periodic tightening and relaxation of the external sphincter leads to eddy current and the milk-back phenomenon, which can carry bacteria colonized at the urethral meatus up into the bladder and cause infection of the residual urine.

Psychological Nonneuropathic Bladder (Hinman Syndrome)

Hinman[244] described an apparent "syndrome" of severe voiding dysfunction that mimics NBD but is likely a learned disorder. At first, this syndrome was believed to be caused by an isolated neurologic lesion,[245–247] but now it is felt to be an acquired abnormality.[214,244,248,249] It is produced by an active contraction of the sphincter during voiding, creating a degree of outflow obstruction. Some investigators believe this phenomenon may be the result of persistence of the transitional phase of gaining control in which the child learns to prevent voiding by voluntarily contracting the EUS.[215,248] Others believe that this pattern results from the child's normal response to DO.[216] This behavior becomes habitual because the child has difficulty in distinguishing between involuntary and voluntary voiding; as a consequence, the inappropriate

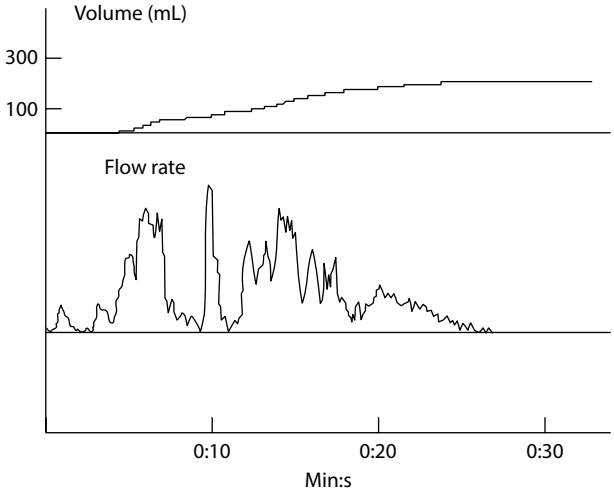

FIGURE 53.19 Staccato voiding is seen in this 8-year-old girl with recurrent infection.

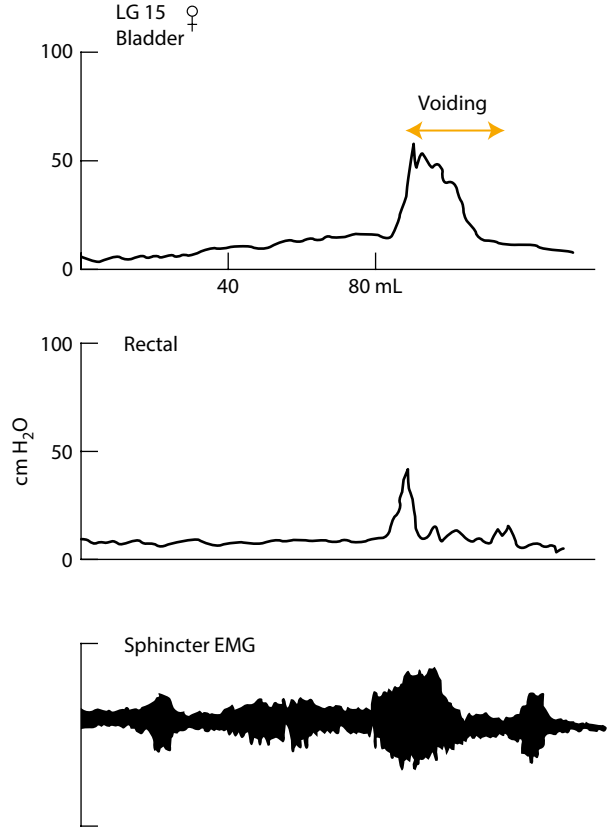

FIGURE 53.20 This urodynamic picture in a teenage female with recurrent infections reveals a small-capacity bladder and a hypertonic sphincter that relaxes only partially during voiding.

sphincter activity occurs all the time.[214] Jayanthi et al.[250] reported similar findings in a group of younger children, newborn to 30 months of age, and Bauer et al.[251] noted these same findings in five newborns and children under 1 year of age. All were managed by either vesicostomy, urinary diversion, or CIC, with spontaneous improvement after vesicostomy closure or urinary undiversion in some.

In general, children have urgency, urge and/or stress incontinence, infrequent voluntary voiding, intermittent urination associated with straining, recurrent UTI, and irregular bowel movements, with fecal soiling in between.[214] Most striking is the similarity in the pattern of family dynamics that is disclosed on carefully observing and questioning the parents.[249]

The Hinman syndrome has been applied to many children with any degree of voiding dysfunction, but it should only be diagnosed as such when most of the following conditions are present:

1. Clinical features
   a. Day and night wetting
   b. Fecal incontinence or constipation
   c. Recurrent UTIs
   d. Prominent parental themes
      i. Domineering or exacting
      ii. Divorce
      iii. Alcoholism
      iv. Punishments (mental and physical) inflicted for wetting
   e. Previous urologic surgery
      i. Ureteral reimplantation
      ii. Bladder neck plasty
      iii. Diversion
2. Radiologic features
   a. Hydronephrosis, with or without pyelonephritic changes
   b. Reflux: III–V in degree
   c. Large-capacity, trabeculated bladder
   d. Large residual urine volume
   e. Posterior urethra sometimes dilated with narrowing at EUS
   f. Colonic fullness
   g. Normal bony spine
3. Urodynamic features
   a. Elevated detrusor filling and voiding pressures
   b. Ineffective detrusor contractions
   c. High resting (but normal) sphincter EMG
   d. Unsustained sphincter relaxation during voiding
   e. Large residual volume.
4. Treatment (individualized)
   a. Bladder retraining
      i. Behavioral modification
      ii. Timed or double voiding
      iii. Biofeedback techniques for sphincter relaxation
      iv. CIC
   b. Drugs (anticholinergics, bladder relaxants, etc.) as detailed in the "general treatment strategies" section
   c. Bowel management
      i. Stool softeners
      ii. Bulking agents
      iii. Laxatives, enemas

A recent publication by Silay and colleagues suggests that children should meet all the following criteria for diagnosis of Hinman syndrome:[252]

1. LUT symptoms with daytime and/or nighttime incontinence
2. UTI with or without fever

3. Presence of any degree of hydronephrosis on initial ultrasound
4. Thickened bladder wall with trabeculations and dilated posterior urethra
5. Increased detrusor pressure and overactivity during filling
6. Inappropriate contractions of EUS during voiding
7. Normal anatomy and function of lower extremities
8. Absence of skin lesions overlying the sacrum
9. Intact perineal sensation and anal tone
10. Normal findings on spinal MRI
11. Absence of anatomic obstruction confirmed with cystoscopy

In the original conception of the syndrome, the parents, especially the father, are described as domineering, exacting, unyielding, and intolerant of weakness or failure. Divorce and alcoholism are common threads that only exacerbate the situation. Wetting is perceived as immature, defiant, and/or purposeful behavior that the parents feel must be counteracted with stern reprimands. The children are often punished, both mentally and physically, for their accidents. Confusion, depression, and withdrawal for fear of wetting, with its added punitive response, become the children's prevalent attitudes because they do not know how to, nor can they, prevent this provocative behavior. They try to withhold urination and defecation further by keeping the sphincter muscle tight, aggravating the situation. Thus, wetting becomes more commonplace, and abdominal pain from chronic constipation is likely.

Radiologic evaluation reveals profound changes within the urinary tract. Hydroureteronephrosis with or without pyelonephritic scarring from recurrent infection occurs in two-thirds of the children (Figure 53.21).[214] Fifty percent have severe VUR. Nearly every child has a grossly trabeculated, large-capacity bladder with a considerable postvoiding residual urine volume (Figure 53.21b). Voiding films show either persistent or intermittent narrowing in the region of the EUS in almost half of the children (Figure 53.21c). Finally, abdominal plain films display considerable fecal material in the colon, consistent with chronic constipation and a normal vertebral column.

Noninvasive uroflow reveals a staccato uroflow pattern. Residual urine varies from 0% to 50% of bladder capacity. Flow EMG demonstrates a urinary flow rate that is often intermittent as a result of the failure of the EUS to relax completely throughout voiding (Figure 53.22b). Invasive urodynamic studies demonstrate a large-capacity bladder with poor compliance, DO, and either high-pressure or ineffective detrusor contractions during voiding (Figure 53.22a).[214,225] Sometimes, Valsalva voiding is needed to empty the bladder. EMG recordings, however, reveal normal EUS innervation and exclude the possibility of a sacral spinal cord lesion. The sphincter fails to relax completely and may actually tighten episodically once voiding commences;[215] this finding, along with the premature contractions, suggests a UMN lesion, but usually, no other signs are present to confirm this urodynamic hypothesis. MRI has failed to reveal any intraspinal process as a cause for the voiding dysfunction in these children.[253]

The dyssynergy created by the incoordination between the bladder and sphincter muscles leads to high voiding pressures initially, and later to ineffective detrusor contractions.[215] Depending on which point of the spectrum one is at, a low or intermittent flow rate and either a minimal or significant postvoiding residual urine volume is noted.

Before this "syndrome" was recognized and the pathophysiology elucidated, many children underwent multiple operations to improve bladder emptying and correct VUR. Failure of these procedures to succeed led to urinary diversion in a number of instances. Some of these individuals were eventually able to be undiverted at an older age after they outgrew the conditions that caused their dysfunction in the first place.[254] Today, an entirely different approach is taken. Treatment is focused on improving the child's ability to empty the bladder and bowel and alleviating the psychosocial pressures that contribute to the aggravation of the voiding dysfunction. A frequent emptying schedule, accompanied by biofeedback techniques to relax the sphincter during voiding,[206,208] anticholinergic drugs to abolish DO, and improved bowel-emptying regimens, is instituted.[214] Despite these measures, CIC may be needed in children who fail to respond and in those individuals who require immediate decompression of their upper urinary tract.[232,255] In some cases, the outflow obstruction may have produced severe renal damage and even chronic kidney failure, which must be managed accordingly.

Psychotherapy is an integral part of the rehabilitative process to reeducate both the child and the parents in appropriate voiding habits. Punishments are stopped and a reward system is initiated in order to improve the child's self-image and confidence.[231] This comprehensive urotherapy approach provides the best means for rehabilitating the child's LUT and for preserving and maintaining renal health.[256]

SUMMARY

NBD is one of the more common severe problems in pediatric urology. The most frequent cause is neurospinal dysraphism, although there are many other etiologies. The treatment of NBD has been revolutionized by the introduction of CIC and targeted medical therapy, resulting in decreased morbidity and mortality and fewer children requiring invasive surgery. Children with neurogenic bladder should be serially monitored by clinical assessment, urodynamic testing, and urinary tract imaging, with treatment strategies adjusted based on the findings.

Functional voiding disorders are also commonly seen entities within pediatric urology. The symptoms can range in severity, and these disorders can cause urodynamic patterns similar to those seen in NBD. The evaluation should only include invasive testing in specific circumstances when noninvasive measures do not provide a clear picture of the patient's LUT function. Treatment strategies for functional voiding disorders are largely behavioral, although pharmacologic therapy and (occasionally) CIC are important adjuncts.

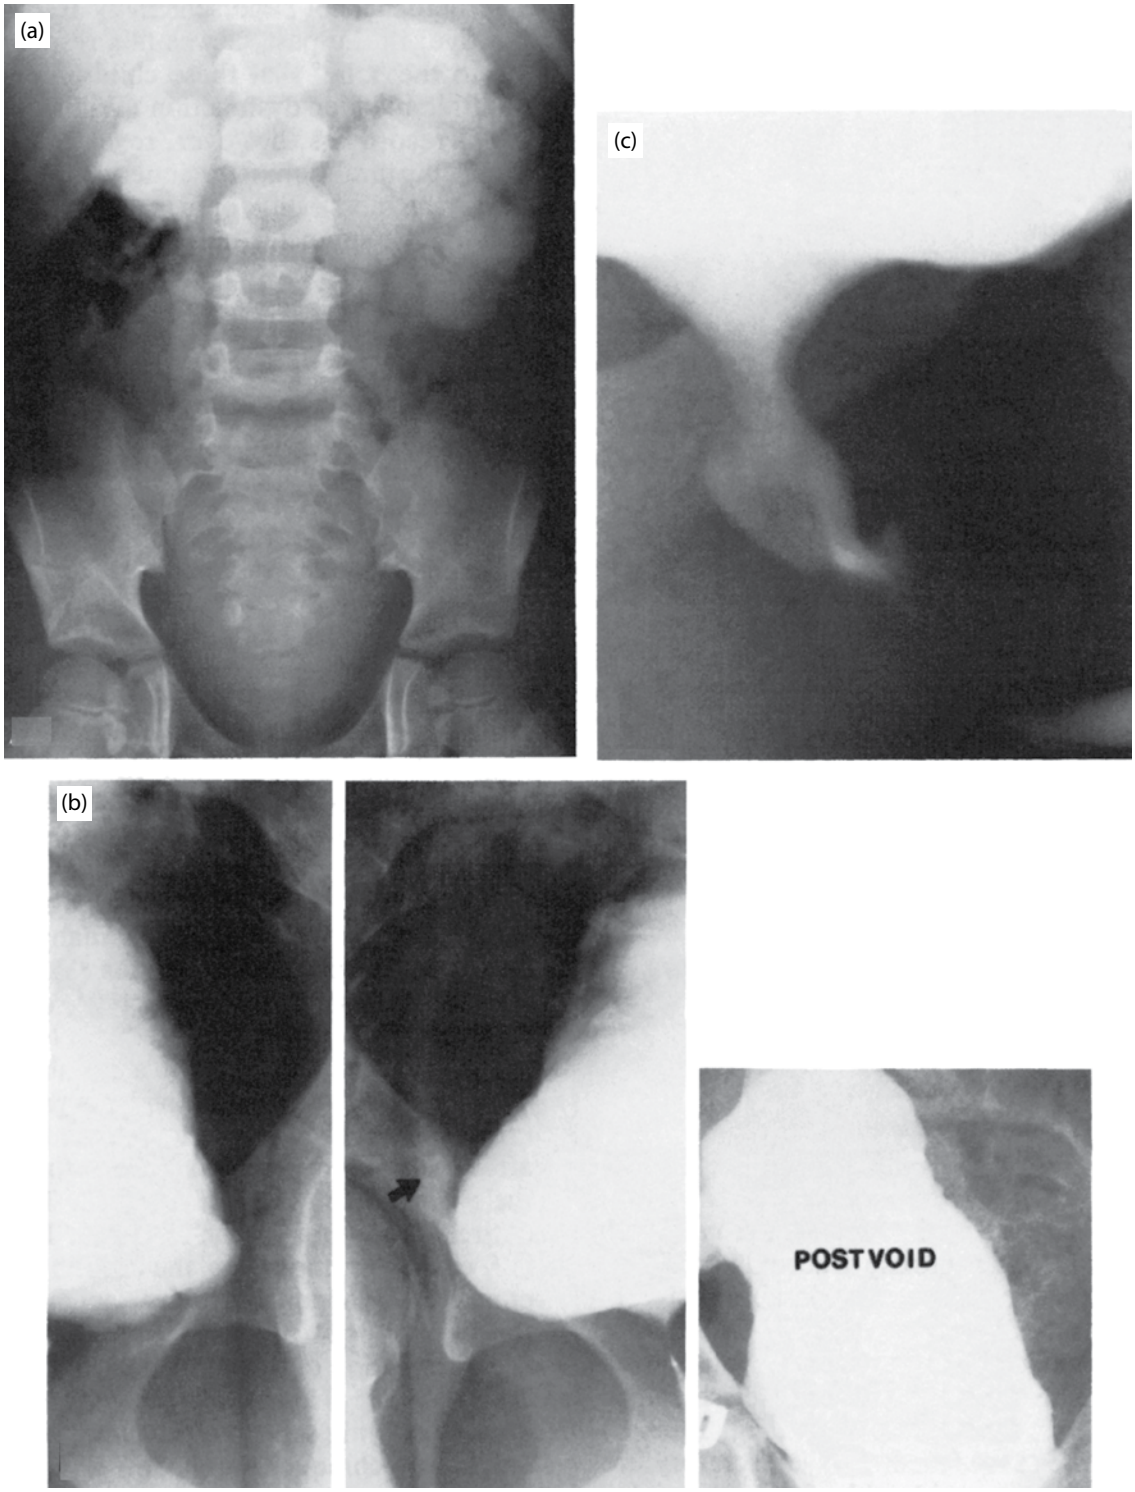

FIGURE 53.21 (a) Excretory urogram in a 14-year-old male with daytime and nighttime incontinence and encopresis. Note the impression of a faintly opacified distended bladder. (b) His voiding cystourethrogram reveals trabeculation, mild right vesicoureteral reflux (arrow), and a large postvoiding residual urine volume. (c) A film during voiding demonstrates intermittent relaxation of the external sphincter area.

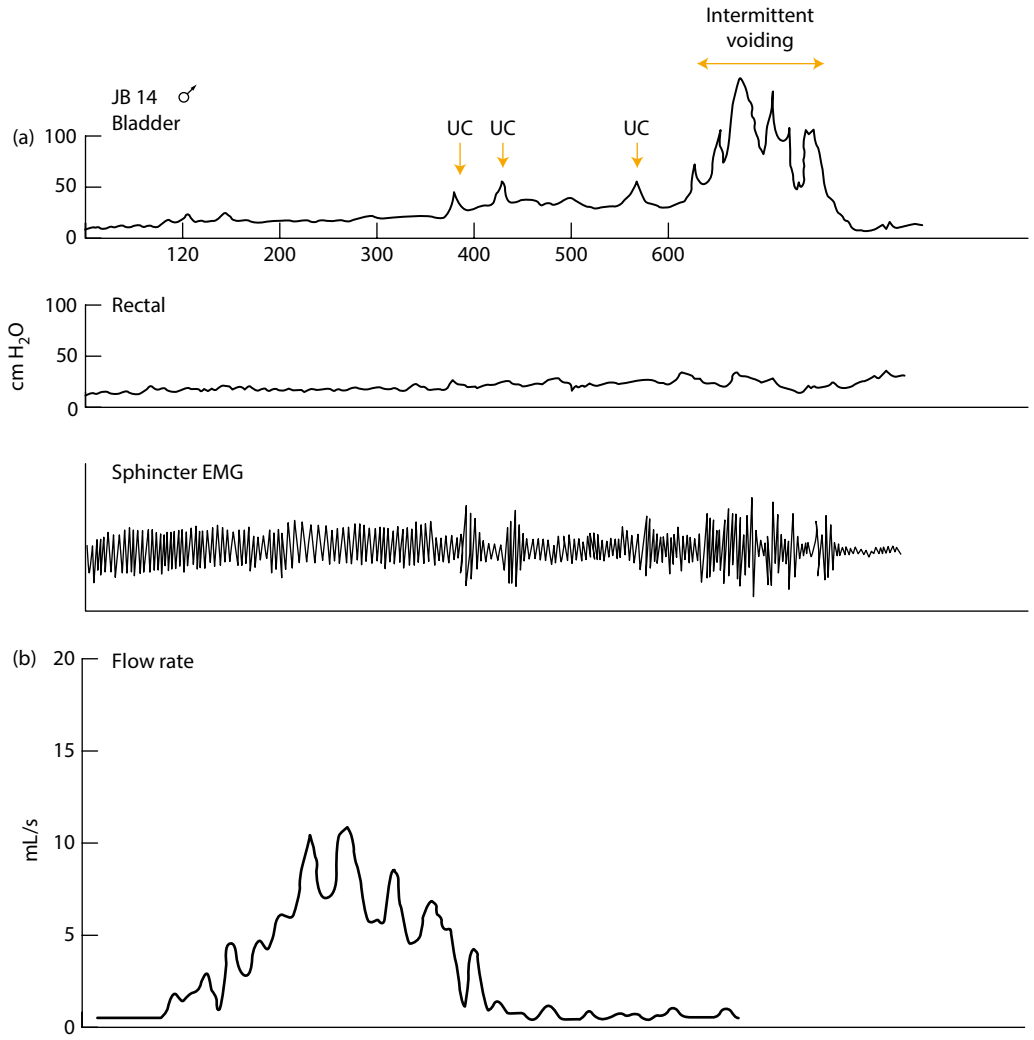

FIGURE 53.22 (a) Uninhibited detrusor contractions (UC) and increases in EUS EMG activity are noted as the bladder is filled. During voluntary voiding, very high bladder pressures (>100 cm H_2O) are generated owing to increased activity and then intermittent relaxation of the external sphincter. (b) The urinary flow rate reflects the voiding pattern seen on urodynamic evaluation.

CHAPTER 54

Diurnal and Nocturnal Enuresis

Mark Horowitz

DIURNAL ENURESIS

In the infant, a simple reflex controls bladder function without input from the supraspinal centers. A full bladder elicits a detrusor contraction via a signal that is sent along afferent pathways to the spinal cord, which then triggers the appropriate motor response, resulting in simultaneous relaxation of the external sphincter muscles. In the absence of an anatomic obstruction, this allows for low-pressure bladder emptying without resistance to flow. The adult pattern of urinary control evolves over time. During this transition, continence is achieved first by voluntary constriction of the external striated sphincter and later by supraspinal inhibition of bladder contractions. The ability to suppress detrusor contractions initially happens during the day, and then at night, and for this reason, children gain daytime continence prior to nighttime continence.

The adult pattern of voiding is characterized by the absence of bladder contractions, voluntary contraction of the external sphincter, and autonomic closure of the bladder neck during bladder filling. The events that occur during bladder emptying include opening of the bladder neck, relaxation of the external sphincter, and a sustained bladder contraction of adequate magnitude, resulting in complete emptying. Bladder capacity increases over time to permit it to function as an adequate-sized reservoir. In the first 2 years of life, the capacity can be estimated by multiplying the patient's weight in kilograms by 8, and this gives the capacity in milliliters. After 2 years of age, bladder capacity in milliliters can be estimated by the formula (Age [in years] + 2) × 30.[1] Deviation in the events of bladder filling and/or emptying result in voiding dysfunction.

Most children achieve day and night control by 4 years of age. The sequence of development of bowel and bladder control is in the following order: nocturnal bowel control, daytime bowel control, daytime urinary control, and nocturnal urinary control. Incontinence may be diurnal, nocturnal, or both. Patients with daytime incontinence often begin having symptoms 3–6 months after achieving urinary continence. The etiology of diurnal enuresis in most children is failure to relax their external sphincter during voiding, resulting in bladder hypertrophy and development of uninhibited bladder contractions (bladder instability). This activity of the pelvic floor muscles (external sphincter) during bladder contractions is known as detrusor sphincter dyssynergia (DSD). In many children, persistence of this learned behavior leads to voiding dysfunction. This dyssynergia between the bladder and external sphincter leads to high storage and voiding pressures, instability of the bladder, increased bladder wall thickness, high postvoid residual volumes, and recurrent infections. Isolated bladder instability in the absence of DSD may be secondary to bladder infection and dietary habits as well. There is a strong association between dysfunctional voiding and urinary tract infections (UTIs), as well as vesicoureteral reflux. Van Batavia and associates identified UTI in 33% of children treated for lower urinary tract dysfunction.[2] Reflux was found in 28% of patients that had an infection *not* associated with fever, and in 69% of those associated with fever. The incidence of infection was highest in patients with DSD and infrequent voiding.

Bladder instability leads to frequency and small voided volumes. More severe forms of this disorder were described as nonneurogenic neurogenic bladder or the Hinman syndrome.[3] Some of the features that were originally characterized by the Hinman syndrome included wetting during the day as well as at night, with fecal retention and soiling; UTI; radiological abnormalities of the bladder and/or kidneys; no demonstrable neurologic disease or bladder outlet obstruction; and improvement after reeducation and suggestive therapy. In addition to features seen in the Hinman syndrome, the Ochoa syndrome is associated with an unusual inversion of facial expression with smiling and a hereditary transmission. In both the Hinman syndrome and the Ochoa syndrome, upper tract damage may occur.

Enuresis is only one of many symptoms seen in the complex of voiding dysfunction. Other symptoms often elicited from patients with voiding dysfunction are urinary frequency, urgency, urge-associated incontinence, and other lower urinary tract symptoms (LUTSs). Additionally, many patients with voiding dysfunction exhibit signs and symptoms of bowel dysfunction, namely, constipation and encopresis. The term *dysfunctional elimination syndrome* has been used to describe patients with bladder and bowel dysfunction. Combs et al. retrospectively divided their patients with lower urinary tract dysfunction into three categories of bowel dysfunction: constipation, encopresis, and constipation plus encopresis. Constipation was the most common bowel dysfunction, being found in 27% of the patients, and 49% of all patients with dysfunctional voiding had some type of bowel dysfunction, i.e., constipation (39%), encopresis (6%), and constipation with encopresis (4%). Of the different types

of lower urinary tract conditions, bladder neck dysfunction had the lowest incidence of bowel dysfunction (19%).[4]

Daytime urinary incontinence represents a major source of concern for families and has potential to disrupt everyday life at home and school. Approximately 20% of children 4–6 years of age wet their pants, 3% wetting twice or more weekly.[5] As children get older, the incidence of enuresis declines but the wetting is less accepted by society and has a greater impact on their lives. Pediatric urologists are second in line to treat children with this problem, often after treatment failure by the primary caregiver. Our mission is to identify the source of the problem and offer specific solutions to improve the situation. It is important to remain minimally invasive and offer a treatment plan that is within reach of both the patient and his/her family, with minimal side effects. Enuresis secondary to neurogenic bladder (spina bifida) and anatomic causes (ureterocele, posterior urethral valves [PUVs], etc.) are not discussed.

Giggle incontinence (enuresis risoria) is the involuntary loss of urine induced by laughter. The cause is unknown, and there are minimal treatment modalities that are effective. The upper tracts are not affected. Chandra et al.[159] reported on a large cohort of children with giggle incontinence, of which 95% had concomitant dysfunctional voiding symptoms. They concluded that this entity is caused by detrusor instability, and therapy should include timed voiding, anticholinergic therapy, and a bowel program. They reported an 89% remission rate within 10 weeks. Some have reported success with the use of methylphenidate (Ritalin).

Constipation and Enuresis

Until proven otherwise, all patients with lower urinary tract disorders have constipation. Constipation is defined by the hard nature of the stool, the pain associated with its passage, or the failure to pass three stools per week.[6] Voluntary withholding of feces, most of the time caused by fear of painful defecation, is the most common cause of constipation. Encopresis or fecal soiling occurs when loose stool leaks per rectum after passing retained harder stool. Children with encopresis hide their underwear even more so than children with urinary incontinence. Because of the close proximity of the bladder to the rectum, impacted stool in the rectum does not allow the bladder to fill to capacity. Patients void smaller amounts with greater frequency and have elevated postvoid residual volume secondary to incomplete relaxation of the pelvic floor muscles during voiding, which may lead to UTIs. Patients with severe constipation and/or encopresis are often found sitting in the corner of a room, holding in a bowel movement. The frequency of bowel movements and consistency of the stool must be included in the history. Parents often know the voiding pattern of their children and the number of urinary and fecal accidents but have little knowledge of their children's frequency of bowel movements.

Treatment of constipation may help to eliminate bladder instability secondary to compression of the bladder base by a large bolus of feces. Loening-Baucke correlated resolution of voiding dysfunction symptoms with treatment of constipation.[7] Within this study, successful treatment of constipation led to resolution of daytime incontinence in 89%, nighttime incontinence in 63%, and UTI in 100% of patients. They recommended reconditioning the child's bowel movements with timed attempts to defecate, teaching proper toilet sitting positions, and modifying dietary habits. Failure to diagnose and treat constipation often hinders the success of therapy for voiding dysfunction. Initial therapy is aimed at adding more fiber to the diet in the form of high-fiber foods, fiber additives, or laxatives, which make bowel movements soft and easy to pass. Treatment options include the use of enemas, fecal disimpaction, and a variety of oral agents, such as Miralax, mineral oil, milk of magnesia, and sorbitol.

The length of treatment may extend beyond that recommended, depending on the patients' clinical response:

1. Mineral oil alone, 15–30 mL/kg/day, up to 8 ounces once or twice daily for 3 days
2. Hypertonic enemas and/or suppositories daily for 2–3 days
3. Polyethylene glycol 3350 (Miralax) orally, up to 1.5 g/kg/day to a maximum of 100 g for 3 days
4. An enema each day for 2 days, followed by milk of magnesia, 1 cc/kg/dose twice daily for 3 days

Following the initial cleanout, maintenance programs keep the patient defecating on a regular basis. Stool softeners used for a prolonged period include

- Milk of magnesia (1–4 mL/kg/day)
- Mineral oil (2–6 mL/kg/day)
- Sorbitol or lactulose (0.7–3 mg/kg/day)
- Polyethylene glycol 3350 (0.27–1.42 mg/kg/day)

WORKUP

The most important aspect in the workup of a patient with incontinence is the history. A thorough, systematic approach is critical in defining the cause and directing the treatment. Most anatomic and neurogenic causes of incontinence can be ruled out by a careful history and physical. The following is a list of questions routinely asked of patients or families of children with daytime incontinence.

- How long has the wetting been a problem? We are more inclined to proceed with a full workup in a patient that has been having accidents for several months than someone who started having accidents a week before their visit. Often symptoms will resolve without intervention if given some time.
- How significant is the wetting? Do they soak through their clothes, or is there simply a stain on the underwear? Many parents only consider soaking episodes or wetting that requires a change of underwear to be incontinence and accept dampness as either normal or inconsequential. Once children get old enough to change their own clothes, parents are often unaware

of the wetting problem. Many children, boys and girls, drip urine because they are in a rush and pull up their clothes before letting all the urine out. These children simply need to spend an extra couple of seconds to complete the process of voiding. Boys are instructed to shake their penis so that the urine in the urethra does not drip into their underwear.

- How often do they void? Some parents complain that their children go very frequently, but with further questioning, these children can sit through a movie or participate in a sporting event without the need to void. A voiding diary for several days eliminates some of the confusion we encounter with conflicting answers between parent and child. They record how often they go and what volumes are voided each time they go. It is easier to do this over the weekend than during the week when the child is at school. The normal frequency of voiding in a child is four to seven times per day or about every 2–3 hours. Children who void eight or more times per day or more frequently than every hour and a half have increased frequency. Voiding patterns are determined by a combination of physiological, behavioral, and social factors. Many children void two or three times a day, and it is these children that often do not urinate upon awakening. Bladder infections are commonly seen in this group.
- Are they more symptomatic at home or at school? Some children are fine at school, where they go two or three times during the day, but have urgency and accidents once they get home because they do not want to void while involved in other activities (watching television, playing with friends, and playing computer games). Others wet at school because the teachers will not let them use the bathroom, and some are afraid to use public restrooms (lack of privacy, poor sanitary conditions, and violence in the bathrooms). These children usually come home wet from school but after school and on the weekends are able to stay dry.
- Are there associated bladder or kidney infections? If yes, try to figure out if the patient's symptoms started after an infection, or did the patient have symptoms that led to an infection (high postvoid residual volumes and/or high-pressure voiding with turbulent flow). The volume of residual urines correlates well with the frequency of UTIs.[8]
- Do the accidents happen all the time or only when associated with certain conditions? Stress at home or in the school may cause daytime accidents.
- Is the flow continuous with a good stream, or is it choppy and slow? Is there a straining pattern? Do they feel like they empty their bladder or have to go shortly after voiding? Although not discussed in this chapter, PUVs, meatal stenosis, and stricture disease can cause a poor stream and must be considered.
- How much fluids are consumed over a 24-hour period? LUTSs may be improved by reducing total intake. Patients are instructed to drink enough to keep their specific gravity between 1.010 and 1.020.
- Other than incontinence, are there other LUTSs? Most children complain of urinary urgency, and many do not feel a warning or urge before becoming wet. In an attempt to stay dry, many girls either squat and sit on the heel of one foot (Vincent's curtsy) or cross their legs. This squatting behavior is a unique learned response to a sudden detrusor contraction and is an attempt to minimize the amount of incontinence. Boys sometimes grab their penis to stay dry.
- What does the urine typically look like, and does it have a discreet smell? Dark yellow, strong-smelling urine indicates a relatively dehydrated state or the presence of infection. Patients are encouraged to drink more or void with greater frequency. If present, infections should be treated with antibiotics. Cranberry and cherry juice (or tablets) help to prevent infections. Bacterial cystitis should be suspected when symptoms include dysuria, cloudy, foul-smelling urine and visible blood or mucus in the urine.

The Dysfunctional Voiding Scoring System Questionnaire (DVSSQ) is a reliable tool used for diagnosing and monitoring treatment of children with voiding dysfunction. Doubrava and Bartkowski performed uroflow with pelvic floor electromyography (EMG) and postvoid residual (PVR) measurements on 51 patients with normal DVSSQ scores for gender.[9] The DVSSQ was able to predict a normal bell-shaped uroflow curve in 73% of patients; however, it correlated poorly with EMG patterns and PVR volumes. Of patients with normal DVSSQ, 65% had abnormal EMG patterns, and there was poor correlation between uroflow curves and EMG patterns, as well as between uroflow patterns and PVR values.

DYSFUNCTIONAL VOIDING SYMPTOM SCORE

Over the last month

1. I have had wet clothes or wet underwear during the day.
2. I wet the bed at night.
3. When I wet myself, my underwear is soaked.
4. I do not have a bowel movement every day.
5. I have to push for my bowel movements to come out.
6. I go to the bathroom only one or two times each day.
7. I can hold on to my pee by crossing my legs, squatting, or doing the "pee dance."
8. When I have to pee, I cannot wait.
9. I have to push to pee.
10. When I pee, it hurts.
11. Parents to answer: Has your child experienced any of the following in the past year: new baby, new home, new school, school problems, abuse (sexual or physical), divorce or death, special events (birthday), accident, injury, or other stressful event?

Questionnaires are the most practical method for measuring the magnitude of incontinence, and many questionnaires exist for evaluating and following children with incontinence. Most take just a few moments to complete and should be used in the evaluation of all patients with daytime wetting. It is easy to overlook certain parts

of the voiding history. It is therefore recommended to choose the questionnaire that you feel most comfortable with and incorporate it into the patient's medical record. Sureshkumar et al. developed a daytime urinary incontinence questionnaire using parent reported data and demonstrated that it is reproducible.[10] The questionnaire was used in a prevalence survey of Australian primary school children to determine the magnitude of the problem in those starting school. Farhat et al. evaluated the performance of an objective instrument to quantify or grade the severity of abnormal voiding behaviors in children.[11] There are 10 voiding dysfunction parameters that are assigned a score of 0–3 according to prevalence, and scores range from 0 to 30. These questionnaires and others help to identify patients with dysfunctional voiding and further their investigative studies and treatment.

PHYSICAL EXAMINATION

Emphasis should be placed on the physical examination in the assessment of the child with voiding dysfunction. Special focus should be placed on evaluation of the abdomen, genitalia, and back. Inspection of the lower back for evidence of skin discoloration, dimples, hair patches, subcutaneous lipomas, or spine defects may indicate the presence of an underlying spinal dysraphism. Asymmetry of the buttocks or motor tone of the buttocks may also indicate the presence of a neurologic disease. An absent or asymmetrical gluteal cleft suggests sacral agenesis. The neurologic examination includes careful attention to the lower extremities, including strength, sensation, reflexes, and assessment of the child's gait. If there is any concern for the presence of a neurologic etiology, consideration should be given toward obtaining an MRI of the lumbosacral spine or requesting a full neurologic examination. Patients with definite abnormalities, such as tethered cord or lipomas, may require neurosurgical intervention. Most patients with spina bifida occulta and a normal spinal cord will experience resolution of their enuresis with conservative management. Ritchey et al. compared outcomes for enuretic children with spina bifida occulta with those for enuretic children with normal spine x-rays.[12] The majority of patients in both groups had resolution of the enuresis with conservative management, and only a small percentage of children with spina bifida occulta required neurosurgical intervention.

Examination of the external genitalia may reveal the source of the problem. Boys with significant meatal stenosis may present with LUTSs, mainly a decreased stream, deflection of the stream, urinary hesitancy, and incontinence. Observation of the urinary stream and uroflowmetry are more objective methods to assess the functional significance of meatal stenosis. Girls with labial fusion may present with LUTSs, including dysuria, dribbling, and incontinence. Examination of the vaginal introitous may reveal a ureterocele or an ectopic ureter. Girls with continuous incontinence between normal voids should be suspected of having an ectopic ureter. Rashes on the genital area or inner thighs may indicate constant exposure of the skin to urine. Skin bacteria break down urine and lead to urea burns. Girls with vaginal voiding often present with labiovulvar erythema and/or leukorrhea that may cause burning and itching.

It is important to assess the child's undergarments. It is common for parents to claim that their child is always wet, and when examined, they are found to be dry. When asked to explain this inconsistency, the parents state that the child voided just before coming to the office. It is clear that if he or she voids frequently, wetting can be avoided. Fecal stains suggest the presence of constipation or encopresis.

A urinalysis is obtained in all patients looking for infection, proteinuria, or glycosuria. A catheterized specimen is obtained for culture and sensitivity if a voided urine culture is positive.

Uroflowmetry, because of its noninvasive nature, is an important tool for evaluating the lower urinary tract. It has been suggested that it is the perfect instrument for revealing voiding disorders in pediatric patients.[13] Patients are instructed to void when they have a "normal" desire to void, and parameters measured include peak flow rate, average flow rate, amount voided, and the shape of the curve. Voided amounts significantly affect the peak and average flow rates. Volumes of less than 50 mL are seldom considered relevant for interpreting uroflowmetry. Gupta et al. determined flow rates and generated flow rate–voided volume nomograms based on healthy children 5–15 years old voiding spontaneously in their natural environment.[14] There were no significant differences noted in uroflow rates from 5 to 10 years, and then again from 11 to 15 years. Their nomograms will hopefully promote wider application of flow testing in the pediatric population. We have found this simple test to be useful in identifying patients with decreased expected capacity for age that might benefit from pharmacotherapy. We instruct our patients to void when they feel full, and if their voided volumes are persistently low for age, we have them keep a voiding diary at home. If their voided volumes at home are low as well, we add anticholinergic therapy to their regimen.

Simultaneous measurement of uroflow rates and pelvic floor EMG tracings (flow/EMG) have been incorporated into the initial assessment of almost every patient we evaluate for daytime incontinence and bladder or kidney infections. The normal, coordinated flow curve is even and bell-shaped in the absence of pelvic floor activity (Figure 54.1). By contrast, voiding with an active pelvic floor results in a ragged curve shape, the so-called staccato, interrupted, or irregular curve.[15] EMG studies typically show increased activity during voiding, instead of the expected relaxation (Figure 54.2).

Combs et al. reported on the utility of pelvic floor EMG lag time in identifying children with detrusor instability.[16] Pelvic floor EMG lag time is the time interval between pelvic floor relaxation on pelvic floor EMG and the start of flow. Pelvic floor relaxation occurs 1–4 seconds prior to the start of a voluntary detrusor contraction and the start of flow. Urine flow that occurs instantaneously with or prior to relaxation of the pelvic floor indicates instability (Figure 54.3). Urodynamics confirmed the presence of instability in all patients that had a lag time that approaches zero or is in the negative range.

Bladder ultrasound is performed to document postvoid residual volumes and record bladder wall thickness and/

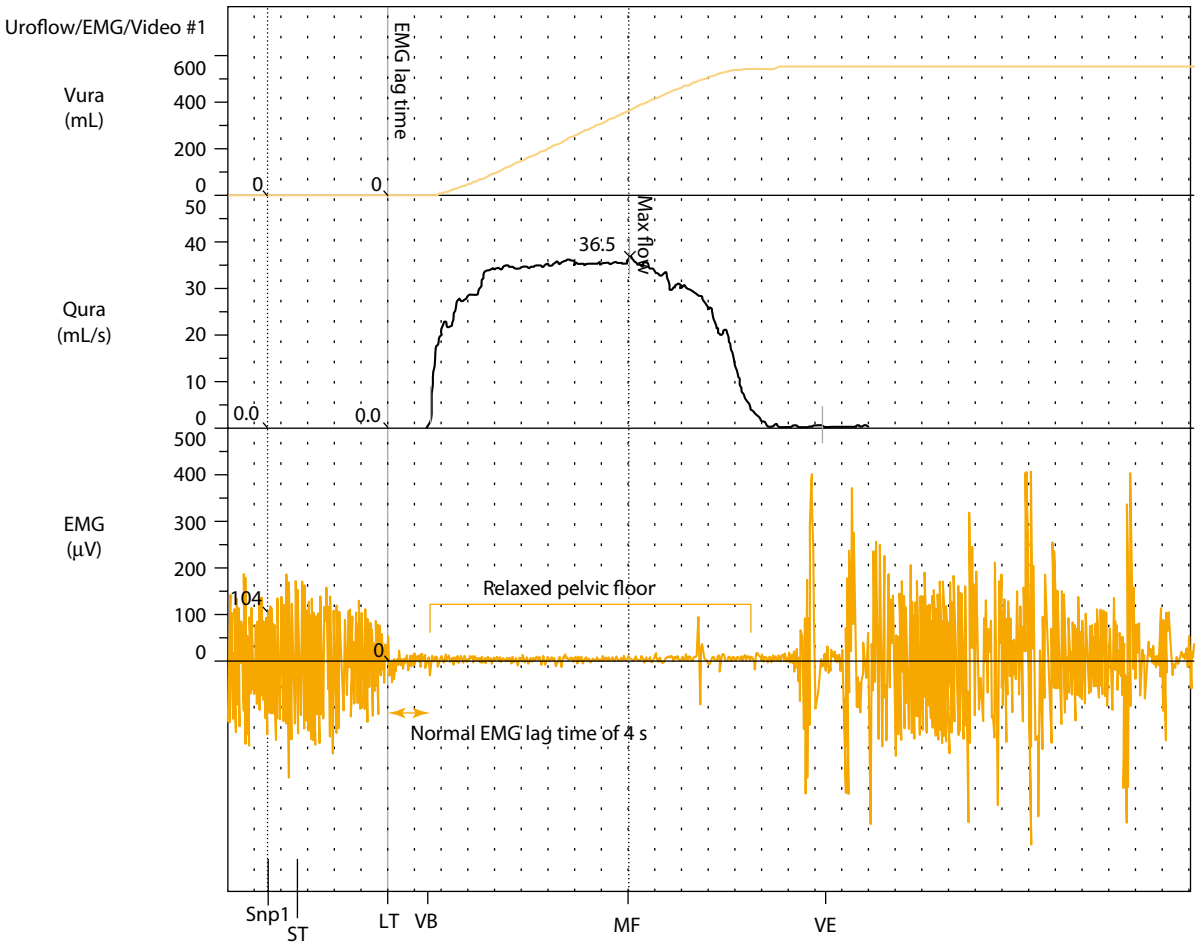

FIGURE 54.1 Normal voiding pattern. Electromyography (EMG) lag time of 4 seconds. Complete relaxation of pelvic floor muscles with voiding. Normal bell-shaped uroflow curve. V_{ura}, volume of voided urine; Q_{ura}, urine flow; ST, start/stop; LT, lag time; VB, voiding begins; MF, maximum flow; VE, voiding ends.

or distal ureteral dilatation. If hydronephrosis is seen on prevoid images, we document resolution, improvement, or no change in the hydronephrosis after the patient voids. Bladder wall thickness should be evaluated only with the bladder full. Increased bladder wall thickness implies detrusor hypertrophy, which is secondary to the bladder working against tightened pelvic floor muscles during voiding. The upper tracts are usually normal in patients with voiding dysfunction, and a renal sonogram is a quick, noninvasive, inexpensive screening tool to rule out most genitourinary anatomic anomalies.

Cystography is often used to look for reflux in a child with a UTI. Other parameters looked at are postvoid residual volumes, urethral anatomy to identify bladder outlet obstruction (PUVs, stricture, and DSD), and bladder capacity. Bladder instability can be detected when at least one of three well-defined radiological signs is detected. These signs include bladder wall irregularity, elongation of bladder shape, and filling of the posterior urethra. The chances of identifying these signs are greatest if films are exposed when unstable contractions occur, which implies that spot fluoroscopy has to be performed more often. Passerini–Glazel et al. considered this process a typical and constant sign of bladder instability.[17] Symptoms of instability are easy to elicit from older children; however, the history has limited use in infants and younger children. In these patients, bladder instability can be recognized on voiding cystourethrography (VCUG) if cystography is indicated.

Kakizaki et al. measured the internal diameter of the external urethral sphincter by VCUG in children with and without suspected voiding dysfunction to evaluate its diagnostic accuracy as a predictor of detrusor sphincter incoordination.[18] A diameter of less than 3 mm had satisfactory sensitivity and specificity for detecting detrusor sphincter incoordination.

We have substituted videourodynamics (VUDS) for VCUG in patients with LUTSs in association with documented UTIs and in those not responding to conventional therapy. The advantages of VUDS over VCUG include assessment of detrusor pressures during filling and emptying and the ability to limit radiation exposure. Monitoring bladder pressures continuously allows us to limit the use of fluoroscopy. We get spot images at the start of the study, two to three times during filling (usually at 25%, 50%, and 75% of expected capacity for age), and when we see unstable bladder activity on cystometry. Burst images are then taken during voiding and a single image taken to document PVR. This is less exposure than used during VCUG, where multiple spot images are taken

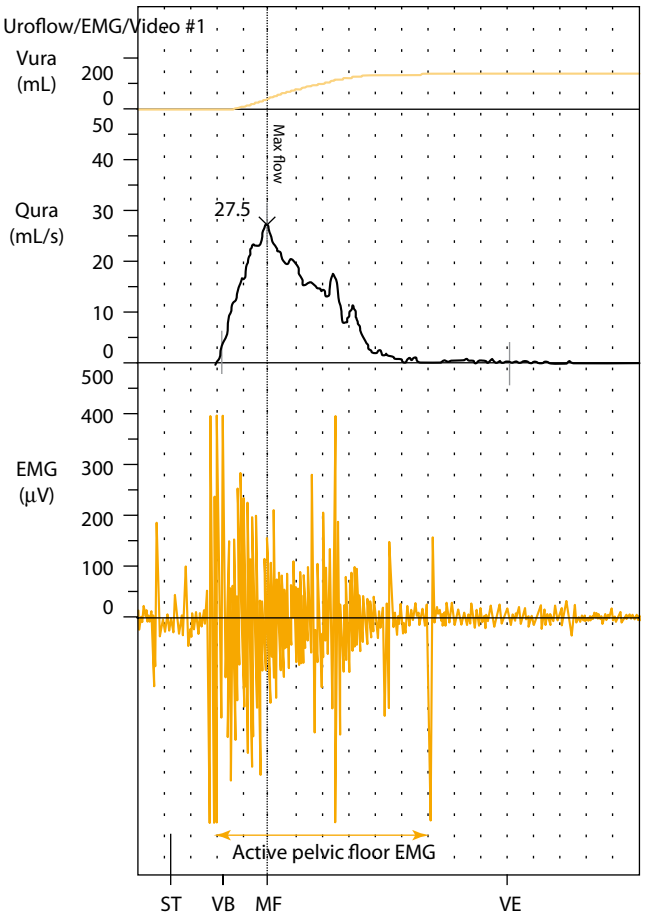

FIGURE 54.2 Type 1 dysfunctional voiding pattern. Persistent activity (nonrelaxation) of pelvic floor muscles during voiding with a staccato uroflow curve.

to look for signs of instability. The added parameters obtained during VUDS, namely, filling pressures, voiding pressures, and EMG activity of the pelvic floor during voiding, help direct us in the management of patients with more specific therapy. Simultaneous EMG activities are recorded during VUDS, and repeat noninvasive flow/EMGs are used to monitor the patient's response to therapy. Other patients studied are those with a history suggesting anatomic problems, i.e., PUVs, or those in whom conventional therapy has failed. Primary bladder neck dysfunction (PBND), PUVs, urethral stricture, and meatal stenosis should be considered in boys with poor uroflow rates despite a relaxed pelvic floor, and VUDS can aid in defining the etiology of the findings. Bladder neck dysfunction patients exhibit narrowing at the bladder neck, in addition to high voiding pressures and low flow rates with an obstructive pattern. Some patients are able to maintain high enough voiding pressures to achieve normal flow rates. Studies typically show detrusor instability and high voiding pressures. In patients with a long history of LUTSs, we may see impaired compliance and/or inefficient detrusor contractions. Urinary flow is often intermittent, and there is often a prolonged opening time, which is defined as the time between the start of a contraction and the start of urine flow. Pelvic floor EMG lag time has been shown to correlate nicely with the opening time seen on VUDS.[19] Prolonged pelvic floor EMG lag time associated with abnormal uroflowmetry is highly suggestive of PBND (Figure 54.4). There may be a disparity between peak pressure and peak flow.

TREATMENT OPTIONS

The first step is having the child void on a timed schedule. Patients are instructed to void every 2–3 hours during the day, even if they do not feel the urge to void. A multiple-alarm watch is a helpful novelty to remind a child to go to the bathroom. A letter is sent to school stating that the patient is being treated for a urologic problem and needs to be reminded and allowed to go to the bathroom every 3 hours. Timed voiding requires a great deal of cooperation by the parents, teachers, and child. In addition to timed voiding, the child must spend at least 30 seconds to one minute voiding and must relax to ensure efficient emptying. Rewards (stickers, gold stars, etc.) are given each time the patient performs satisfactorily. Girls are instructed to pull their pants or skirts down to their ankles and sit with their legs apart. Toilets are designed for adults, and the one-size-fits-all concept is not suitable for a child. When a child sits on an adult-sized toilet, the child cannot relax the pelvic floor muscles. Girls with vaginal voiding experience postvoid dribbling. Urine that enters the lower vagina leaks into the underwear when they stand up. Toilet seat adaptors and footstools should be available at both home and school. Girls are instructed to sit backwards on the toilet (straddling the toilet seat) to help relax the pelvic floor muscles. At times, measuring and recording voided volumes may be added to the routine.

Patients who develop acute onset of severe frequency (more than once an hour) have nothing to gain by voiding every 3 hours. Severe frequency in the absence of burning, dysuria, or incontinence is often self-limiting and can last for many months. Anticholinergic medications have little role in the treatment.

Patients with LUTSs often require pharmacologic therapy in addition to timed voiding. The common view is that in overactive bladder, the drugs act by blocking the muscarinic receptors on the detrusor muscle, which are stimulated by acetylcholine released from activated cholinergic (parasympathetic) nerves. Anticholinergic medications act mainly during bladder filling, decreasing urge and increasing bladder capacity. In the dose range needed for beneficial effect in the overactive bladder, there is little evidence for a significant reduction of the voiding contraction during bladder emptying.[20] Ditropan is a potent anticholinergic agent with strong independent smooth muscle antispasmodic activity at a site distal to the cholinergic receptor. In young children who cannot swallow pills, we initiate treatment with Ditropan suspension two or three times a day. Children who can swallow are started on Ditropan XL once a day. Patients on Ditropan experience a decrease in the frequency and intensity of uninhibited bladder contractions. Reported side effects that are more common in the summer months and with the suspension preparation of the drug include dry mouth and flushing.

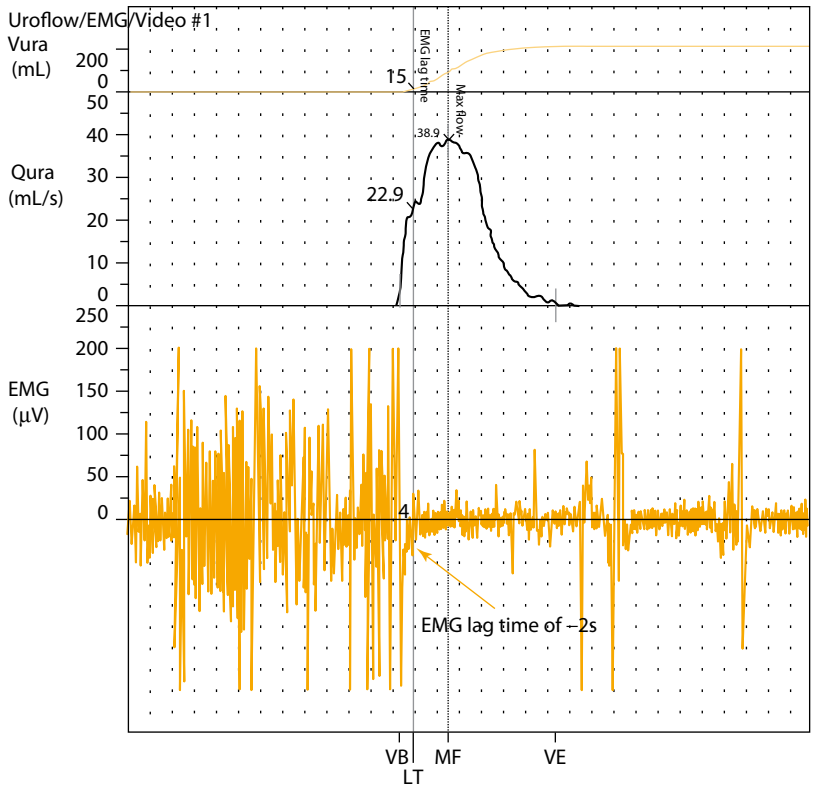

FIGURE 54.3 Type 2 dysfunctional voiding pattern (bladder instability). No lag time noted, which indicates initiation of flow prior to relaxation of pelvic floor muscle activity. Vura, volume of voided urine; Qura, urine flow; ST, start/stop; LT, lag time; VB, voiding begins; MF, maximum flow; VE, voiding ends.

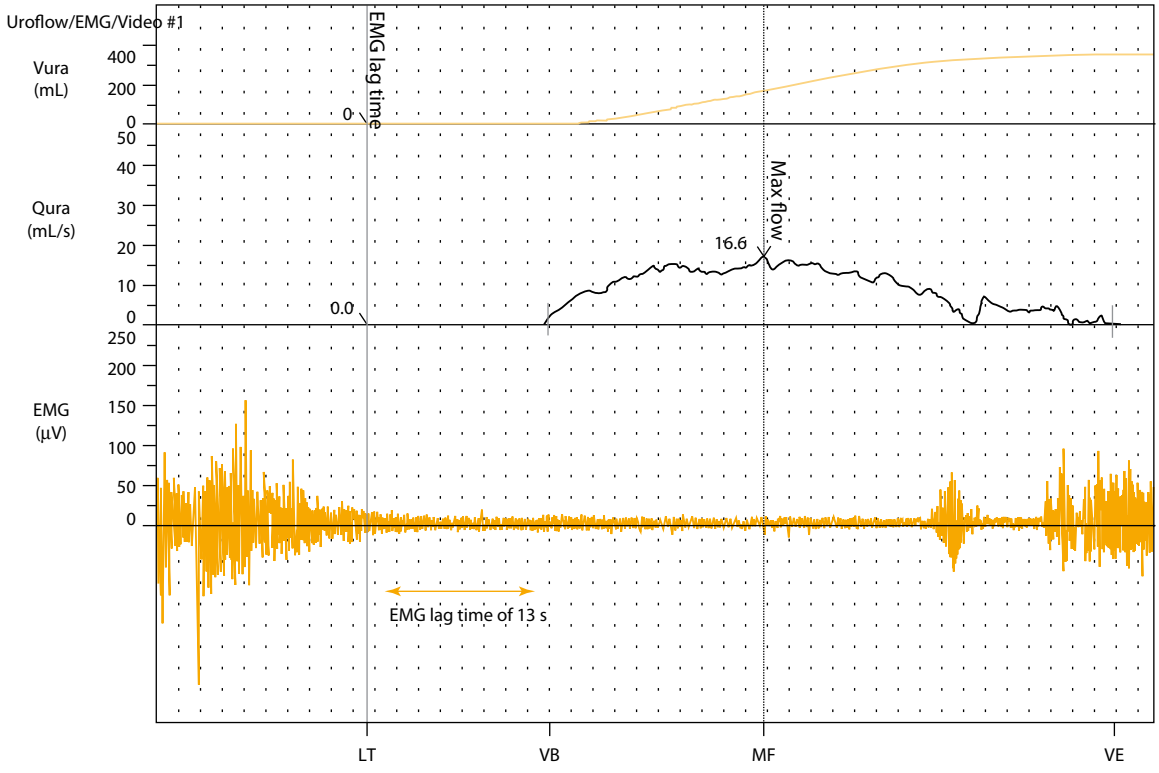

FIGURE 54.4 Bladder neck dysfunction. Lag time of 10 s (normal lag time = 2–4 s). Complete relaxation of pelvic floor muscles with voiding.

Ditropan decreases the natural ability to sweat, which can cause overheating in the very active child in extreme climates. Other side effects include dizziness, blurred vision, and excessive sleepiness. The medication is more effective on an empty stomach, so patients are instructed to take Ditropan either 30 minutes before a meal or an hour after meals. If patients have not already restricted their fluid intake, they are instructed to do so to maximize the voiding interval. Many patients are instructed to drink plenty of fluids to avoid infection and minimize the side effects of Ditropan, which gives them mixed messages.

The above-mentioned therapeutic strategy is considered simple behavioral therapy without biofeedback. Wiener et al. reported on the long-term efficacy of simple behavioral therapy for daytime wetting in children.[21] Formalized management of bowel elimination was not included. There was improvement in daytime urinary control in 59.4% at a mean of 4.7 years after completion of therapy. Frequency and urgency demonstrated long-term improvement in 51% and 46%, respectively. Assessment of symptoms during the first year after therapy revealed similar results, with 73% reporting improvement at 12 months. Behavioral therapy may lose some efficacy with time without return visits to reinforce therapeutic interventions. They concluded that simple behavioral therapy without biofeedback should be first-line therapy for children with daytime incontinence.

Biofeedback is the use of modern instrumentation to give a person better moment-to-moment information about a specific physiologic process that is under control of the central nervous system, but not clearly or accurately perceived. With biofeedback, patients can be made aware of and gain control over certain bodily functions. Biofeedback therapy is very successful in the treatment of voiding dysfunction. It can be used alone or in combination with other treatment modalities discussed in this chapter. With respect to voiding dysfunction, biofeedback teaches the patient how to relax the pelvic floor muscles during voiding, thereby improving flow parameters and decreasing postvoid residual volumes. To be successful, patients should be attentive and motivated so they can be taught to isolate the pelvic floor muscles. The success of biofeedback depends on patient and parent compliance, as well as on careful patient selection based on the motivation to learn and participate in the program. Few patients are cured with a single session of biofeedback. Most patients require several sessions, the number determined by improvement using clinical and urodynamic criteria. Each session starts with a review of the prior session; review of symptoms, with special emphasis on improvement or deterioration of LUTSs and incontinence; and review of current medications. Biofeedback is time-consuming for clinicians, children, and families, which may lead to problems with compliance.

Nelson et al. reported on the use of biofeedback in 81 patients with voiding dysfunction in whom conservative management failed.[22] Of 73 patients with incontinence, 30% became dry, 49% improved, and 21% had no change after biofeedback. Recurrent UTIs resolved in 78% of patients. Noninvasive urodynamics after therapy showed a significant increase in maximum and average flow rates and a significant decrease in postvoid residual volumes. Children were taught to void with a more normal flow pattern and greater voiding efficiency, even in the absence of improving continence.

Herndon et al. reviewed their experience with a conservative medical program and computer-assisted pelvic floor muscle retraining in patients with voiding dysfunction.[23] Patient compliance with the program was reported at 95%, and subjective improvement was seen in 87% of the group. Predictors of failure included a bladder capacity of less than 60% of the predicted volume and patient noncompliance. With adding medications, 83% of the nonresponders improved.

Kajbafzadeh et al. evaluated the efficacy of animated biofeedback in bowel and voiding dysfunction in 80 children with dysfunctional elimination syndrome.[24] Half the group of patients received animated biofeedback in addition to behavioral modification (hydration, high-fiber diet, and scheduled voiding), and the other half underwent behavioral modification only. They found that animated biofeedback in combination with pelvic floor exercises resulted in promising improvements in subjective and objective manifestations of dysfunctional voiding, as well as notable resolution of bowel dysfunction, vesicoureteral reflux, and recurrent UTIs.

Different methods of direct sacral nerve stimulation have been used to treat refractory lower urinary tract dysfunction in adults. The invasive nature of this procedure precludes its use in children. In contrast, genital, anal, intravesical, and percutaneous tibial stimulation have been reported in children. However, these techniques require either genital manipulation, placement of an anal probe, bladder catheterization, or needle insertion, all considered somewhat invasive in children. De Gennaro et al. reported on percutaneous tibial nerve stimulation in children and found it to be minimally invasive and feasible in children.[25] There was improvement in micturition symptoms, incontinence, flow rates, and PVRs with no adverse effects.

PBND is a fairly new entity that has received much attention in the past few years. Perhaps it is one of the entities that had a treatment prior to knowing what we were actually treating. On VUDS, it is characterized by the constellation of prolonged opening time, incomplete bladder neck funneling, quiet pelvic floor EMG during voiding, and abnormal pressure flow parameters. As mentioned earlier, the diagnosis can be made with noninvasive uroflowmetry combined with pelvic floor EMG.

Alpha-blocker therapy is being used with greater frequency in patients with voiding dysfunction. Austin et al. were one of the first groups to investigate the role of alpha-blockers for the management of incomplete bladder emptying in children.[26] They looked at 17 children with documented poor emptying due to various etiologies, including both neurogenic and nonneurogenic causes. With the use of an alpha 1-adrenergic receptor antagonist, bladder symptomatology and/or emptying improved in 82% of patients and was well tolerated by most. Because of this success, they looked at a larger group of 55 patients with voiding dysfunction and poor bladder emptying.[27] There was an 88% reduction in the pretreatment PVR volume, with only three patients showing no change in PVR. There was improvement in diurnal continence in 83% of

patients and urgency in 70%. They concluded that selective alpha-blocker therapy might be used as either replacement for or in addition to biofeedback in patients with significant PVRs. At this time, alpha-blockers have yet to be Food and Drug Administration (FDA) approved and are being used off-label.

Yucel et al. compared the efficacy of biofeedback and alpha-blocker therapy in children with PVR who had symptoms of incontinence, urgency, and UTIs.[28] There was no statistical difference between the two arms ($p > 0.05$) when looking at posttreatment reduction in PVR as the end point. Combined treatment of biofeedback and alpha-blocker helped 83% of the children with refractory high PVR treated with either biofeedback or alpha-blocker therapy alone. A group that responds nicely to alpha-blockers is children with PBND. Donohoe et al. used alpha-blockers to treat 26 patients with PBND.[29] With alpha-blockers, average and maximum flow rates improved from 5.5 to 12.6 cc/second and from 10.3 to 19.7 cc/second, respectively. Postvoid residual volumes decreased from 98.9 to 8.9 cc ($p < 0.001$). No patient experienced any major adverse side effects.

Kajbafzadeh et al. evaluated the effect of prazosin on vesicoureteral reflux resolution and urodynamic parameters in 62 children with idiopathic primary reflux and PBND.[30] Patients with documented reflux and urodynamics-proved primary PBND were randomized to receive either an alpha-blocker or placebo. In the placebo group, no uroflowmetry or urodynamic parameters changed significantly at 1-year follow-up. They observed a 60% decrease in reflux grade in the treatment grade compared with 17% in the placebo group. Significant decreases in maximal detrusor pressure, postvoid residual volumes, and opening time were seen in the treatment group, as was improvement in average flow rates.

Diet can have a profound effect on voiding patterns, and dietary changes can alleviate symptoms associated with bladder dysfunction. Avoiding the 4Cs (caffeine, chocolate, carbonated beverages, and citrus beverages) is an integral part of therapy, as they are known to cause urgency, frequency, and/or incontinence.

Clean intermittent catheterization (CIC) is a last option in a subset of patients that do not respond to standard treatment modalities. Alpert et al. reported their experience with 20 patients requiring CIC.[31] CIC was an easy technique for 80% of the children to learn in a single visit and master in a short period of time. If necessary, CIC is often used as a temporary measure until the patients can be taught to void in a correct manner. When all these modalities have been tried and failed, surgical intervention may be necessary. Augmentation cystoplasty with CIC will provide a large-capacity, low-pressure, compliant bladder that allows for preservation of renal function and urinary continence. However, this is a long haul for a problem with no neurologic or anatomic etiology.

There are numerous approaches for the treatment of urinary incontinence in children. The aggressiveness of evaluation and intervention usually depends on the age of the patient, chronicity of the problem, and other associated issues, such as recurrent infections. A systematic review of randomized controlled trials led to the conclusion that there is lack of proof for optimal treatment of pediatric incontinence.[32] Historically, antimuscarinic drugs have been the first line of treatment for urinary urgency, frequency, and urge-associated incontinence. Although associated with side effects that limit their use in some children, these drugs have undisputed effectiveness in the treatment of the overactive bladder. These medications are better tolerated with the advent of once-a-day formulation. They are often used in combination with other treatment modalities, including alpha-blockers, antibiotics, and bladder and bowel retraining. Newer once-daily M3-selective receptor antagonist agents are now available for treatment of the overactive bladder. With greater affinity for the M3 receptors than the M1 and M2 receptors, there is less dry mouth and less constipation. There are also significantly less central nervous system and cardiac side effects. The use of botulinum types A and B toxin injections into the detrusor muscle has been studied extensively for the treatment of incontinence due to neurogenic causes. These treatments are safe and minimally invasive and can be injected repeatedly but to date have had no role in the treatment of nonneurogenic voiding disorders.

SUMMARY

Voiding dysfunction is a common childhood problem. Use of a checklist for both the history and physical examination is highly recommended. Patience, diligence, and consistency are critical in the evaluation of these patients. Most children will respond to simple measures, such as timed voiding and relaxation techniques to facilitate bladder emptying. A select population of patients in whom single-modality therapy fails, multiple-modality therapy, including timed voiding, biofeedback, and medications, is advised. In our experience, almost all patients can be treated successfully with combination therapy. The objective improvements we aim for are a decrease in postvoid residual volumes, increased uroflow rates, and normalization of EMG patterns. Effective treatment also helps control the secondary complications of reflux, UTIs, and in extreme cases, urinary tract deterioration.

NOCTURNAL ENURESIS

One of the most common urologic complaints in children is nocturnal enuresis (NE). Most children achieve nighttime continence by the age of 5. The significance of NE is dependent on the patient's age, the parents' and child's expectations, and his or her social situation.

Our understanding of the pathophysiology of NE has progressed greatly in recent years, and the disorder is now understood to be heterogeneous and genetically complex in nature. Abnormalities in nocturnal urine production, bladder reservoir function, arousability, molecular genetics, or a combination of these may be responsible for nighttime wetting. This new understanding of NE has had enormous impact on both the diagnosis and treatment of the disorder. Nevertheless, much is left to learn and many controversies still remain.

DEFINITIONS

In accordance with the International Children's Continence Society recommendations, the term *primary nocturnal enuresis* is used to describe bedwetting in a child who has never had a dry period of longer than 6 months. A child with *secondary NE* is one that wets the bed but had previously been dry for at least 6 months prior.[33] *Monosymptomatic nocturnal enuresis* (MNE) describes bedwetting in children with no daytime urinary symptoms to suggest an underlying voiding dysfunction. *Nonmonosymptomatic or primary nocturnal enuresis* (PNE) is used to describe NE associated with bladder overactivity.[34]

EPIDEMIOLOGY

The overall prevalence of NE declines with age. By the age of 4 years, it is estimated that 20%–25% of children frequently wet the bed. This decreases to 5%–10% by the age of 7.[35–38] Fourteen percent of children between the ages of 5 and 9 years and 16% between 10 and 19 years will stop wetting the bed annually.[39] In this longitudinal cohort study, 92% of 1129 children born in 1 year were followed for 6 years with primary enuresis remission rates of approximately 15% per year.[39]

Although spontaneous cure occurs throughout childhood and adolescence, the problem may persist in 0.5%–3% of the adult population.[40–43]

Although PNE is more common in young boys, by adolescence the incidence in males is equivalent to that in females.[44] The prevalence of NE is similar throughout the world.

PSYCHOLOGICAL IMPACT

Primary NE may have a profound psychological and social impact on both the child and his or her family. Enuresis may affect a child's normal activities and development. This, in turn, may affect the child's family.[45–47] There is some controversy regarding how enuresis affects self-esteem. A recent review concluded that there is no evidence that bedwetting leads to lower self-esteem.[47] Conversely, some studies have shown that children with NE have worse self-esteem and significantly more behavioral and psychological problems, including anxiety, depression, aggressiveness, and attention deficit, when compared with normal age-matched nonenuretic patients.[45–47] After a successful cure, abnormal behavioral and psychological problems have been shown to improve in some studies, possibly indicating that the problems are a result of the NE and not vice versa.[46,48,49] Surely, attaining dryness will not negatively impact a child's self-esteem. The child's age itself may change his or her attitude toward enuresis. Butler reported that younger children focus on the immediate consequences of enuresis, whereas older children are more likely affected by the social and emotional aspects of the condition.[50] Interestingly, comorbid psychiatric disorders can be found in up to 75% of secondary nocturnal enuretics.[51,52] At least 46% of parents have some concern with regards to NE, while 17% worried a great deal.[53,54]

In a study by Haque et al., the mean anticipated age of dryness according to parents was 3.18 years. When asked for possible causes for their child's NE, parents believed that emotional problems (35.5%), heavy sleeping (38.2%), physical problems (21.4%), familial problems (28.9%), and small bladders (10.7%) may be responsible.[55]

NE may also lead to punishment. Some mothers believe that their child is wetting on purpose and choose not to treat their children and may even punish them.[54] The reported rates of punishment in the 1980s were 37% in the United Kingdom and 35.8% in the United States.

ETIOLOGY

Family studies have repeatedly demonstrated high rates of relatives affected by enuresis. The risk for a child to be enuretic is 40% if one parent and 70% if both parents had been enuretic.[56] Early studies reported that 32% of fathers and 23.9% of mothers of children with enuresis were enuretic as children.[57]

Based on twin studies, the most common mode of transmission is autosomal dominant with high (90%) penetrance.[58] Additionally, about 45% of patients with NE were found to have an autosomal dominant mode of inheritance.[59] Linkage analyses have been used in the study of NE, and several loci have been identified; however, there is no clear association of any of the loci with any particular type of enuresis.[60,61]

PATHOPHYSIOLOGY OF NOCTURNAL ENURESIS

One or more of several pathophysiological mechanisms may cause NE.

Nocturnal Polyuria

In classic studies, Rittig and colleagues and Norgaard et al. demonstrated abnormalities in the circadian rhythm of antidiuretic hormone (ADH) secretion in bedwetters.[62–64] In these patients, urine production during sleep exceeds bladder capacity.[62,64,65] Children with NE associated with nocturnal polyuria will often wet in large quantities soon after going to sleep.[66,67] However, nocturnal urine production may vary considerably from night to night, and urine volume is significantly larger on wet nights compared with dry nights in enuretics.[68] Therefore, nocturnal polyuria is best evaluated during nights when enuresis is experienced.[69]

Based on the abnormalities in diurnal ADH production, desmopressin (dDAVP) was introduced for the treatment of PNE. Response rates using desmopressin of approximately 70% have been reported by various studies.[64,70] Other factors that may also contribute to excessive nocturnal urine production are currently being investigated. These include an increase in the nocturnal

release of other hormones that regulate solute excretion, e.g., angiotensin II, aldosterone, and atrial natriuretic peptide. Abnormalities of renal function may also contribute to PNE. A study examining renal function in enuretic children found decreases in free water and solute reabsorption in the thick ascending limb of Henle's loop.[71] Hypercalciuria, prostaglandin production, aquaporin 2 (AQP2) dysfunction, and sleep apnea may also play a role in the pathophysiology of NE.[71–74]

Nocturnal urine production is approximately 50% of daytime production in early childhood.[75] This decrease in urine production is controlled by decreases in free water excretion secondary to nocturnal increases in the release of ADH and/or decreases in solute excretion related to the release of angiotensin II and aldosterone.[76,77]

Children with NE and increased nocturnal urine output generally have normal functional bladder capacity and a favorable response to treatment with desmopressin.[78]

Impairment in Sleep Arousal Response

Problems with arousal must exist in order for a child to wet his or her bed. Enuretic children have been shown to have poor arousability in response to acoustic stimuli, and specific brainstem dysfunction has been suggested.[79,80] In Wolfish's study, acoustic stimuli of up to 120 dB were successful in waking 39.7% of the control group and only 9.3% of enuretic patients. Enuretic male patients have also been found to be more difficult to arouse than age-matched controls.

Bladder Dysfunction

Small functional bladder capacity and detrusor overactivity may play an important role in the pathophysiology of NE.[69,81–84] Despite normal daytime voiding, approximately 30% of enuretic patients studied with simultaneous sleep electroencephalogram and cystometric monitoring were found to have detrusor instability while sleeping at night.[85] In studies by Yeung et al. and Oredsson and Jorgensen, a majority of enuretic patients with symptoms refractory to treatment were found to have a small functional bladder capacity.[69,83] When the results of cystometric studies obtained during the daytime were compared with those obtained during sleep, enuretic patients were categorized into two groups: (1) those with normal urodynamics and bladder capacity during daytime and marked detrusor instability, diminished nocturnal functional bladder capacity, and small volume voiding only after sleep at night, and (2) those with abnormal daytime urodynamics associated with various types of occult underlying bladder dysfunctions and significantly reduced functional bladder capacity and small volume voids, both day and night.[83,84] Additionally, up to 70% of adult patients with persistent PNE have been found to have detrusor instability and reduced functional bladder capacity.[86]

The incidence of significant anatomical and functional bladder abnormalities is low in primary MNE; however, patients with severe, treatment-resistant enuresis and *adults with new-onset* NE may have an underlying abnormality that should be thoroughly investigated.[83,84,87]

EVALUATION

In order to properly manage a child with primary NE, it is first necessary to determine possible causes for the condition. Is the bedwetting a result of nocturnal polyuria (increased nocturnal urine production during sleep), or is it due to a reduction in nocturnal functional bladder capacity? Although a good voiding history may illicit these occult abnormalities, it is often after a failed course of desmopressin that the clinician becomes suspicious that nocturnal polyuria may not be the cause. The initial recommendation for these children is limiting fluid and solute intake in the evening, void before bedtime and have the parents take the child to void before they go to bed. If this does not work, nocturnal enuretics will often improve with desmopressin alone or in combination with an anticholoinergic agent and/or enuretic alarm therapy.

To avoid a delay in effective treatment, patients should have a detailed history and physical examination. A voiding diary is often useful. Occasionally, ultrasonography, uroflow, and even urodynamic studies may be indicated.

HISTORY

A careful history should include questions to help determine whether the enuresis is primary or secondary. The number and time at which nighttime wetting occurs should be noted. Every effort should be made to rule out the possibility of an underlying voiding dysfunction. Questions regarding daytime incontinence, urgency, frequency, posturing, infrequent voiding, and difficulties voiding should be asked. Additionally, questions not directly related to voiding, including questions regarding fluid intake, sleep habits, bowel habits, and clumsiness, should be asked.

The answers to such questions may be useful in helping to determine whether the NE is due to nocturnal polyuria or a diminished functional capacity. With careful questioning, daytime voiding symptoms may be elicited, helping to successfully structure a treatment plan for bothersome NE. Optimally, a structured, validated questionnaire should be used.

Voiding Diary or Frequency Volume Chart

It is difficult for most parents and children to precisely answer questions regarding the number of episodes of NE per week, urinary frequency, and voided volumes. Hence, a voiding diary or frequency volume chart is extremely useful. Despite day-to-day variation, a voiding diary is an important tool in helping to determine the etiology of the NE, devising a treatment plan, and monitoring response to treatment. Optimally, a voiding diary should include record of a child's fluid intake and urine output. The frequency and volume voided should also be recorded. Attempts should be made to quantify the amount of urine voided during the enuretic episode. Although somewhat controversial, the functional bladder capacity is assumed to be the volume of the largest single void that occurs overnight.[88]

After analyzing various studies, Hjalmas and colleagues recommend a 2-day, 3-night voiding record.[65,88,89] As volumes of urine produced and storage capacity may vary from day to day, Hjalmas and colleagues suggest that a uroflow with measurements of postvoid residual may be helpful to screen for dysfunction voiding.[88]

In children with secondary enuresis, a social and psychological history becomes important. Various factors may affect a child's voiding habits, including the family situation, the school environment, and other changes in the child's daily way of life. It is very important to discuss the family's response to the child's enuresis. Children may feel punished by having to wear a pull-up. They may be ridiculed by siblings and other family members, worsening the child's social situation.[88]

When children have extended periods of dryness, they should be congratulated by both their parents and the professionals caring for them. Not only does the child feel better for not wetting, but also it becomes apparent to him or her that this is a condition he or she may outgrow. Parents may become reassured that anatomic problems are unlikely to be the cause of the enuresis.

A thorough sleep history should be taken, and it should be noted how much the child is sleeping compared with other children his or her age.[90] Obstructive sleep apnea may contribute to the child's NE. Parents should be asked if the child snores, is a mouth breather, or has restless sleep. Teachers may have noted morning tiredness.

NONMONOSYMPTOMATIC NOCTURNAL ENURESIS

Hjalmas and colleagues describe complex bedwetting as nonmonosymptomatic bedwetting.[88] These are children whose NE is refractory to therapy or those that are noted to have anatomical or neurological abnormalities. Here the challenge remains that of identifying urological causes for the wetting. As previously described, this search is often aided by a thorough history. If dysfunction storage or voiding is identified, the cause for the refractory nighttime wetting may become treatable.

Further evaluations, including uroflow examinations, urodynamics, and radiographic evaluation of the upper tracts, often become necessary. The signs and symptoms of dysfunctional voiding were previously described in this chapter.

PHYSICAL EXAMINATION

Anatomical and behavioral causes for enuresis may be ruled out by a thorough physical examination. From the moment a child enters the examination room, his or her behavior and gait should be noted. Possible signs of neuropathic voiding dysfunction include abnormal gait, spinal deformities, and foot abnormalities, including asymmetry, high-arched feet, or hammertoes. *Physical signs of occult spinal abnormalities, such as dimples, tufts of hair, skin discoloration, lipoma, asymmetrical buttocks, and gluteal clefts, are also important.* Anal sphincter tone and perineal sensation and reflexes should be checked.

The abdomen is then palpated to evaluate a distended bladder and stool. If stool is palpated, the possibility of dysfunctional elimination syndrome should be considered.[91]

In *boys,* a genital examination may reveal an abnormal meatus, e.g., stenotic, hypospadiac, or epispadiac. The significance of these meatal abnormalities may vary and can often be elicited when a voiding history is obtained. If the significance of the anomalies remains unclear, a more objective uroflow may be obtained.

Abnormalities of the female perineum that may contribute to abnormal voiding include labial adhesions, urogenital sinuses, ectopic ureteral orifices, and hypospadiac urethra. Some of these conditions may be related to dysfunctional voiding in girls.[92] Both girls and boys should be carefully examined for signs of sexual abuse.[93,94]

Laboratory Tests

For a healthy child with MNE, laboratory tests rarely contribute to the evaluation and treatment of the condition. A urinalysis and urine culture may be considered to screen for UTI, diabetes mellitus, and diabetes insipidus.

Urodynamics and Imaging

Urodynamic evaluation and upper tract imaging are necessary where there is a suspicion of neurological dysfunction or in a severely refractory patient.

TREATMENT

Only after carefully reviewing the child's history and physical examination can a sound treatment plan be devised. It is imperative to answer these two questions before treating the patient: (1) Is an underlying voiding dysfunction present? (2) Is bedwetting the only complaint? (Is this truly MNE?) If the condition is truly MNE, does the child have increased nocturnal urine production (nocturnal polyuria) or a small functional bladder capacity?

It is argued that treatment of enuresis should be based on its etiology.[66,95] The treatment plan should be tailored to the individual child's needs.

Starting Out

Prior to initiating therapy with an alarm or a medication, the clinician should review some basic guidelines with the child and his or her parents. It has been shown that educating them about the problem will help compliance and outcome of therapy.[96] These guidelines include encouraging regular daytime voiding schedules, avoiding the intake of excessive food or fluid intake for several hours before bed, emptying the bladder before bedtime, and encouraging the child to get adequate amounts of sleep for age.[88,90] A low-calcium and low-sodium dietary content of the afternoon and evening meals may also be useful.[73,97] Some parents find it useful to arouse and escort the child to the bathroom before they themselves are going to sleep.

Additional motivational tools, such as having children mark a calendar to signify wet and dry nights, have had some success. The literature has reported success in up to 18% of children utilizing such tools.[98]

Comorbid conditions, such as encopresis, constipation, and psychiatric disorders, should be treated at this point in time as well. Up to 72% of enuresis has been cured with treatment of these comorbid conditions.[99,100] If present, daytime voiding symptoms should be treated prior to initiating therapy for NE.[101,102]

For treatment of enuresis to be successful, the child and family must be motivated and the clinician must be prepared to be patient and supportive. Expectations should be realistic, and relapses should not be considered complete failure. If a child does not consider wetting a problem, the outcome of therapy may be poor and waiting may be more appropriate. Children younger than 6 years old are rarely interested in becoming dry at night. Wetting should not be punished, and successes should be rewarded.

The condition may be treated using these simple guidelines alone. It is our practice to provide baseline counseling prior to the initiation of specific treatment in most enuretic children.

Alarm Therapy

Currently available enuretic alarms are small devices that are clipped to the undergarments and worn throughout the night or placed at the bedside. Alarms worn on the body are as effective as bedside alarms.[103] Although highly effective, the exact mechanism by which alarm treatment works is not known. The behavioral modification is not classical conditioning, as the stimulus is a result of the behavior. Instead, the alarm appears to work by negative reinforcement or avoidance. It goes off and awakens the child during voiding; the child then must get out of bed and finish voiding in the toilet or hold his or her urine until later.

Alarm therapy is a successful treatment for bedwetting with initial and long-term success rates of 70%–90% and 50%–70%, respectively.[104,105]

Evidence-based medicine teaches us that alarm therapy is among the most effective interventions for treating childhood NE. Several systematic reviews and meta-analyses report success rates of 65%–70%, with a treatment duration of 5–12 weeks, and stated relapse rates of 15%–30% in the 6 months after treatment.[106–108] As efficacy improves with time, enuresis alarms may not be suitable in families unwilling to wait several months for improvement.[109]

A Cochrane review was recently published on alarm interventions, including 22 randomized controlled trials involving 1125 children.[109] After considering 952 potentially relevant studies, only 22 were considered of quality sufficient to be analyzed. Therefore, although highly successful in certain situations, the review concluded that studies comparing alarms with pharmaceuticals are warranted.

Expectations and commitment to the alarm's use must be discussed, as alarm therapy requires a motivated child and family, and significant effort and time. The alarm may interrupt not only the affected child's sleep but also that of the parents and other siblings. Once the alarm is activated, a parent will often have to wake up and get out of bed to assist the child to the bathroom to finish voiding, change the sheets and pajamas, return the child to bed, and reset the alarm. Often, the child is not fully awake during this entire process. The parent, on the other hand, is fully awake, and unless he or she is fully committed to the cause, he or she may begin to resent the child, leading to parental intolerance.[110] Parental intolerance may lead to discontinuation or early withdrawal from alarm treatment.[111]

When using the alarm, biweekly follow-up has been suggested to monitor therapy and continue motivation.[88] The alarm should be used for at least 1 month after a period of sustained dryness. Twenty-nine to sixty-six percent of children may relapse; however, this does not preclude repeated use of the alarm.

Use of the alarm may affect arousal, overnight urine production, and nocturnal bladder capacity. Oredsson and Jorgensen reported increase of bladder capacity but no change in nocturnal urine output or vasopressin secretion.[69]

Butler has defined outcomes to aid in the evaluation of the effectiveness of alarm treatment: *initial success*, a minimum of 14 consecutive dry nights within 16 weeks of alarm treatment; *relapse*, two wet nights in 2 weeks; *continued success*, no relapse within 6 months of initial success; and *complete success*, no relapse within 2 years of initial success.[112]

Alarm treatment is widely believed to be the most effective therapy for NE with the best long-term results.[113] In the metanalysis by Houts et al., 62% of children were dry at the end of treatment, with 47% dry at follow-up.[114] Similar successes with up to 77.9% dry have also been reported, with the likelihood for 14 consecutive dry nights 13.3 times higher than that without treatment.[100] Successes using the alarm are also considered to be more durable by some, as treatment using desmopressin and tricyclics has not been sustained once therapy has been withdrawn.[109] However, *long-term* desmopressin treatment has also been shown to produce sustained improvement, although reported cure rates with alarm are generally higher.[115,116]

Predictors of poor response with the enuresis alarm have been summarized by Butler and Stenberg 95 and Hjalmas et al. and include parental intolerance and annoyance, children with low self-esteem, behavioral problems or lack of motivation, family history of bedwetting, associated daytime wetting, lack of supervision, inconsistent use, family stress, psychiatric disorder in the child, failure to awaken in response to the alarm, unsatisfactory housing conditions, and more than one wetting episode per night.[88,105,111,117–120]

PHARMACOLOGICAL TREATMENT

Desmopressin (dDAVP)

Many patients with MNE lack the nocturnal rise of ADH, therefore causing an imbalance in the normal circadian variation in urine production. This results in the production of large quantities of dilute urine at night. When the amount of urine produced overnight exceeds the bladder capacity, NE will occur.[121] A study by Hansen and

Jorgensen confirmed that nighttime urine production was reduced during desmopressin treatment.[122]

Arginine vasopressin (also known as ADH) is a polypeptide produced in the hypothalamus and released from the pituitary gland. Its release is due to hyperosmolality or a low effective circulating blood volume. The polypeptide's effect is on V2 receptors of the collecting ducts and distal tubules to enhance water reabsorption.[123] It is also a potent vasopressor, through independent actions on V1 receptors.

Desmopressin is an analogue of vasopressin. Unlike ADH, this analogue has increased antidiuretic activity without vasopressor activity. The half-life is 1.5–3.5 hours. Desmopressin is commercially available in an oral and intranasal formula. The usual dose is 0.2–0.6 mg orally or 10–40 μg intranasally at bedtime with immediate clinical effects. Fluid intake should be limited when the drug is used. A simple suggestion is to avoid drinking for 2 hours before bed and to limit fluid intake to 8 ounces after dinner.

Desmopressin is regarded safe for use in children and is generally well tolerated with a low incidence of adverse events.[115,116] Continued safety has been demonstrated with long-term use. Klauber reported no serious adverse reactions in 516 cases.[124] In the SWEET study, only 6 of 242 children (2.5%) withdrew during the long-term intranasal treatment due to very mild adverse events. All monitored clinical and laboratory parameters remained within normal in this study.[115]

The risk of water intoxication should be discussed with parents prior to initiating dDAVP therapy, and it is for these reasons that fluid intake during dinner and before bedtime should be limited. In this case, hyponatremia is due to a large amount of fluid intake while taking the drug.[125]

Although children with nocturnal polyuria and low nocturnal urine osmolality should respond best to dDAVP treatment, some studies have not found any significant differences in urine output, osmolality, or vasopressin secretion in responders and nonresponders.[126,127]

Prior to labeling a child as a nonresponder, it is important to know whether the medication has been administered correctly. In children who do not respond to treatment with dDAVP, nocturnal hypercalciuria and hypernatriuria should also be considered.[73,97]

Other predictors of good response to desmopressin therapy include larger bladder capacities,[88] older children,[128,129] fewer wet nights at presentation,[128,130] normal functional bladder capacity,[127,129] primary as opposed to secondary NE,[131] only one wet episode during the night, enuresis that occurs during the first 2 hours of sleep,[127] a family history of NE,[132,133] and initial good response to the smallest dose of desmopressin used in the study (20 μg intranasally).[134]

Several controlled studies have demonstrated the effectiveness of desmopressin in the treatment of NE,[135–138] regardless of the route of administration. Positive response (defined as more than a 50% reduction of wet nights) has been reported in 60%–70% of patients.[64,70,65] A review of randomized trials comparing desmopressin to placebo found that desmopressin was significantly better in 13 of the 14 studies.[70] Based on the Cochrane report by Glazener and Evans, patients treated with dDAVP were 4.6 times more likely to achieve 14 consecutive dry nights than those treated with placebo.[139] With a more selected population of children with primary NE, Caione et al. found a 79% success rate after the administration of desmopressin.[140]

When dDAVP treatment is successful, the drug should be stopped for 1 week every 3 months to evaluate whether the problem has been corrected. The annual cure rate in children that have been treated with dDAVP is approximately 30%.[115] Permanent cure may increase to 74.5% by gradually discontinuing the drug and positively reinforcing dry nights over a 10-week period.[141]

Unfortunately, relapse after the cessation of treatment is common, and long-term treatment may yield a better response. Of 399 enuretic children recruited in the Swedish Enuresis Trial,[115] 61% responded to desmopressin treatment initially, and of those responders, 61% were dry after 1 year of treatment. However, using an intent-to-treat analysis, only 19% of patients remained dry after the cessation of therapy.[115]

Desmopressin may be helpful in children who have failed alarm therapy or in families where motivation to use the alarm is lacking. In the short term, desmopressin is reported to produce more rapid improvement than alarm therapy. As children who do poorly with the alarm may do well with dDAVP, the converse may also be true.

Oxybutinin

The antimuscarinic agent oxybutynin is often used as part of combination therapy in enuretic children with a small bladder capacity, daytime incontinence, or detrusor overactivity. Oxybutynin should not be the first recommended therapy for a child with MNE. Yeung et al. found that 30% or more of enuretic children refractory to therapy had detrusor overactivity at night.[84] When using oxybutynin, bladder training should also be considered, as in unselected populations of children with NE, oxybutynin has not been effective in randomized controlled studies.[142] Watanabe and Kawauchi[143] reported a 67% success rate with oxybutynin in a group of children with bladder instability as a cause of their NE; Kass et al.[144] reported a 90% success rate. The drug is also indicated in children with day- and nighttime incontinence and dDAVP nonresponders. The efficacy may improve when combined with desmopressin.[145,146]

Tricyclic Antidepressants

Tricyclic antidepressants, such as imipramine, were extensively used in the treatment of enuresis in the 1970s and 1980s. Imipramine has fallen out of favor for several reasons, including cardiotoxic side effects, risk of death with overdose, and its psychopharmacological properties. The mechanism of action for this drug in the treatment of NE is unclear, although it may act by reducing detrusor activity and increasing bladder capacity secondary to anticholinergic and smooth muscle relaxant effects. Additionally, it may enhance arousal and suppress REM sleep or decrease urine production by a stimulating vasopressin release.[147,148]

Due to the lower efficacy and more dangerous side effect profile of this drug compared with desmopressin

(only 17% of children who were dry during treatment with imipramine remained dry 6 months after cessation of medication and alarm treatment), it should only be used when all else has failed. Due to its dangerous nature, it may be wise to have the treatment be followed by a physician with experience using the drug.[115]

OTHER THERAPIES

Combination Therapy

Some children with NE may have more than one cause for their condition. The most common combined cause of NE is lack of Anti-diuretic hormone (ADH) with poor arousability. In these children, combined therapy may be more successful than a single therapy alone.

Studies using combined desmopressin and the enuresis alarm on unselected groups of children have been published. In a study by Bradbury and Meadow, 71 children were randomized to alarm plus desmopressin (40 μg) or alarm monotherapy for 6 weeks.[149] The combined therapy was more effective than the alarm alone, particularly where the child had severe NE and behavioral problems. In a study by Sukhai et al.,[150] with a crossover design, children were randomized into two treatment groups, i.e., alarm plus desmopressin or alarm with placebo. The results suggested that alarm plus desmopressin was better ($p = 0.05$) than alarm with placebo in treating NE. In a double-blind placebo-controlled study, Leebeek-Groenewegen et al.[151] examined 93 children with MNE. Children were treated with alarm plus desmopressin or alarm plus placebo for 9 weeks. Based on the results of this study, the authors concluded that desmopressin does not result in higher cure rates, and that combined treatment is not justified in all enuretic children at the outset of treatment.

For children with enuresis associated with bladder overactivity, a combination of bladder training and anticholinergic therapy yields success rates of 67%–100%.[85,113,146] Combination therapy with oxybutynin and desmopressin has also been found to be effective in this subgroup of patients.[140]

Behavioral Therapies

Houts suggested that the addition of selected behavioral procedures produces better outcomes than alarm monotherapy.[152] These behavioral procedures include arousal training, normalized voiding, and dry-bed training. *Arousal training* involves reinforced waking and toileting in response to the alarm's trigger. *Normalized voiding* encourages children to increase their fluid intake and participate in timed voiding during the daytime in an attempt to increase cognitive control over voiding. *Dry-bed training* uses the enuresis alarm. The child takes responsibility for removing wet sheets and remaking the bed and also has two waking schedules to ease arousability from sleep.[153] However, in a study by Bollard and Nettelbeck,[154] it was found that the enuresis alarm accounted for most of the success achieved through dry-bed training.

Alternative Therapies

Numerous studies using traditional Chinese acupuncture and laser acupuncture for the treatment of NE have been published.[155,156] In a prospective randomized study comparing laser acupuncture with desmopressin in patients with nocturnal polyuria, laser acupuncture was found to be as efficacious as desmopressin.[156]

Treatment for Nonresponders

Absorptive nocturnal hypercalciuria may be responsible for NE in some children that remain nonresponders despite therapy with dDAVP and anticholinergics. Pace et al. demonstrated that enuretic patients with hypercalciuria that failed to respond to dDAVP became desmopressin responders once they were treated with a low-calcium diet.[157]

Abnormalities in AQP2 urinary excretion have recently been reported as another possible cause of NE.[73] Urinary AQP2 and hypercalciuria correlated with the severity of enuresis in children. The association between AQP2 and hypercalciuria was further strengthened in a recent study by Valenti et al.[158] After 6 months of combined treatment with desmopressin and a low-calcium diet, enuresis resolved in 80% of patients. Arginine vasopressin levels returned to normal, hypercalciuria resolved, and day/night AQP2 ratios returned near normal levels. Based on these recent report, Hjalmas and colleagues suggest that "it may become mandatory to study the CaU/CrU ratio to determine if the enuretic patient is hypercalciuric or not, as a first step to a correct therapeutic strategy for nocturnal enuresis."[115]

CONCLUSION

Despite advances in our understanding of NE, the condition remains complex. The key to success involves a motivated patient and family.

CHAPTER 55

Constipation and Lower Urinary Tract Symptoms

Nicol Corbin Bush, Anjana Shah, Karen Pritzker, Janelle Traylor, and Shabina Walji-Virani

INTRODUCTION

Constipation is a common childhood problem and is thus frequently encountered by pediatric urologists, particularly given the common embryological origin, location, and innervation of the gastrointestinal and genitourinary tracts. This chapter reviews criteria, prevalence, and treatments for constipation and provides an evidence-based review of its relationship with lower urinary tract symptoms (LUTSs) and urinary tract infections (UTIs). In bulleted lists, a summary of evidence is shown, with details about the supporting studies included below the summary for each section.

CRITERIA FOR THE DIAGNOSIS OF CONSTIPATION

- Rome II, Rome III, and Paris Consensus on Childhood Constipation Terminology (PACCT) diagnostic criteria (Table 55.1) are the most commonly used.
- Rome III and PACCT criteria are less restrictive than Rome II criteria.
- Ninety-five percent of children would have met diagnostic criteria for constipation without rectal exam in one study.
- The Bristol Stool Form Scale (BSFS) has not been validated as a tool to diagnose constipation in children.
- Radiographic studies alone, including abdominal radiograph and pelvic ultrasound (US), do not reliably distinguish constipated and nonconstipated children.

Diagnostic Criteria

The International Children's Continence Society (ICCS) provided guidelines for the diagnosis of constipation in children with LUTSs in 2006.[1] They recommended use of either Rome II criteria or the PACCT Group criteria (Table 55.1). Rome II criteria were established by expert consensus, modeled after a similar meeting by experts in Rome, 7 years prior, to establish adult gastrointestinal terminology (Rome I). However, Rome II criteria are often considered too restrictive, and experts convening in Paris at the Second World Congress of Pediatric Gastroenterology, Hepatology and Nutrition in 2004 formed an alternative definition of chronic constipation, referred to as PACCT chronic constipation. In 2006, Rome II criteria to diagnose constipation in children and adolescents were modified by expert opinion and literature review into Rome III criteria.[2]

Studies have compared the various definitions for "functional constipation" (symptoms not explained by structural or biochemical abnormalities). A longitudinal prospective study of 128 children referred to a tertiary clinic for symptoms of chronic constipation was performed, evaluating children based on Rome II and PACCT criteria.[3] The children had a mean age of 5.6 years (standard deviation [SD] 3.8) and 62 (48%) were boys. The authors found functional constipation according to Rome II criteria in 60 (48%) versus in 112 (89%) using PACCT criteria ($p = 0.001$), with poor agreement between the two sets of criteria (kappa = 0.173), implying that these two sets of criteria identify different groups of patients. Most children had symptoms of straining with defecation of scybalous stools (80%) and painful defecation (66%).

A study comparing Rome II and Rome III criteria found that more patients met criteria for functional constipation using Rome III criteria.[4] Retrospective chart review of 336 consecutive patients referred to a tertiary clinic for symptoms of constipation (mean age 6.4 years, SD 3.5 years, 61% boys) revealed constipation by Rome II criteria in 34% versus 87% with Rome III criteria ($p < 0.0001$). While all patients in this report underwent rectal exam for palpable fecal mass, the authors noted that 95% of patients met criteria for functional constipation without the rectal exam. The authors concluded that Rome III criteria were less restrictive than Rome II criteria for functional defecation disorders (symptoms not explained by structural or biochemical abnormalities).

Indicators for Gastroenterology Referral

In addition to the diagnostic criteria for constipation, pediatric urology providers should be aware of "red flags" on history and physical exam, listed in Table 55.2, that can apply to children with constipation and should prompt referral to gastroenterology.

TABLE 55.1 Diagnostic criteria for functional constipation

	Rome II[51]	Rome III[2]	PACCT[52]
Age	Infant to 16 years	Developmental age of ≥4 years	Not specified
Duration of symptoms	Not specified	≥2 months	≥8 weeks
No. of symptoms/exam findings to meet criteria	At least 2	At least 2	At least 2
Diagnostic criteria	1. Majority of stools scybalous, pebble-like, hard 2. Firm stools ≤2 times/week 3. No metabolic, endocrine, structural disease	1. ≤2 defecations per week 2. At least 1 episode of fecal incontinence per week 3. Stool retentive posturing 4. Hard or painful bowel movements 5. Large-diameter stools that could obstruct the toilet 6. Large fecal mass in rectum	1. <3 defecations per week 2. >1 episode of fecal incontinence per week 3. Large fecal mass in rectum or palpable in abdomen 4. Large-diameter stools that could obstruct the toilet 5. Stool retentive posturing 6. Hard or painful bowel movements

TABLE 55.2 Findings on history and/or physical exam in children with constipation that should prompt referral to gastroenterology

Constipation red flags	
History	**Physical**
Failure to thrive	Absent/brisk lower limb reflexes
Delayed passage of meconium >24 hours	Mouth ulcers
Abnormal bowel habits since birth	Blood/mucous mixed with stool
Sensitive to cold, fatigue, dry skin, pallor	Perianal skin tags or fistulas
Change in bowel pattern with cow's milk	Associated hypotonia
Weight loss	Tight empty rectum
Vomiting	Pilonidal dimple covered by a tuft of hair

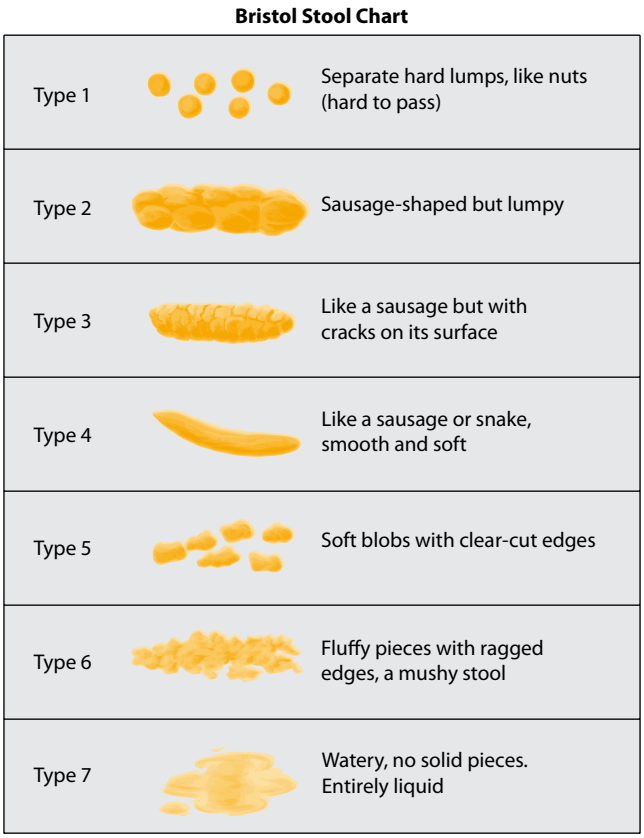

FIGURE 55.1 The Bristol stool scale source, this form is now owned by the ROME foundation. (Adapted from Lewis SJ, Heaton KW. *Scand J Gastroenterol* 1997;32(9):920–4.)

Bristol Stool Form Scale

Although many authors use stool Type 1 (separate hard lumps, like nuts, hard to pass) and Type 2 (sausage shaped but lumpy) as a diagnostic proxy for constipation, the Bristol stool form scale (BSFS) (Figure 55.1) was originally validated to measure gastrointestinal transit time in adults and is not specific for the diagnosis of functional constipation.[6,7] In addition to being nonvalidated to diagnose functional constipation, the BSFS has not been validated for use in children. The only study validating a stool form scale for use in children was published in 2011 and used a modified version of the BSFS.[8] The authors shortened the scale to five categories instead of seven, omitting Type 3 (like a sausage or snake but with cracks on its surface) and Type 5 (soft blobs with clear-cut edges) in order to decrease the amount of discrimination that must be made by children while maintaining a range of stool forms. A total of 310 children aged 3–18 years were shown 10 standardized pictures of stool (2 pictures per category, previously shown to have high interrater agreement among 14 pediatric gastroenterologists).[9] Initial testing by showing the scale without reading the descriptors aloud showed low reliability among the first 119 children for children of <8 years (intraclass correlation coefficients 0.16, 0.61, 0.72, 0.81, and 0.86 for ages 3–5 years, 6–7, 8–10, 11–13, and 14–18, respectively). Patients aged ≥8 years correctly rated the stool pictures >78% of the time. The descriptors were then read aloud

for the subsequent 191 patients, which improved reliability for children aged 6–7 years (intraclass correlation 0.74), with >80% ratings correct for children of ≥6 years old, leading the authors to conclude that the scale is valid and reliable for children of >6 years with descriptors read aloud and children of >8 years without descriptors read aloud. Now that a stool form scale has been validated for use in children, it can be applied to children meeting Rome III and/or PACCT diagnostic criteria to determine if Type 1 and Type 2 stool indeed reflect functional constipation, as has been commonly attributed in the literature. It remains to be seen whether the scale is valid for multiple ratings across time in children.

Abdominal Radiograph

Multiple radiographic fecal load scoring tools exist to diagnose constipation, which are nicely reviewed by Reuchlin-Vroklage et al.[10] This review points out the subjective nature of most of these grading systems and demonstrates that there is high intra- and interobserver variability in these studies, questioning the utility of abdominal radiography as a reliable diagnostic tool. The synthesis of evidence in this review showed that radiographically defined constipation was equally present in clinically constipated and nonconstipated children. Furthermore, these x-ray studies have only been used to diagnose constipation and have not been validated to see whether score changes reflect symptoms over time and/or with therapy. One retrospective study evaluated the variability among pediatric urology providers grading constipation using three commonly accepted grading scales: Barr, Blethyn, and Leech.[11] The abdominal radiographs of 80 children aged 4–12 years were separately reviewed in random order by six providers, including two experienced pediatric urologists (17 and 20 years), a pediatric radiologist with 20 years' experience, and three pediatric nurse practitioners with variable experience (2–10 years). Interrater reliability (the agreement between raters) using kappa statistics (where kappa values of >0.75 indicate excellent, 0.4–0.75 good, and <0.4 poor reliability) was poor to marginally good using all three rating systems: Barr 0.049–0.481, Blethyn 0.045–0.451, and Leech 0.119–0.273. Similarly, intraclass correlations (another measure of reliability testing describing the reproducibility of measurements made by different observers rating the same image measured with a scale similar to kappa statistics) were quite poor for all three rating systems (Barr 0.026, Blethyn 0.201, and Leech 0.331). None of the scoring systems provided reliable results between observers in grading constipation.

Ultrasound

Recently, abdominal and pelvic US has been evaluated as a means of diagnosing constipation. Four case-control studies have been performed to evaluate the transverse diameter of the rectum on US as a diagnostic tool for constipation.[12–15] In total, 265 children with constipation (various definitions) and 237 controls were evaluated by measuring the transverse diameter of the rectal ampulla approximately 1–2 cm above the symphysis, with the bladder moderately full, with angles varying from 15° from the transverse plain to 90° to the abdominal wall, with the largest diameter recorded in three studies and the mean of three values in one.[15] All four studies found significantly larger mean and median rectal diameters among patients with constipation compared with controls; however, there was substantial overlap between constipated patients and controls in two of the three studies.[12,13] Furthermore, rectal diameter was found to increase with age in both constipated children and controls,[12,14] such that a cutoff value to diagnose constipation has not been proposed. In one study of 51 children (27 with Rome III constipation and 24 without, average age 9.1 years, SD 2.7), a cutoff determined by the mean of healthy controls + 2 SD (3.34 mm) would misclassify 13/51 (25%) children if used as the only diagnostic criteria for constipation.[15] A similar cutoff for constipation (3.00 mm) in another study of 95 constipated children versus 82 controls (median age 5.5 years, intraquartile range 3.75) would also misclassify 25% of children in both groups.[12] Given the subjective nature of US evaluation, it has been recommended that inter- and intrarater reliability, validity, and objectivity are determined prior to adopting US as a mainstay diagnostic tool to diagnose constipation, particularly since it is unknown if the diameter changes in relation to the timing of the last defecation.[14]

PREVALENCE

- Constipation, defined by <3 bowel movements per week, is present in approximately 10% of children (range 1%–30%).
- In five epidemiologic studies, constipation was equally prevalent in boys and girls, whereas in two studies, girls had a higher prevalence.

TABLE 55.3 Normal frequency of bowel movements in infants and children

Age	Bowel movements per week (mean ± 2 SD)	Mean number of bowel movements per day
0–3 months breastfed	5–40	2.9
0–3 months formula fed	5–28	2.0
6–12 months	5–28	1.8
1–3 years	4–21	1.4
>3 years	3–14	1.0

Source: Adapted from Fontana M et al. *Acta Paediatr Scand* 1987;78:682.

- Fecal soiling is present in ≤10% of children and is more commonly reported in boys.

Table 55.3 depicts the normal bowel habits based on a population-based sample of 662 healthy Italian children, endorsed by the Constipation Subcommittee of the Clinical Guidelines Committee of the North American Society for Pediatric Gastroenterology and Nutrition.[16]

Population-based epidemiologic studies of both urinary and bowel habits among healthy children are scarce. Approximately 10% of children aged 0–18 years have <3 bowel movements per week according to a 2006 systematic review of 18 epidemiologic studies (range 0.7–29.6%, intraquartile range of average bowel movements per week 1.3–21.3).[18] The wide variation was thought to be attributable to various definitions of constipation, as well as differing durations of symptoms for inclusion. Of the seven studies reporting gender-specific prevalence, boys and girls had an equal prevalence of constipation in five, whereas two reported a higher prevalence in girls. Additional relevant studies not included in the aforementioned systematic review are listed below.

1. A questionnaire-based study of parents of 16,516 Korean school children aged 5–13 years demonstrated the following symptoms in the 3 months prior to the survey: decreased stool frequency (<3 times/week) in 1103 (6.7%), painful or difficult defecation in 2609 (15.8%), Bristol stool Type 1 or 2 in 1941 (11.8%), and fecal incontinence in 1293 (7.8%). Parents of girls were more likely to report decreased frequency, painful defecation, and constipation on the Bristol scale, whereas parents of boys reported fecal incontinence more often (9.8% boys vs. 5.8% girls).[19]
2. A cross-sectional study of 5282 Japanese school children (mean 9 years, range 7–12), found constipation (<3 times/week, duration not specified) in 971 (18%).[20]
3. Constipation defined by Rome II criteria was present in 5.7% of 2856 Australian children (mean 7.3 years, SD 1.3) whose parents answered a validated questionnaire about bowel and bladder habits. Fecal soiling was present in 10%.[21]
4. A cross-sectional school-based study of 1694 Turkish children (49% boys, 9.2 ± 1.2 years) demonstrated constipation defined by PACCT criteria in 6.9% and fecal incontinence in 3.1%.[22]
5. Healthy children from kindergarten and elementary schools were invited to participate in a study about voiding and defecation function, with 778 participants (53% boys, 7 ± 2 years). Constipation (<3 times/week) was present in 85 (11%); BSFS Types 1 and 2 were present in the past month in 213 (28%) children. There was no difference between genders.[23]
6. In a retrospective chart review, constipation defined by PACCT criteria was present at some point in the child's life in 109 (23%) of 482 children followed in a primary care clinic, including 55 (22%) boys and 54 (23%) girls ($p = 0.9$). The mean age at first visit for constipation was 4.9 years, ranging from <1 in 14 (13%) to 12–14 years in 6 (6%) of the 109 patients. Fecal soiling was documented in the charts of 4.4% of patients, with more boys than girls affected by fecal soiling (7% vs. 1%, $p < 0.001$).[24]

RELATIONSHIP WITH URINARY SYMPTOMS

LUTSs for Daytime Urinary Incontinence: Summary of Evidence

- Constipation was not associated with overactive bladder (OAB) symptoms in three population-based studies and one randomized controlled trial (RCT); it was marginally associated with frequent voiding ± urgency in one population-based study.
- Fecal incontinence was associated with OAB symptoms in two population-based survey studies.
- One study showed slightly increased postvoid residual (PVR) and decreased voiding efficiency and percent children with a PVR of >20 mL in those with <3 bowel movements a week, but no difference in voided volumes, uroflow patterns, urinary urgency, or daytime incontinence.
- One study in children with refractory LUTSs demonstrated no predictable urodynamic (UD) changes when UD was performed with and without pressure-controlled rectal filling.

A questionnaire-based study of parents of 16,516 Korean school children aged 5–13 years defined OAB by ICCS guidelines as urgency with or without urge incontinence. OAB was present in 2740 children (16.6%), which decreased with age from 22.9% at age 5 years to 12.2% at 13 years ($p = 0.0001$).[25] Constipation, as defined by Bristol scale Types 1 and 2, present in 1941 (11.8%) children, was marginally associated with OAB on multivariate analysis ($p = 0.045$, odds ratio [OR] and confidence interval [CI] not provided), but constipation defined by a frequency of <3 times/week and painful defecation was not. Fecal incontinence also increased risk ($p = 0.0001$, OR and CI not provided).

Among the 5282 Japanese school children reported above, constipation was defined as <3 bowel movements per week, and OAB was defined as ≥1 SD beyond the average number of voids per day per age ± urge incontinence at least one time per month.[20] OAB was equally present in children with and without constipation (20% with vs. 18% without, $p > 0.05$). Polysymptomatic enuresis (OAB + nocturnal enuresis) was slightly more common in children with constipation (3% with vs. 2% without, $p < 0.05$).

A population-based survey of 580 Brazilian children (47% boys, 6.1 ± 2 years) that administered a modified Farhat validated voiding dysfunction scale found urinary urgency in 50%, with voiding dysfunction (defined by >6 points for girls, >9 points for boys) present in 23%.[49] Straining to defecate in the past 15 days occurred in 8.8%. Constipation, defined by >72-hour intervals between bowel movements, was present in only 3.1% and was not associated with dysfunctional voiding on the questionnaire.

Healthy children from kindergarten and elementary schools were invited to participate in a study about voiding and defecation function, including uroflow and US-measured PVRs.[23] Among 778 participants (53% boys, 7 ± 2 years) with eligible data, results were reported for children with constipation (<3 times/week), present in 85 (11%). Patients with low defecation frequency had higher PVRs than those without (9.0 mL vs. 5.9 mL, $p = 0.01$), decreased voiding efficiency (93% vs. 95% of expected bladder capacity [Age + 2] × 30 mL, $p = 0.04$), and a higher percentage with PVR > 20 mL (18% vs. 7%, $p = 0.01$). There were no differences in percent with non-bell-shaped curves (19% vs. 14%, $p = 0.32$). Responses to questions regarding urinary urgency ($p = 0.93$), daytime urinary incontinence ($p = 0.53$), or fecal incontinence ($p = 0.62$) were similar between groups, and there was no correlation between urinary urgency and defecation frequency (Pearson $R = 0.06$). There were no differences in PVR, voiding efficiency, percent elevated PVR, or flow patterns between patients with and without constipation defined by BSFS Types 1 and 2, present in 213 (28%) children.

An analysis of fecal load by abdominal radiograph in one RCT found no association of urinary urge symptoms with constipation defined by the Leech and Blethyn abdominal radiograph rating systems.[26] A total of 138 children (62% girls, 7.3 ± 2.3 years) underwent baseline urinary and bowel symptom questionnaires and abdominal radiograph, of whom 61 (47%) had radiographically defined constipation using either scale. Fecal load scores as judged by a pediatric radiologist blinded to treatment group had no correlation with OAB or fecal symptoms at baseline or after 1 month of therapy (Spearman's correlation $R = -0.155$, $p = 0.08$ baseline, and $R = -0.149$, $p = 0.28$ posttherapy). Fecal load scores before and after treatment with polyethylene glycol (PEG) or placebo did not change, yet 45% of children in both groups had improvement in OAB symptoms, including complete response in five patients taking placebo and six patients taking PEG.

A prospective study by Loening-Baucke of 234 children (75% boys, 9 ± 3 years) referred for both constipation (not defined) and fecal soiling showed incontinence at least one time per week in 46% (duration not defined), including nocturnal enuresis in 17%, daytime and night wetting in 17%, and daytime wetting in 12%.[27]

In a prospective study, 26 consecutive children undergoing urodynamics (UD) for severe LUTSs were evaluated by gastroenterology specialists for constipation.[28] Of these, 20 (77%) meet Rome III criteria for constipation, while 6 did not. Clinical symptoms and UD findings were not different between these groups, including median bladder capacity (percent estimated), voiding pressures, median flow rate, peak flow rate, and PVR estimates. UD study was performed with and without inflation of a barostat pressure-controlled balloon, with no predictable change in UD patterns when the rectum was balloon filled.

A retrospective chart review of 482 children (51% boys, 8.6 ± 3.9 years) seen in a primary care office in Iowa demonstrated that 109 (22.6%) had been evaluated for constipation (PACCT criteria) at some point in their life.[24] Fecal incontinence was documented in 4.4%. Daytime urinary incontinence (≥1 time/week at any point after age 5 years, duration not specified) was recorded in the charts of 9.1% of 389 children (selection criteria not specified) in whom constipation was documented versus 3.9% in whom constipation was not documented; however, the author does not address whether urinary symptoms were routinely recorded as part of the review of systems in children presenting with constipation versus all patients.

Retrospective chart review of 40 patients referred with complaints of urinary urgency, frequency, and/or incontinence revealed constipation by Rome III criteria in 45% and BSFS Types 1 and 2 in 30%. Fecal soiling occurred in 12.5% (Kim 2011).

Nocturnal Enuresis: Summary of Evidence

- Three cross-sectional studies reported that constipation was not a risk factor for nocturnal enuresis.
- Two stated that fecal incontinence was associated with enuresis, found in 11% of enuretics in one study.

Among the 2856 Australian children in the cross-sectional study described above, enuresis was categorized as mild (1–6 episodes in the past month), moderate (≥7 episodes in past month), and severe (nightly the past 1 month).[21] Constipation, defined by ROME II criteria, was not associated with nocturnal enuresis (mild OR 0.7 [95% CI 0.4–1.2], moderate OR 1.5 [95% CI 0.7–3.6], and severe OR 0.7 [95% CI 0.3–1.9]). However, fecal incontinence was an independent risk factor for enuresis in multivariate logistic regression adjusting for age (mild OR 1.6 [95% CI 1.0–2.4], moderate OR 2.1 [95% CI 1.1–4.3], and severe OR 2.7 [95% CI 1.6–4.4]).

A survey study of 5350 children (mean 9.1 years, SD 2.9) demonstrated enuresis ≥2 times/week in 679 (12.7%).[29] Constipation (defined as <3 bowel movements per week for at least 6 months) was present in 48/679 (7.1%) enuretic children versus 68/4671 (1.5%) without nocturnal enuresis ($p < 0.0001$). However, it was not specified how daytime urinary symptoms were assessed, and logistic regression controlling for factors such as age and gender was not performed.

Among the 5282 Japanese school children reported above, monosymptomatic nocturnal enuresis was equally present in children with (3.0%) and without (3.6%) constipation (<3 times/week, $p > 0.05$).[20]

Among the 1694 Turkish children (49% boys, 9.2 ± 1.2 years) reported above, enuresis (≥2 nights/week) was present in 108 (6.4%).[22] While constipation defined by PACCT criteria was associated with enuresis in univariate analysis, it was not a significant predictor on multivariate analysis (OR 0.88, 95% CI 0.19–4.20). However, fecal incontinence was a risk factor for enuresis on multivariate analysis (OR 6.13, 95% CI 1.46–4.83). Fecal incontinence was present in 17 (11%) children with enuresis versus 35 (2%) without. This study did not differentiate patients with mono- or polysymptomatic enuresis, with 64% and 36% of enuretic children reporting urination >5 times/day and history of UTI, respectively.

A prospective study of 277 children (66% males, mean 8.6 years) referred for nocturnal enuresis (unclear if mono- or polysymptomatic) reported fecal soiling in 125 (45%), bowel movements <1 time/day in 114 (41%), straining to defecate in 158 (57%), and hard stools in 62 (22%).[30] The

clinician reported that 100 (36%) children were constipated based on a compilation of these symptoms, whereas only 39 (14%) children were identified as constipated by parental response on a (nonvalidated) questionnaire.

A retrospective chart review of 482 children (51% boys, 8.6 ± 3.9 years) seen in a primary care office in the study detailed above found nocturnal enuresis occurring ≥1 time/week in 5.4% of a subset of 389 children (selection criteria not specified, duration of incontinence not specified), including 13% of children meeting PACCT criteria for constipation and 3% of children without constipation.[27]

UTI and VUR: Summary of Evidence

- In one series, 11% of constipated patients had a history of UTI and 2% had vesicoureteral reflux (VUR).
- One case-control study demonstrated that encopresis was more likely in patients with >1 vs. 1 UTI.

Of 234 consecutive children (75% boys, 9 ± 3 years) referred for chronic constipation (not defined), UTIs were present in 25 (10.7%, including 6/176 boys and 19/58 girls).[27] A total of four (1.7%) patients (one male, three females) had VUR on voiding cystourethrography, which was obtained in all children with UTIs or any unexplained fever. No additional UTIs were noted during a follow-up of at least 12 months in these children who were treated with disimpaction, maintenance laxatives (typically milk of magnesia), and antibiotic prophylaxis until constipation resolved.

A retrospective review of 94 children aged 2–14 years demonstrated moderate to severe fecal load via the Blethyn grading system (Grade 2 or 3) in 7/33 (21%) controls, 9/24 (38%) with 1 UTI, 12/24 (50%) with 2–5 UTIs, and 7/13 (54%) with >5 UTIs.[31] However, reading of the abdominal radiographs was not blinded, and there was unequal gender distribution among the groups, with females comprising nearly all the patients with two or more UTIs compared with a substantial portion of males with 0 or 1 UTI.

A case-control study compared dysfunctional voiding rates among children with and without febrile UTI who presented to the emergency room with fever between 0 and 2 years of age by mailing Dysfunctional Voiding Symptom Score (DVSS) questionnaires to them several years later, after the age of toilet training (mean age 7 years).[32] Among 248 children (123 with a history of UTI in infancy and 125 controls), 13% had to push or had pain with defecation >50% of the time, and 64 (26%) had encopresis defined by the DVSS questionnaire. They found an overall rate of dysfunctional elimination syndrome (DES) in 53/248 (21%) children, with no difference between children with and without febrile UTI in infancy (22% vs. 21%, $p = 0.82$). Among the 115 children with UTI in infancy, 18% of children with VUR (diagnosed at the time of their original UTI) and 25% without VUR had DES symptoms after toilet training ($p = 0.52$). VUR was not associated with DES on univariate or multivariate analysis. Of these 115, 31 children had one or more confirmed additional UTIs. Univariate analysis demonstrated that encopresis and VUR were seen in a higher percentage of patients with >1 versus 1 UTI, while DES (DVSS score >6 for girls and >9 for boys and present in 11 [36%]) was not (OR 2.2, 95% CI 0.99–5). Multivariate analysis demonstrated that encopresis was the only significant risk factor for UTI recurrence (OR not given, $p = 0.03$).

Therapy for Constipation: Summary of Evidence

Does therapy for constipation impact LUTSs of daytime urinary incontinence?

- Two RCTs showed LUTSs improved irrespective of the presence or absence of constipation at follow-up.

Several nonrandomized uncontrolled studies report urinary symptom improvement with the use of laxatives; however, given a high placebo response rate for urologic symptoms (approximately 40% based on a Cochrane meta-analysis of patients receiving placebo for OAB), uncontrolled studies are unable to address whether therapy directed specifically toward constipation offers additional benefit beyond placebo.[33]

To our knowledge, only one RCT has evaluated the use of a laxative on symptoms of OAB without additional bladder therapy, such as timed voiding or anticholinergics.[26] A total of 138 children (85 [62%] girls, mean age 7.3 years, SD 2.3) underwent baseline urinary symptom questionnaires (modified DVSS) and were randomized to daily PEG (mean 0.5 mg/kg/day) or placebo in this double-blind study. Symptom questionnaires were repeated after 1 month, with improvement defined as ≥20% decrease in urge symptoms (≥3-point decrease on a 16-point scale). The randomization process, power calculation, and primary outcome variables were specified, and patients and providers were blinded to the treatment group; however, the study had a high dropout rate, with 71/138 (51.4%) completing the study per protocol. Demographics were similar for the study noncompleters and completers, and five of six patients able to be contacted by phone said that they did not follow up due to symptom improvement. Patients in both groups showed significant improvement in urinary symptoms (pre- and posturine scores: 13.9/10.5 for placebo and 13.9/10.2 for PEG, $p < 0.0001$ for both), with 17/38 (44.7%) and 16/33 (48.5%) assigned placebo and PEG, respectively, showing symptom improvement. PEG did not demonstrate an added benefit over placebo in intention-to-treat ($p = 0.77$) or per-protocol ($p = 0.84$) analyses. Two patients assigned PEG and one assigned placebo developed diarrhea as the only adverse events.

A multicenter, prospective RCT (European Bladder Dysfunction Study) evaluated urinary and bowel symptoms at baseline and after 6 months of treatment.[50] Of the 179 enrolled children (89% girls), 17 (9%) had <3 bowel movements per week and/or painful defecation, and 57 (32%) had fecal soiling. After therapy (biofeedback, placebo, or oxybutinin), fecal soiling decreased to 38/179 (21%, $p = 0.035$), with no difference in the three treatment arms. However, children with resolution of their fecal soiling and/or constipation had outcomes for their urinary incontinence similar to those with persistent fecal soiling and/or constipation, leading the authors to conclude that disordered defecation does not cause urinary incontinence, and that both conditions improve with demystification and behavioral training.

In the Loening-Baucke study mentioned above, urinary incontinence was present at least one time per week in 107 (46%) of 234 children (75% boys, 9 ± 3 years) referred for both constipation and fecal soiling.[27] At a mean follow-up of 15 months, daytime incontinence was cured (not defined) in 47 (73%) of 64 children, and nighttime wetting was cured (not defined) in 39 (49%) of 80 children who had wetting episodes at baseline at least one time per week (some patients had both day and night wetting; thus, the total number of patients does not total 107). After ≥12 months of therapy, patients were considered cured of constipation when >3 bowel movements per week without soiling was achieved without the need for laxatives, which was achieved in 121 (52%). Incontinence decreased significantly in patients both with and without cure of their constipation.

Does therapy for constipation impact nocturnal enuresis?

- No RCTs using laxatives or other bowel regimens as monotherapy for monosymptomatic nocturnal enuresis have been performed
- Two studies showed nocturnal enuresis improved with constipation therapy.

In a prospective study, 234 patients with functional constipation and encopresis, mean age 9 years (SD 3), were evaluated for urinary incontinence one or more times per week at baseline and at least 12 months after therapy, which consisted of disimpaction and maintenance with milk of magnesia, mineral oil, or sorbitol, plus high-fiber diet and behavioral therapy.[27] Nocturnal enuresis was present in 80 (34%) children, equally split between patients with and without daytime incontinence. With a mean follow-up of 15 months, nocturnal enuresis resolved in 39 patients, including 26 (63%) whose constipation resolved and 13 (33%) who had continued constipation (<3 bowel movements per week and/or fecal soiling off laxatives) ($p < 0.05$). Results were not substratified by those with and without daytime incontinence.

A retrospective review of 30 consecutive patients, mean age 9 years (5–15), with a "chief complaint of nocturnal enuresis" found that 10% reported constipation (bowel movement less than every other day).[34] Using a novel measurement of the ratio of the widest point of the rectal diameter to the pelvic outlet diameter on abdominal radiograph, all children had "fecal rectal distention" therapy with PEG for ≥2 weeks and the enuresis was cured in 25 (83%). The indications for radiography and number of wet nights per week before bowel therapy were not stated, and it was unclear if these patients had daytime incontinence.

Does therapy for constipation impact UTI or VUR?

- There are no RCTs using laxatives or other bowel regimens as monotherapy in patients with recurrent UTIs.
- There are no RCTs using laxatives or other bowel regimens as monotherapy for VUR.

CONSTIPATION TREATMENT

Behavioral Therapy

Behavioral treatment is the mainstay in relieving anxiety surrounding toileting issues for both the families and the patient and begins with education of the diagnosis. It is important to convey that fecal soiling is usually involuntary and a result of constipation, and a child should not be punished for the soiling. The goal for each child should be one or two soft bowel movements without straining daily. The Bristol stool scale has typically been used as a visual reference tool to evaluate treatment success. A 4 or 5 on this scale should be the goal daily without straining or discomfort.

Behavior recommendations typically include a regular toileting routine, such as sitting to have a bowel movement for 5–10 minutes approximately 30 minutes after breakfast, lunch, and dinner to prevent stool withholding. Parents should be counseled about correct toilet posture and provide support under the child's feet with stooling to decrease straining. Some advocate a reward system, such as stickers placed on a calendar, with a reward after success during a defined time interval.[35]

Biofeedback can be used in patients who show pelvic floor dysfunction (prolonged and excessive straining) and poor response to traditional laxative therapy. The therapist helps the patient learn how to relax the pelvic floor musculature and the external anal sphincter rather than straining to produce a bowel movement.[36] The frequency of therapy varies from program to program. However, a 2011 meta-analysis showed no evidence that biofeedback training added benefit to conventional therapy in managing pediatric fecal incontinence.[37] However, behavioral interventions plus laxative therapy showed decreased soiling at 3 and 12 months in one small trial (OR 0.14, 95% CI 0.04–0.51, and OR 0.20, 95% CI 0.06–0.65, respectively).

Diet

Families should be encouraged to increase daily consumption of fresh fruits, vegetables, whole-wheat, and whole-grain products in their diet and limit processed foods that are constipating. Some children benefit from a brief trial of withholding cow's milk.[38] One study showed that dried plums (prunes) resulted in improvement in the number of bowel movements per week (primary outcome) and stool consistency scores compared with psyllium in 40 adults with chronic constipation.[39]

Fiber

Dietary intake of fiber using the following equation is recommended to decrease constipation: grams of fiber/day = age in years + 5 g.[40] Systematic review of six RCTs of dietary fiber compared with placebo in adults with chronic idiopathic constipation demonstrated improvement in the following: global symptoms (86.5% vs. 47%), straining (56% vs. 29%), increased mean number of stools per week (3.8 vs. 2.9), and decreased pain with defecation.[41]

Probiotics

Probiotics have recently gained in popularity for the treatment of constipation and irritable bowel–related conditions. While meta-analysis has recently shown probiotics to have a protective effect on antibiotic-induced diarrhea in children, research has not come to a firm conclusion

TABLE 55.4 Osmotic laxatives

Osmotic agents	
Mechanism of action: Increases stool frequency and loosens stool	
Side effect: Abdominal pain, diarrhea, electrolyte disturbance	
Oral PEG	0.26–1 g/kg/day maintenance 1–1.5 g/kg/day for 3 days (disimpaction)
Oral lactulose	5 mL bid (1–5 years) 10 mL bid (6–10 years) 15 mL bid (11–18 years) 1–3 mL/kg divided twice daily (disimpaction)
Oral magnesium hydroxide	5–10 mL daily (3–12 years) 25–50 mL (13–18 years) 1–3 mL/kg/day of 400 mg/5 mL for 3 days (disimpaction)
Oral magnesium citrate	100–150 mL/day (6–12 years) disimpaction 150–300 mL/day (>12 years) disimpaction
Rectal glycerin suppository	1 infant suppository per rectum (<6 years) 1 adult suppository per rectum (> 6 years)

Source: Adapted from NASPGHAN Constipation Guideline Committee. *J Pediatr Gastroenterol Nutr* 2006;43(3):e1–13.

for use in pediatric constipation.[42] One crossover, double-blind study of 59 children (range 5–15 years) treated with goat yogurt or goat yogurt supplemented with 10^9*Bifidobacterium longum* showed improvement in defecation frequency and abdominal pain in both groups, with additional improvement in the *B. longum*–supplemented group.[43] A prospective randomized double-blind controlled trial in 159 children with constipation (<3 bowel movements per week) treated with a dairy product containing 10^9 *Bifidobacterium lactis* versus a control product showed significant improvement in stool frequency in both groups, with no difference between groups.[44]

Laxative Therapy

When dietary and behavioral interventions fail to improve symptoms of constipation, laxative therapy is often considered. The immediate concern may be disimpaction, followed by maintenance therapy (Tables 55.4 and 55.5) for long-term management to prevent reaccumulation of feces. Typically, the maintenance course is 3–6 months, after which symptoms should be reevaluated. When performing disimpaction and titrating medications, frequent follow-up should be performed. Children who do not respond to initial treatment strategies or continue to have trouble with fecal soiling with a maintenance regimen should be evaluated by a pediatric gastroenterology specialist.

Osmotic Agents

These agents increase water in the intestinal lumen to increase frequency and consistency.[45] PEG, lactulose, Kristalose®, glycerin suppositories, and magnesium hydroxide are examples of osmotic laxatives (Table 55.4). Side effects include electrolyte disturbance, diarrhea, and abdominal pain. Increasing fluid intake with these medications to prevent electrolyte imbalance is important, particularly when using these agents for disimpaction. Clinically, it is often recommended to mix or take

TABLE 55.5 Bulking, stimulant, and lubricant laxatives

Agent	Mechanism of action	Therapeutic effect	Dose	Side effects
Psyllium husk	Bulking agent	Increases stool frequency and improves consistency	0.85–1.7 g once daily to tid (<6 years) 1.7 g daily to tid (6–11 years) 3.4 g daily to tid (>12 years)	Gas, bloating
Senna	Stimulant laxative	Stimulation of nerve endings in colonic mucosa	Dosage form (8.6 mg tablet) ½–1 tablet once daily (2–6 years) 1–2 tablet daily or bid (6–12 years) 2 tablets daily (>12 years)	Abdominal pain, diarrhea
Mineral oil	Lubricant	Lubricates and softens stool	15–30 mL/year of age up to 240 mL daily for disimpaction Maintenance 1–3 mL/kg/day Not recommended for infants of <1 year of age	Lipoid pneumonia if aspirated, staining of undergarments, abdominal cramps

medication with an electrolyte replacement solution, such as Gatorade®.

PEG has been extensively studied and is used frequently due to ease of dosing, accessibility, palatability, and effectiveness. A Cochrane review of 1643 children from 18 RCTs reports that PEG increases the number of stools per week compared with placebo, and it appears to be superior to placebo, lactulose, and milk of magnesia in terms of effect and/or adverse events, but the authors also recommend interpreting the results with caution due to poor study quality and significant risk of bias due to lack of blinding and selective reporting.[46] PEG appears to be well tolerated with minimal adverse effects in the short term.

Bulking Agents

Bulking agents can be used for occasional constipation as an initial treatment option (Table 55.5). They are readily available over the counter for a low cost and are available in multiple forms (powder, tablet, cracker, etc.). Psyllium husk (Metamucil®) has been shown in adults to help retain fluid in the stool and increase fecal mass to improve the frequency and consistency of bowel movements. Other similar agents containing calcium polycarbophil (Fibercon®) have the same mechanism of action; however, research shows an unknown positive value of therapeutic effect. *Bulking agents may be particularly beneficial to the patient with both constipation and diarrhea by addressing both symptoms*. The bulking tends to reduce the soiling related to diarrhea while helping to soften the stool and increase stool mass. To reduce uncomfortable side effects, such as gas and bloating, increasing the dose slowly is helpful.

STIMULANT AND LUBRICATION LAXATIVES

Stimulant laxatives such as senna and bisacodyl (Senokot® and ExLax®) may be used for occasional constipation (Table 55.5). These agents are thought to act on the enteric nervous system by stimulating nerve endings in the colonic mucosa and inhibiting water absorption to create a bowel movement.[45] The therapeutic effect of stimulant laxatives is typically 8–12 hours.[47] Side effects include abdominal pain, diarrhea, and electrolyte disturbance. *Chronic use of stimulant laxatives may cause permanent injury to the enteric nervous system*.[45]

Lubricants such as mineral oil may also be used to produce a bowel movement. They can be used for disimpaction or daily to soften stool. Side effects observed in infant populations, such as aspiration pneumonia, must be considered (Table 55.5). Mineral oil also appears to be well tolerated and effective in a meta-analysis of two studies of 287 patients.[46]

Enemas

Enemas are typically used for disimpaction. Phosphate enemas at a dose of 6 mL/kg up to 135 mL in children 6 years and older can be used.[48] This therapy is highly successful and should be used where clinically relevant, but it can cause fear and discomfort for a child. When appropriate, a lubricant or stimulant laxative may be preferable over an enema for disimpaction.

CHAPTER
56

Operations for the Weak Bladder Outlet

Anthony J. Casale

INTRODUCTION

Surgery to correct urinary incontinence began in 1852 with a procedure to divert the ureters into the sigmoid colon of a boy with exstrophy.[1] Our understanding of the physiology and cause of urinary incontinence has grown slowly over the past century, and more has been learned in the past 25 years than in prior medical history. Early surgeons did not have the necessary technology to define the physiology of the bladder neck, but they were keen observers of anatomy. As early as 1906, the German surgeon Trendelenburg had suggested dividing the symphysis pubis to gain access for surgical narrowing of the bladder outlet in epispadias patients with the goal of improving urinary control.[2] Hugh Hampton Young was the first American urologist to identify the abnormal anatomy of the bladder neck as the cause of the patient's urinary incontinence and devise surgery to correct it in 1908. In 1919, Young presented his original procedure to provide continence in patients with bladder outlet incompetence.[3]

By examining these patients with early cystoscopes and at the time of open surgery, Young noted that the bladder neck and proximal urethra were enlarged and funnel shaped. The remainder of the bladder appeared healthy. He surmised that if he could restore the bladder neck and proximal urethra to a more normal appearance, then function would improve. He excised a wedge of mucosa from the posterior urethra and bladder below the trigone and narrowed the muscle with a single layer of sutures.

Since Young's bold procedure, surgery for the weak bladder outlet has progressed from the goal of re-creating normal anatomy to that of constructing continence mechanisms that bear no resemblance to the normal bladder outlet. Other developments in urinary tract reconstruction, such as intermittent catheterization, bladder augmentation, and continent catheterizable stomas, have made new procedures to repair the weak bladder outlet possible and offer solutions to problems that early surgeons saw as incurable.

After decades of becoming bolder in our approach to the bladder neck, the last few years have seen a realization of the limitations of reconstructive surgery to the bladder outlet and a turn to less aggressive and disruptive bladder surgery. A better understanding of the physiology of the bladder and stresses on the bladder outlet has led to a more selective approach to increasing bladder outlet resistance. Increased awareness of long-term negative consequences of altered anatomy and physiology has led surgeons to aspire to alter the bladder outlet anatomy only enough to achieve the desired result of socially acceptable continence.

INDICATIONS AND EVALUATION

Urinary incontinence may be the result of bladder outlet inadequacy in conditions such as epispadias, exstrophy, cloacal exstrophy, traumatic injuries of the urethra and bladder neck, urogenital sinus, bilateral ectopic ureters, and neurologic conditions. Indications for bladder outlet surgery in these conditions include evidence that weakness of the outlet is a cause of incontinence and the failure of maximal medical therapy to correct the problem.

The bladder outlet includes the bladder neck and proximal urethra; together, they may be considered a unit and normally function as a sphincter in both boys and girls. There is no identifiable anatomic sphincter, but a mixture of smooth and striated muscle, intracellular matrix, and mucosal factors that combine to make up a functional sphincter.[4] Compression of the urethral lumen and the resultant outlet resistance depends on several factors. Among the components that make up the normal sphincter mechanism are smooth and striated muscle tone and contractions, elastic properties of the urethra, mechanical forces transmitted from the abdomen, and structural support of the posterior urethral wall and bladder neck against which the urethra is compressed with increased abdominal pressure. The conditions that cause incontinence in children often present inadequacies in several, if not all, of these components.

In health, the bladder neck provides a variable resistance to the flow of urine through the urethra. The resistance is stable when the bladder pressure is low and increases as the pressure rises with bladder filling. It also increases reflexively with increased bladder pressure due to coughing or Valsalva's maneuver, and it decreases dramatically when the patient begins to void. For the bladder neck to maintain continence, it must be able to generate pressure within the lumen that is greater than the pressure within the bladder at all times except during voiding.

There are several methods to evaluate the competency of the bladder outlet. Just as Young noted, the cystoscopic appearance of the bladder neck reflects its function. When viewing from the proximal urethra, the posterior lip of the bladder neck should be elevated above the level of the

urethra and the base of the bladder. The bladder neck should close easily when fluid flow through the cystoscope is stopped. Although these observations are helpful, they are by no means completely reliable in predicting continence.

The bladder outlet may also be evaluated by imaging with a radiographic cystogram. A competent bladder outlet appears closed as the bladder is filled, and contrast should not leak into the urethra. The incompetent bladder outlet may remain open and funnel shaped during the filling process or may open with Valsalva's maneuver or suprapubic pressure (Figure 56.1).[5] Lateral views of the cystogram may reveal the lack of adequate elevation and suspension of the posterior bladder outlet.

Urodynamic studies of the bladder are important in determining causes of incontinence. Bladder leak point pressure and sphincter electromyography (EMG) are commonly used to measure bladder neck function. Leak point pressure is simply the pressure within the bladder at which fluid begins to leak through the bladder outlet into the urethra. Sphincter EMG is the measurement of electrical activity of the striated muscle of the sphincter. The sphincter EMG is most helpful in evaluating coordination of the detrusor and sphincter and may be of some benefit to document neural innervation of the sphincter in incontinent children. It is seldom helpful in children who are candidates for bladder outlet surgery.

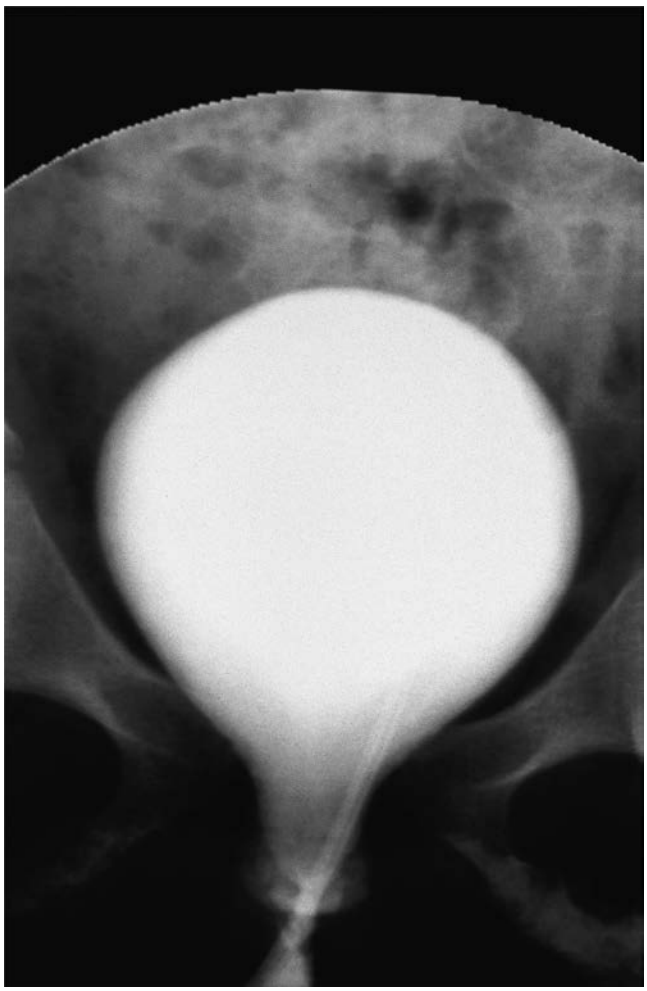

FIGURE 56.1 Voiding cystourethrogram of a patient with an open bladder neck during filling with contrast. The bladder neck is funneled during the entire study.

On the other hand, bladder leak point pressure is the most reliable objective study in incontinent children due to bladder outlet dysfunction. Low leak point pressures indicate incompetence of the bladder outlet and may cause incontinence independent of detrusor function. McGuire et al. defined the importance of leak point pressure in children with myelodysplasia and neuropathic bladder when they found that high leak point pressures of >40 cmH_2O resulted in upper tract deterioration due to reflux and hydronephrosis.[6] Children with pressures of <40 cmH_2O were protected from such changes but were prone to leak urine easily owing to weak bladder outlet. They also found that the radiographic appearance of an open bladder neck did not correlate well with measured leak point pressures.

McGuire found that children with myelomeningocele have fixed bladder outlet resistance that is located distal to the bladder neck and does not vary with filling or leaking. When these children were treated with intermittent catheterization and anticholinergic medications, patients with closed bladder necks on cystogram were uniformly continent, whereas only 60% of those with an open bladder neck became continent. This finding was independent of leak point pressure, indicating its limits in predicting continence in all patients.

Leak point pressure should be measured with a small urethral catheter (5 or 7 Fr). The water should be infused with a pump rather than by gravity. The technique should be standardized for each measurement, since Decter and Harpster have demonstrated that measured values of leak point pressures in children vary with catheter size and with rate and method of infusion.[7]

Patients should be encouraged to cough and sit or stand if possible to measure leak point pressures in a dynamic, more normal, setting. The volume at which leaking occurs is important because it reflects the functional capacity of the bladder and prognosis for continence.

Other urodynamic measurements are critical in diagnosing the cause of incontinence. Bladder pressures and volumes indicate the storage capacity of the bladder and must be adequate for continence. Compliance may be considered the inverse of stiffness and is a helpful indicator of bladder adaptability. Poorly compliant bladders tend to produce higher pressures with lower volumes of urine, making patients more prone to upper tract deterioration and incontinence.[8]

Detrusor measurements in children with completely incompetent bladder necks may be performed by inflating the balloon of a Foley catheter at the bladder neck and pulling it down to occlude the bladder outlet.[9] It is fruitless to consider treatment of bladder outlet incompetence unless the bladder itself has adequate volume and pressure characteristics for the storage of urine.

When evaluating incontinent children as candidates for bladder outlet surgery, a voiding or catheterizing diary can yield invaluable and practical information. Unlike radiographic and urodynamic examinations, these diaries represent the level of incontinence during normal activity. Some parameters, such as functional storage capacity of

the bladder, may be quite different from values that hospital tests may imply. We have patients measure voided or catheterized amounts of urine obtained, the times that the bladder is emptied, when incontinence occurs, the degree of incontinence, and activities associated with leaking. This information, along with urodynamic data, examination by cystogram, and cystoscopy, may be needed to define the cause or causes of incontinence.

If incontinence is due to incompetence of the bladder outlet, the physician has two basic treatments available, medical and surgical. Medical treatment must always be exhausted completely before considering surgery. This is important not only because some patients will become dry with medical management alone, but also because medical regimens requiring family and patient participation may demonstrate that the family is committed and willing to comply with similar catheterization and medicine schedules that necessarily accompany most surgical procedures to create continence. If the family can give medication and catheterize the child prior to surgery, it is likely that they will do so after bladder outlet surgery.

MEDICAL THERAPY

Children found to have inadequate bladder outlet resistance may be treated with various nonsurgical modalities. Some therapy helpful in incontinent adults has no role in children. Pelvic floor exercises, biofeedback, and electric stimulation of the bladder outlet have not been helpful in children with incontinence who suffer from anatomic and neuropathic conditions.

There are medications that have been effectively used to stimulate muscles of the weak bladder outlet. They include α-sympathomimetic agents such as ephedrine and ephedrine-like compounds that stimulate the large number of α-adrenergic receptor sites found in the proximal urethra and bladder neck and cause smooth muscle contraction.[10] These compounds produce troublesome side effects in some patients, such as hypertension, anxiety, and palpitations. Results have not been reliable in this group of children because most have severe anatomic and neurologic defects at the bladder outlet. We have had little success with medical stimulation of the bladder outlet to improve continence.

Other nonsurgical therapies include clean intermittent catheterization (CIC) to completely empty the bladder on a prearranged schedule. Intermittent catheterization remains the single most important contribution to the treatment of incontinence in children. In children with neuropathic bladder, intermittent catheterization alone will provide continence in 19%–24%.[11,12] The addition of anticholinergic medications, which lower bladder pressures and inhibit detrusor contractions, to CIC programs raised the continence rates to 68%–89%.[13,14] It is important to recognize that various authors have defined continence differently in the past. Whereas most patients gain some social or daytime continence with medical therapy, complete dryness is possible in less than one-third. Even if bladder outlet function is marginal, continence may be improved by maximizing other aspects, such as bladder storage capacity, with medication and emptying the bladder regularly with catheterization.

PROCEDURES TO INCREASE BLADDER OUTLET RESISTANCE

Once the bladder outlet has been identified as a cause of incontinence and medical therapy has been exhausted without acceptable improvement, the next options are surgical procedures to enhance bladder outlet resistance. This may be done by three basic surgical methods: procedures to change the suspension, support, or angle of the bladder outlet; procedures to compress the lumen of bladder outlet either with an external compression device or by injection of material under the mucosa; and procedures to reconfigure the bladder outlet into a more efficient continence valve.

Procedures to Suspend the Bladder Outlet

For the past century, inadequate support or insufficient elevation of the bladder neck and proximal urethra has been identified as a cause of urinary incontinence.[15] Inadequate suspension contributes to incontinence by making the bladder outlet too mobile, allowing it to descend into the pelvis. Normal suspension of the posterior bladder outlet is necessary to provide resistance from below to counter increased abdominal pressures from above, and thus compress the lumen. Suspension of the bladder outlet may be accomplished in several ways, including procedures that fasten the existing periurethral fascia to the anterior pelvic wall and procedures that reinforce the posterior bladder outlet with a sling made of fascia or some other external material.

In 1949, Marshall, Marchetti, and Krantz (MMK) introduced a procedure to improve stress incontinence by surgically elevating and suspending the bladder neck and proximal urethra.[16] The procedure is based on sewing the anterior vaginal fascia just lateral to the urethra and bladder neck to the cartilaginous portion of the symphysis pubis (Figure 56.2). These sutures suspend and support the bladder outlet and re-create its posterior angle. The MMK procedure was for many years the gold standard of incontinence surgery, and the concept is still critical in correcting these problems. Burch's procedure to suspend the bladder outlet from Cooper's ligament was another form of suspension that gained wide acceptance.[17]

Both suspension surgeries produce cure rates in patients with a pure stress incontinence of >90%.[18]

Today, suture suspension of the bladder outlet in children is utilized usually as an adjunct procedure with other incontinence surgery and helps to produce continence in up to 88% of patients.[19,20]

Pereya (1959), Stamey (1973), and Raz (1981) developed procedures that were also designed to elevate and suspend the weak bladder outlet.[21–23] They supported and elevated the bladder neck using sutures from the perivesical and periurethral fascia to the rectus abdominal fascia. These procedures were clear advances because they could be done through small incisions using long needles to place the suspension sutures (Figure 56.3). The surgeons could confirm correct suture placement at the time of the procedure with the cystoscope, and the patients suffered minimal discomfort.

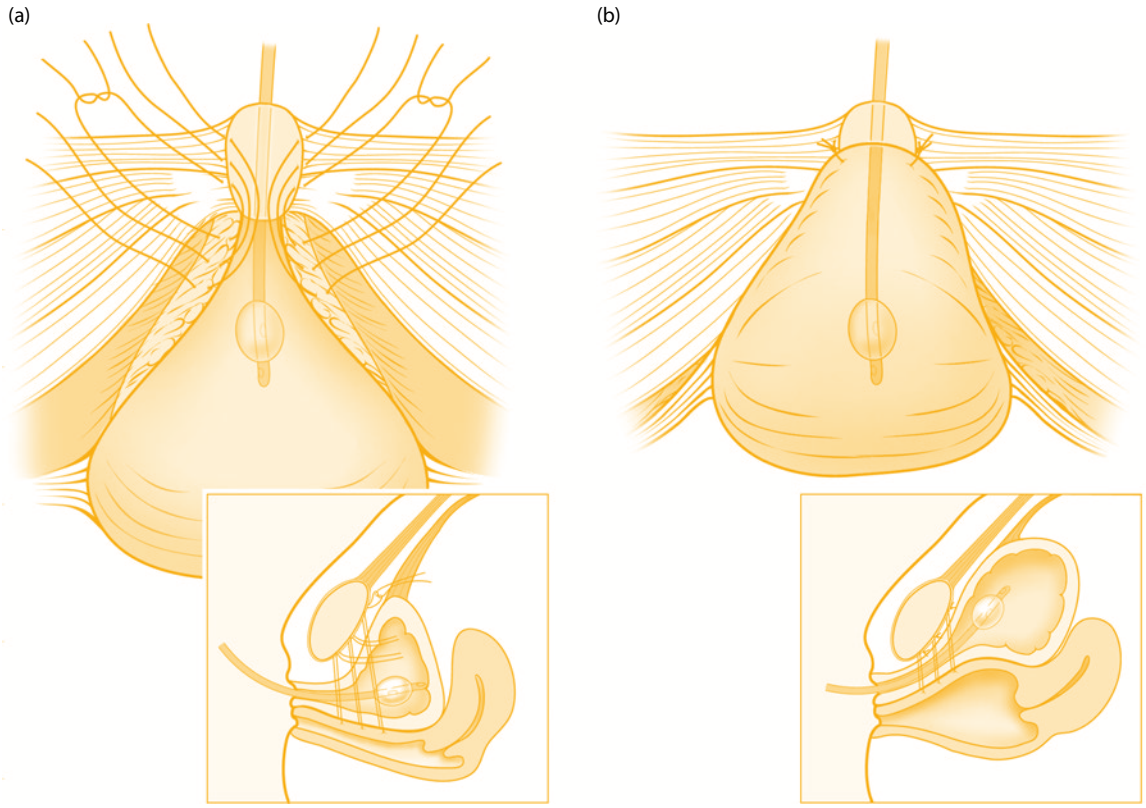

FIGURE 56.2 The Marshall–Marchetti–Krantz procedure elevates and suspends the bladder outlet, including the proximal urethra, by sewing the anterior vaginal fascia to the underside of the symphysis pubis. These are permanent sutures and re-create the posterior angle of the bladder neck. The concept of bladder neck suspension is still a cornerstone in incontinence surgery. (a) Placement of sutures between the anterior vaginal fascia and underside of the pubis. (b) Suspension and elevation of the bladder outlet.

McGuire improved on a concept introduced in 1911 by Goebell of suspending the bladder outlet with a sling of fascia or muscle.[24] McGuire developed a method of passing an isolated strip of rectus fascia beneath the bladder neck and reattaching it to the anterior abdominal wall at the insertion of the rectus fascia and the pubis (Figure 56.4).[25] Slings may improve continence by compressing the urethra, elevating the bladder outlet into the abdomen, or providing a stable point against which the urethra is compressed during increases in abdominal pressure.

This fascial sling and its variations have proven valuable for children with bladder outlet incompetence.[26]

The use of fascia under the bladder neck is more reliable in these children than sutures alone, which must rely on the strength of the native fascia adjacent to the bladder neck and proximal urethra to hold the suspension sutures.

At the time of open surgery, the most popular form of sling suspension involves a long strip of rectus fascia that is passed around the bladder outlet and sewn to the anterior abdominal wall fascia on each side. This suspension depends completely on the fascia to support the bladder outlet and is done entirely through a lower abdominal incision (Figure 56.5).

Slings may also be placed transvaginally in girls, just as is done in adults with good results.[27] This procedure would seem to be limited somewhat by the age of the child and size of the introitus. It is a useful approach in adolescent girls who are not undergoing simultaneous bladder reconstruction.

Bladder neck suspension, usually in the form of a rectus fascia sling, has been most helpful in girls with myelomeningocele on intermittent catheterization.[28] The female urethra is more easily manipulated in this way, and results have been good in this population, with continence rates of 78%–90%.[29–31]

The success rate in males in our hands has been considerably less than in females when suspension is used alone, although some authors report good experiences.[32–34,35] The combination of slings with other bladder neck surgery, such as narrowing the outlet, has been successful for some surgeons.[36]

Snodgrass reported an 82% continence rate in 17 patients who had a bladder neck repair and sling compared with a 45% success rate with slings alone.[37]

In the author's experience, the one group of patients who most often fail sling suspension is males who subject their bladder outlet to very high pressures that result from physical activity, such as ambulation and play.

Fascial sling suspension of the bladder outlet is not without complications. Decter has reported erosion of the sling into the bladder and late degeneration of detrusor compliance after sling placement.[38] Often, patients have difficulty catheterizing through the urethra after sling placement owing to the altered angle of the urethra. We

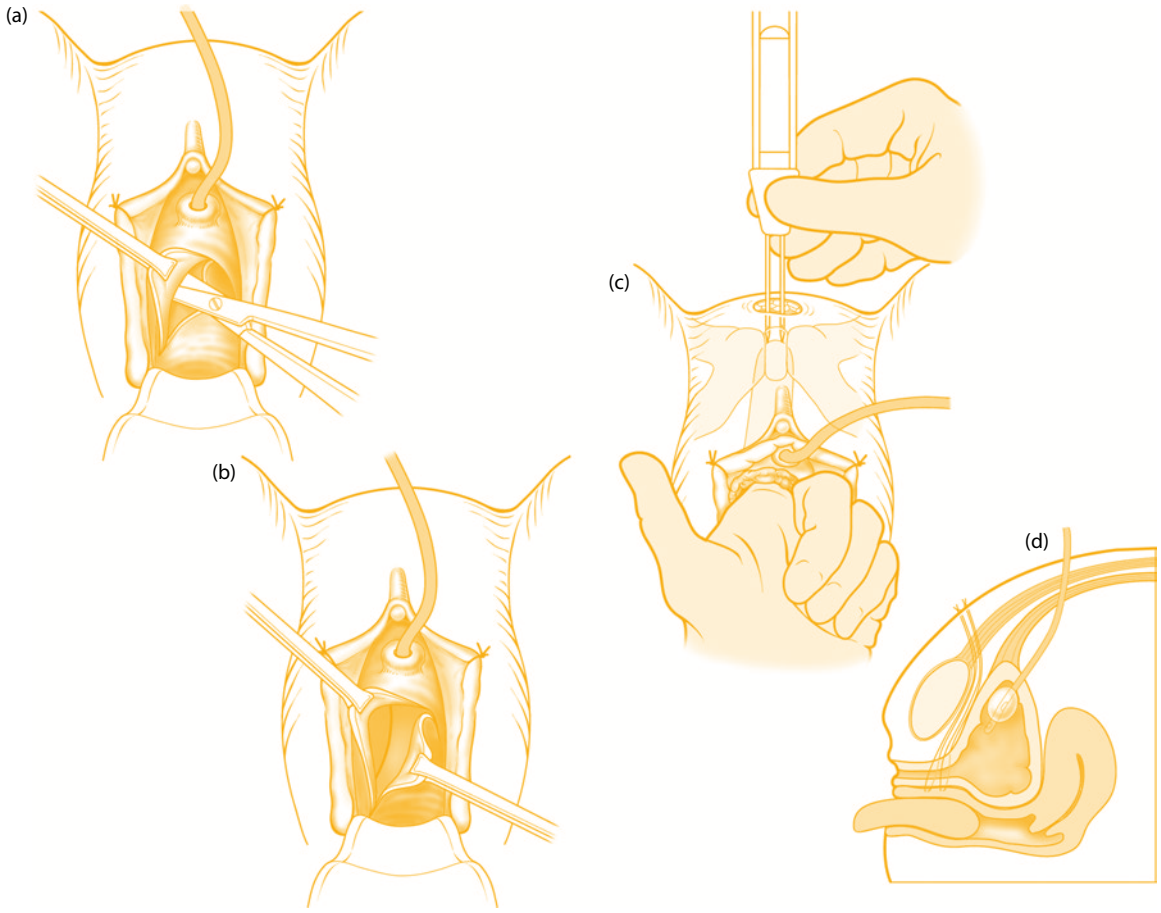

FIGURE 56.3 The Raz sling suspension uses long needles to pass permanent sutures from the anterior rectus fascia to suspend the bladder outlet from the anterior abdominal wall. The sutures support and elevate the bladder outlet and re-create the normal position and anatomy of the posterior bladder neck. They are dependent on the strength of the fascia surrounding the bladder neck and posterior urethra. (a and b) Exposure of the anterior vaginal fascia on either side of the bladder outlet. have also witnessed the sling break during physical activity, acutely returning the child to a state of incontinence. There has been concern about the effects of slings on erectile function in males with spina bifida, but this function appears to be preserved in more than 90% in one series of 14 patients.[39] Like many other procedures to improve bladder outlet resistance, augmentation cystoplasty has often been required to provide a large low-pressure reservoir for optimal continence.

Slings made of exogenous material have been introduced at various times and include true synthetic and processed biologic material, such as porcine small intestinal submucosa. The early-generation pure synthetics, such as silicone rubber and Gore-Tex, have a high risk of erosion into the urinary tract and are not in common use today.[40] A new generation of material is available, including synthetic polypropylene mesh tape. This material has been useful in adult stress incontinence and has a much lower risk of erosion than prior synthetic materials.[41,42] The use of newer synthetic mesh slings has yet to be documented in children, but their use in full-grown adolescents seems promising.

The processed porcine biomaterial, small intestinal submucosa, has been in use for some time and has similar efficacy for producing continence. It offers an off-the-shelf replacement for rectus fascia, thus shortening surgical time and simplifying abdominal wall closure at the time of reconstruction.[43,44]

Procedures to Compress the Weak Bladder Outlet

Surgery to compress the bladder neck externally can take one of two forms: variable or fixed. Since the normal bladder neck offers variable outlet resistance, this form is the most desirable, so that the resistance can be relaxed to allow voiding or easy catheterization. The artificial urinary sphincter developed by Scott et al. in 1972 has been valuable in the management of incontinence for many years.[45]

Artificial Urinary Sphincter

The artificial urinary sphincter is a hydraulic device that is composed of three parts: an inflatable cuff that surrounds and compresses the bladder neck or bulbous urethra, a pressure-generating balloon, and a pump control module (Figure 56.6). The artificial sphincter gives the patient the

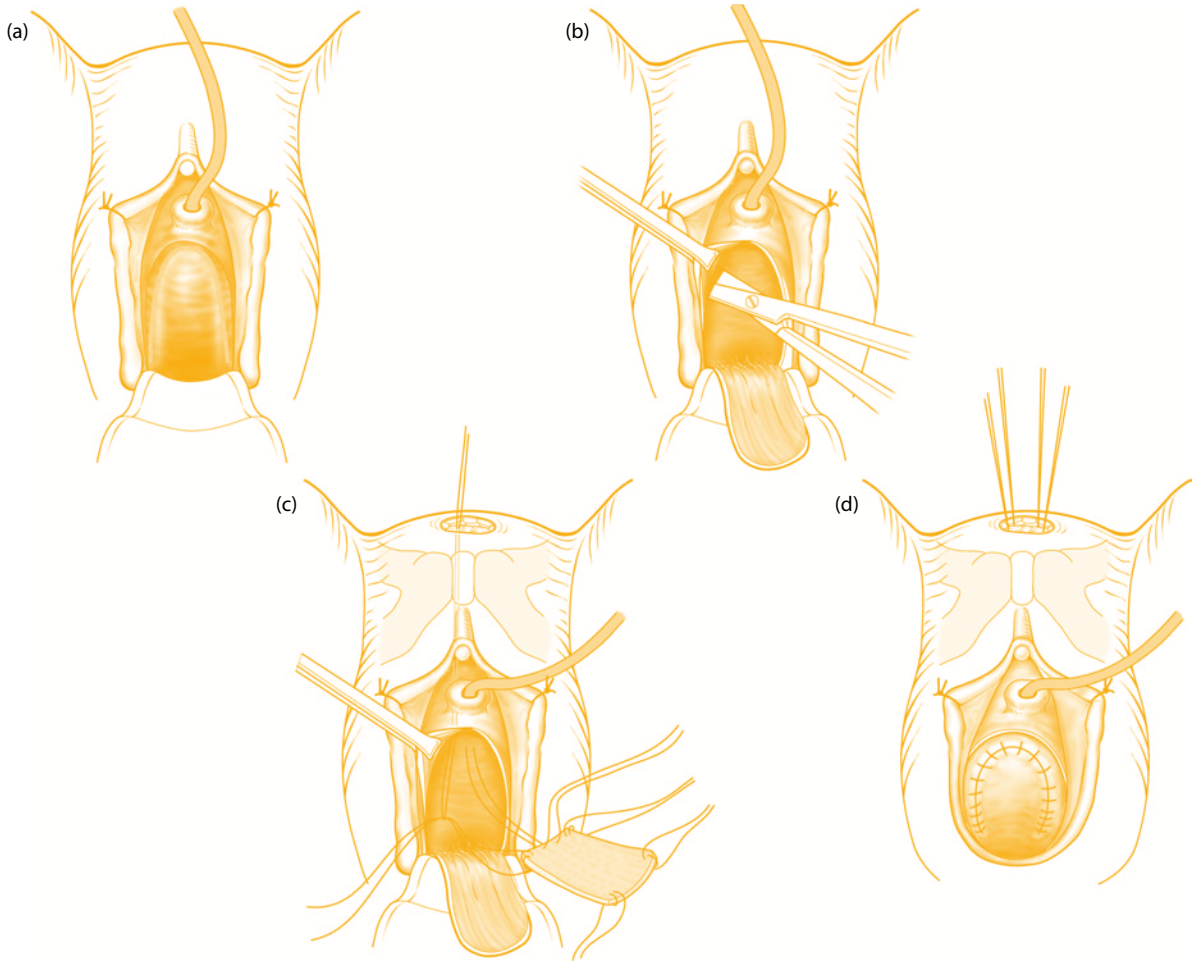

FIGURE 56.4 McGuire developed a suspension procedure that uses long sutures from the anterior abdominal wall to support a short strip of fascia. This fascia is passed posterior to the bladder outlet and supports and elevates the bladder outlet. This procedure provides more uniform support to the posterior bladder neck and does not rely on the native fascia around the bladder neck and urethra. ability to deflate the cuff and reduce the compression of the bladder neck at will. The pump is placed in the scrotum or labia, and the entire device is contained within the body. Continence rates are close to 90% after placement of the device.[46–48]

The bladder neck is the preferred site of placement in children (Figure 56.7). The usual minimal age for placement of artificial sphincters is 6 years for boys and 8 or 9 years for girls.[49] The pressure exerted on the urethra is regulated by the balloon or reservoir, and most children need 61–70 cmH_2O pressure to safely control the bladder outlet. The device is not activated immediately, as cuff pressure immediately after surgery may cause erosion of the cuff into the bladder. The sphincter may be activated after 6–8 weeks with less risk of erosion.[50]

Initially, there were concerns that performing intermittent catheterization through the implanted sphincter could cause damage to the tissue compressed by the cuff and lead to erosion. Sphincters were only placed in patients who could void, but as many as 50% of children cannot void efficiently after sphincter placement, making catheterization necessary.[51] Barrett and Furlow reported a series of children with neuropathic bladders who could not void after artificial sphincter surgery and found that intermittent catheterization could be performed safely if the cuff was deflated to pass the catheter.[52,53] Continence was good, and no patients suffered erosion due to catheterization. It appears that the ability to void may deteriorate with time, particularly in boys with neurogenic bladder. Gonzalez et al. reported that 74% of patients followed for a mean of 8 years after sphincter placement required intermittent catheterization.[47] Upsizing the sphincter cuff size in adolescent boys who suffer delayed voiding failure after sphincter placement has not been successful in restoring the ability to void.[54]

Historically, there has been a higher rate of reoperation with artificial sphincters than with bladder outlet reconfiguration.[55] This rate appears to be improving with better technique and newer devices. Kryger et al. reported an average of 0.03 revisions per year with the newest model, and 70% of children who had sphincters placed since 1987 have not required revision.[56] The long-term (7–10 years) survival of the artificial sphincter in children in two large series is approximately 80%, with most being lost

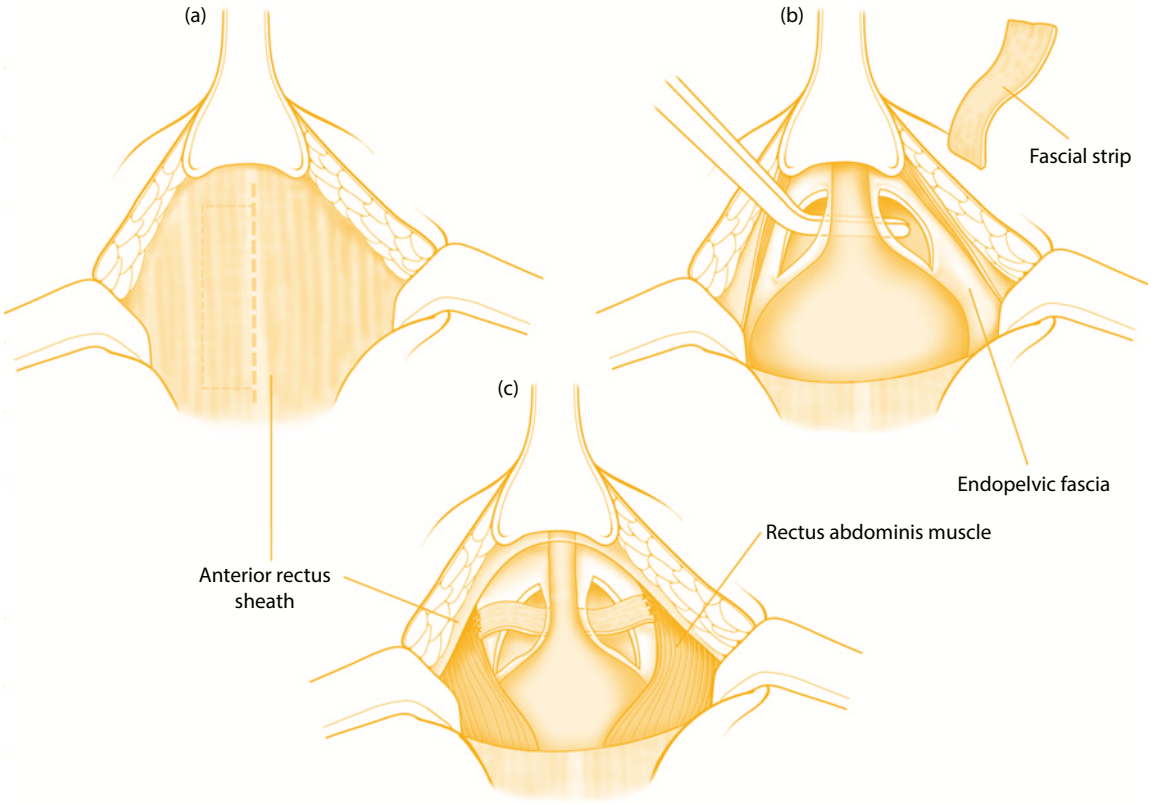

FIGURE 56.5 Fascial slings may be harvested from the anterior rectus fascia at the time of open surgery and used to suspend the bladder outlet from the anterior abdominal wall. (a) A single strip of fascia can be taken from the lateral aspect of a midline incision and (b) passed behind the bladder outlet. (c) Each end of the sling can then be sewn to the anterior rectus fascia on each side to elevate and support the bladder neck and urethra.

to the complications of device infection and erosion.[48,57] Eventually, all devices will wear out and fail, requiring replacement, but if complications can be avoided, the mean survival of the new devices in children is more than 12 years.[46] The newest model (AS 800), with a narrow backing cuff, was developed in 1988. It had a mechanical failure rate of 7.6%, a nonmechanical failure rate of 9%, and a sphincter survival rate of 92% in 184 adult patients, with a mean follow-up of 40.8 months.[58]

Roth and others reported an important complication of artificial sphincter placement in 1986 when they discovered that some patients suffered late deterioration of the upper urinary tracts.[59–61] This deterioration was due to two factors: a failure to void efficiently in some patients and the new development of detrusor hypertonicity in others. Deterioration of detrusor function after sphincter placement occurs in as many as 20% of patients, and there is currently no reliable method to predict which patients will undergo these changes or the timetable for risk.[57,62] Because of this threat, it is necessary to follow patients with artificial sphincters with upper tract imaging and urodynamics, as needed indefinitely after placement of the sphincter.

Augmentation cystoplasty, as either a simultaneous or later procedure with artificial sphincter placement, is necessary in approximately 30% of children.[47,63]

Augmentation increases storage volume and decreases storage pressures of the bladder due to poor compliance or hypercontractility of the detrusor. Augmentation may be performed at the same time as sphincter placement but has been associated with an increased risk of device infection if colon and small bowel are used for the augmentation.[64] Apparently, augmentation with the stomach does not present an increased risk of infection in simultaneous sphincter placement.[65]

Patient selection for artificial urinary sphincter is important. Although there has been an increased risk of erosion with girls who had prior bladder neck surgery, Bosco et al. have demonstrated that the risk to girls and boys is similar if they have not had prior bladder surgery.[66] The condition of the bladder outlet that will be compressed with the cuff is critical, and prior bladder neck surgery or excessive scarring increases the risk of erosion and infection.[67] Castera et al. have reported that prior bladder neck surgery also impacts the continence rate after sphincter placement, resulting in only 37.5% continence in this group.[68]

The artificial urinary sphincter is the only method of producing variable bladder outlet resistance and thereby allowing volitional voiding. Its main indication today is in children who have the ability to void prior to surgery and the potential to do so after placement of the device. Use of the artificial sphincter in patients who require augmentation and intermittent catheterization offers little advantage over other methods to increase bladder outlet resistance.

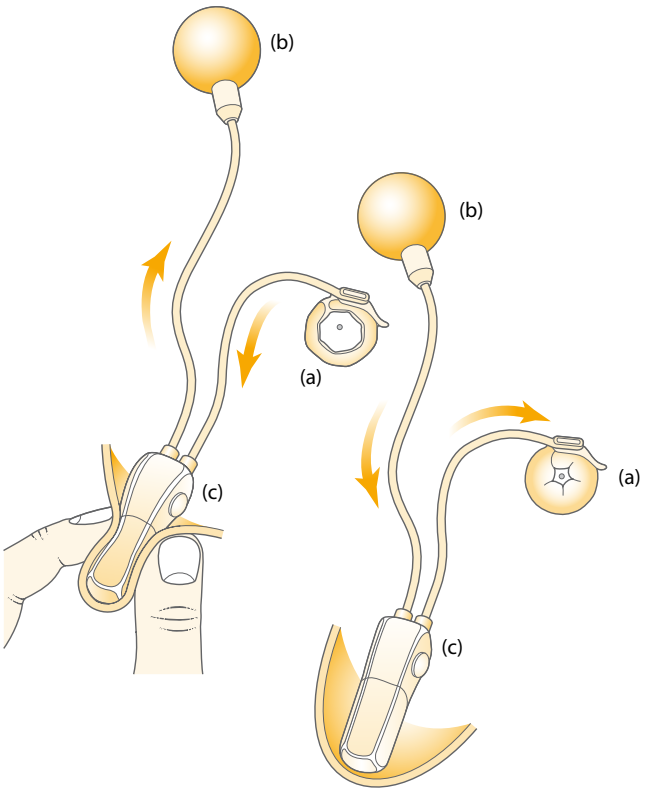

FIGURE 56.6 The artificial urinary sphincter is a mechanical device composed of three components: (a) an inflatable cuff, (b) a pressure-regulating reservoir balloon, and (c) a control pump. It functions by using hydraulic pressure to inflate the cuff, which compresses the urethra and provides continence. By squeezing the pump (implanted in the scrotum or labia), the patient can manually deflate the cuff and allow voiding or catheterization through the urethra. The pressure in the balloon then restores pressure throughout the system and reinflates the cuff in 3 minutes.

Bladder Outlet Wraps

There have been a few attempts to compress the bladder neck with a fixed resistance, and these have usually been in conjunction with bladder neck reconstruction surgery. Silicone rubber sheaths have been placed around the narrowed bladder neck, but in early series, more than 60% eroded into the lumen and required removal.[69] Quimby et al. presented a large series of 94 patients treated with silicone sheaths used in conjunction with a Young–Dees–Leadbetter (YDL) bladder neck reconstruction. The authors continued to modify their technique until the erosion rated dropped to 7% in 35 patients. This improvement was attributed to using omentum to wrap the sheath and using a single-layer short silicone wrap. Satisfactory continence in this group was achieved in 72% of patients with this method (Figure 56.8).[70] Two other groups have reported synthetic constrictors or cuffs. de O Vilar et al. reported a new device called a constrictor that compresses the bladder neck. It produced continence in all 42 patients in whom it was used; however, it had to be removed in 4 patients because of erosion or infection.[71] Kohn et al. presented a series of children treated with a purse-string cuff around the bladder neck made of polytetrafluoroethylene (PTFE) tubing surrounding woven polyester tape:[72] 75% of patients were dry after surgery, but 30% of the devices had to be removed because of complications.

Walker et al. described a procedure to wrap and compress the bladder neck circumferentially with rectus fascia with good results.[73] Some of their patients also needed bladder neck narrowing at the same time. Unlike silicone rubber, there were no erosions of the fascia, and postsurgery urodynamics showed that 70% of patients could not be made to leak at any pressure. Long-term follow-up of these patients indicates that the facial wrap and bladder dynamics are stable.[74] Bugg and Joseph presented a rectal fascia cinch that wraps around the bladder neck and is anchored to the pubis.[75] This procedure produced 60% continence. A myofascial flap made from rectus muscle can be used as a vascularized wrap and has been wrapped

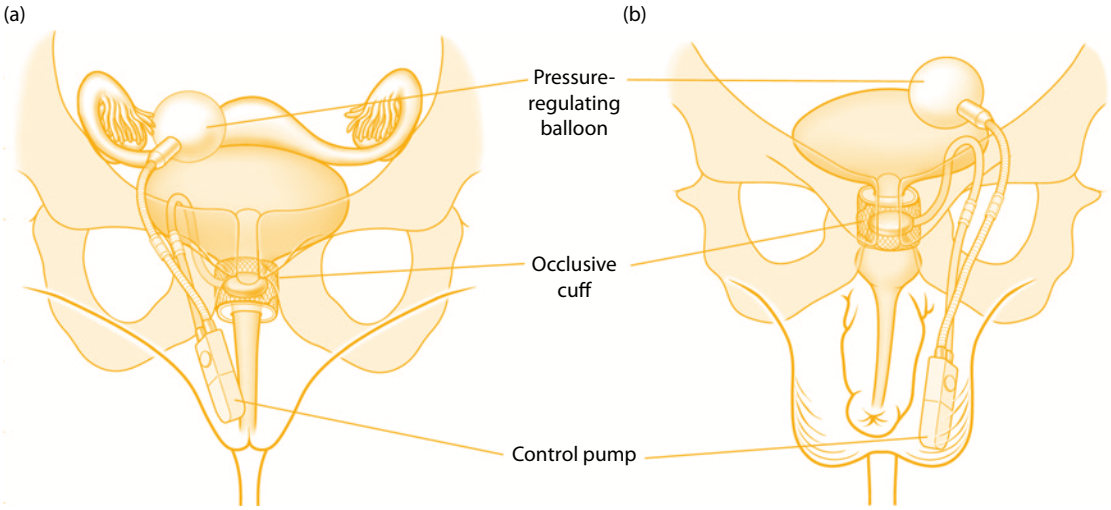

FIGURE 56.7 (a) Artificial urinary sphincter components in a female with the pump implanted in the labia. (b) Artificial urinary sphincter components in a male with the pump implanted in the scrotum. Both examples show the cuff implanted around the bladder neck.

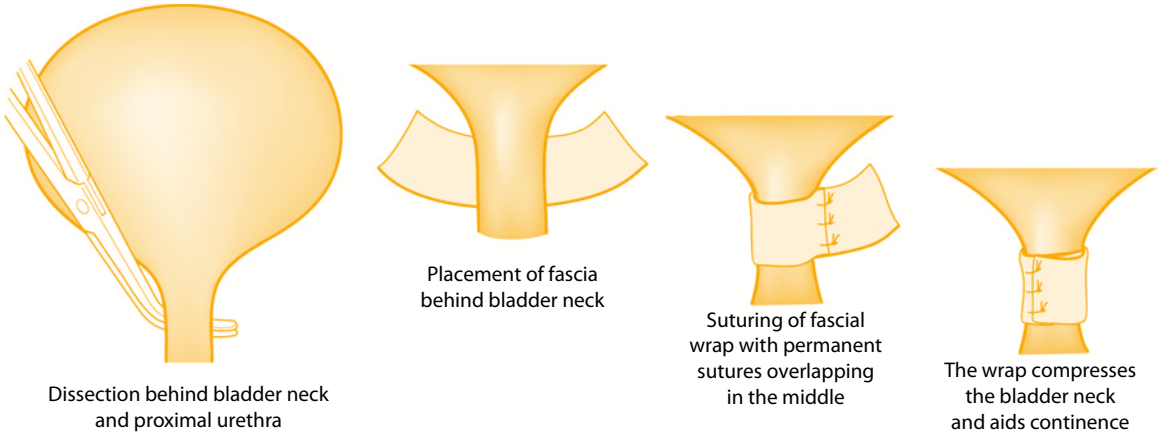

FIGURE 56.8 Walker described a fascial wrap of the bladder outlet in incontinent children. A strip of rectus fascia was harvested and wrapped around the bladder outlet and sewn together with permanent sutures. This provides consistent compression of the open bladder outlet and constant outlet resistance. Some patients with wide bladder outlets required bladder neck narrowing.

around the bladder neck and anchored to the pubic bone. This method has produced 75% continence in limited numbers.[76] Finally, a flap of bladder detrusor has been harvested and used to wrap around the bladder neck to compress the bladder neck.[77] Of course, any increase in fixed resistance at the bladder neck almost always precludes voiding and requires that the patient rely on CIC.

Injection Therapy of the Bladder Outlet

Several substances have been injected under the mucosa of the bladder neck in order to increase intraluminal pressure generated by the weak bladder outlet and provide continence. The first substance used in significant numbers of patients was PTFE paste or polytef.[78] Politano et al. popularized its use in adults and eventually applied the concept to children.[79,80]

They reported 86% success rates in patients who were incontinent from bladder neck surgery and 50% in patients with neuropathic bladder. Injection therapy was relatively easy to perform and required no incision, so it could be done on an outpatient basis. Unfortunately, particles of polytef were found to migrate to other organs in animal studies, and particles were found in pulmonary granulomas in a human after periurethral injection.[81,82] Safety concerns have caused abandonment of its use in the United States. A newer form of silicone, polydimethylsiloxane, or Macroplastique, has been used in Europe with continence achieved in 34% of patients.[83] It is not currently available in the United States. Other agents have been used, including autologous fat and collagen. Gonzalez de Garibay et al. reported periurethral injection of fat obtained from liposuction of the abdominal wall in 1989.[84] Initial success in treating incontinence was never as good as with polytef, and the effects diminished with time because the fat did not survive due to poor neovascularity.[85] Eventually, 80%–90% of the injected fat was absorbed by the local tissue.

Gluteraldehyde cross-linked collagen has been one of the most common agents used to increase bladder outlet resistance. It has been used in the same manner as polytef paste and is injected beneath the mucosa using a needle passed through a cystoscope (Figure 56.9). The success in treating children with incontinence has been inconsistent, with around 50%–88% of patients considered to have a good result and 20%–63% becoming dry.[86,87] Bomalaski et al. reported a large series of collagen injections in children in 1996.[88]

They reported a 22% cure rate of incontinence in 40 children, with improvement in another 54%. Of those patients with a mean follow-up of 4.5 years, the cure or improvement rate remained stable over time. Other clinicians have noted the biologic degradation of collagen and expressed concern about long-term durability.[89] Kassouf et al. demonstrated poor results with collagen injections, in children with neuropathic bladder dysfunction. Only 20% of their patients improved after injection, and all these eventually deteriorated within 2 months of treatment.[90]

The limited success and potential degradation should be explained to the patient and family. Also, 2.5% of patients are allergic to the collagen from dietary exposure, and an additional 0.9% may develop late hypersensitivity.[91] Preoperative skin testing is necessary to establish that the patient does not have antibodies to the collagen and is less likely to react to the injection.

The newest agent to be used for injection of the bladder neck for incontinence is Deflux (dextranomer/hyaluronic acid copolymer). We have injected Deflux into the bladder neck of 16 children with bladder outlet incompetence. Of the 12 with neuropathic bladder, 25% were dry and an additional 33% improved after injection therapy, with a mean follow-up of only 9 months. None of the patients with other causes of incontinence achieved continence, whereas 33% showed improvement. No patients who performed intermittent catheterization through their urethra improved.[92] Dyer et al. reported on 34 patients who were treated primarily with injection therapy using either Deflux or Teflon Paste. Only four children had improved continence with injection alone.[93] Alova et al. presented a 39% failure rate in 89 patients who had primary Deflux injection therapy, noting that repeat injections have a very low success rate. They note that the presence of Deflux in the bladder neck does not impede secondary surgical bladder neck repair.[94] Lottmann et al. reported a gradual degradation of continence in patients treated primarily with

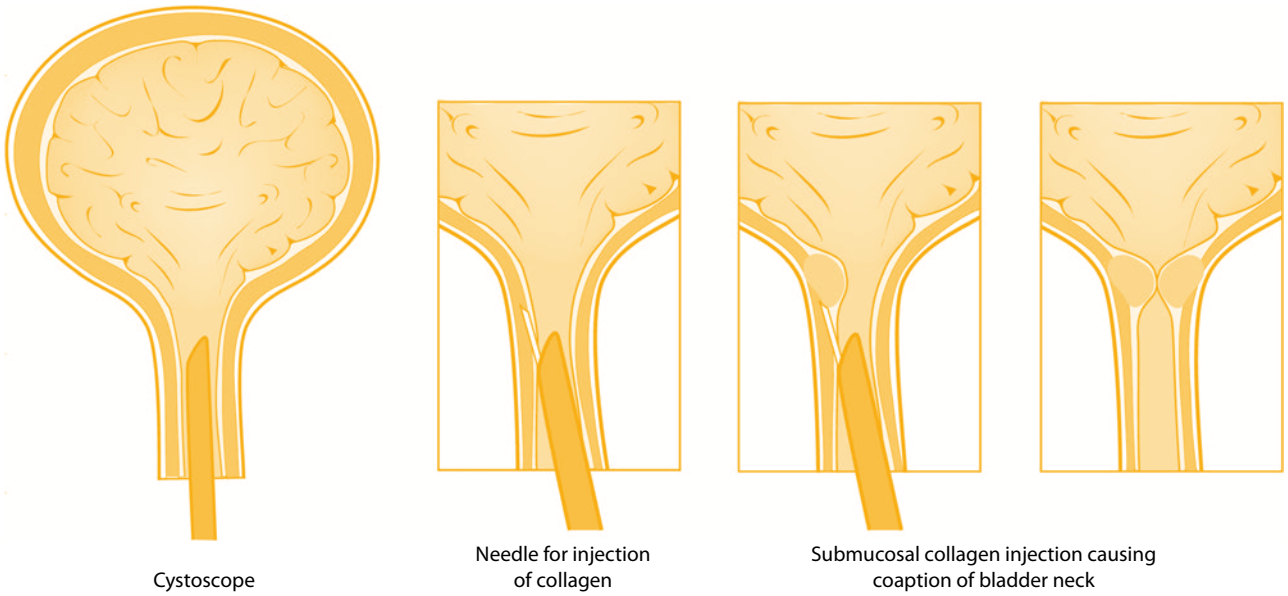

FIGURE 56.9 Injection of the bladder neck with various materials, such as polytef paste and collagen solutions, has been used with more success in adults than in children. The needle is passed through a cystoscope and the material is injected submucosally either from the urethra or from a suprapubic approach. The material provides passive pressure to help to occlude the bladder outlet.

Deflux from an initial dry rate of 79% at 1 month to 40% at 7 years, with a rapid drop in the first year to 52%.[95]

With the widespread use of catheterizable urinary stomas in children with neuropathic incontinence, antegrade bladder neck injection of bulking agents through the catheterization channel has merit. The visualization of the bladder outlet from above is superior to the visualization from the urethra.

These mixed findings have limited injection therapy in most pediatric urologist's hands to incontinent patients who have had failed bladder neck reconstruction surgery. Up to 50% of these patients may become dry with injection therapy, but some require multiple injections.[96] This is a simple and safe outpatient procedure, but the results may degrade with time and its effects may diminish.

Surgical Reconfiguration of the Bladder Outlet

Young–Dees–Leadbetter Procedure

In 1922, Hugh Young presented a refined procedure to reconfigure the inadequate bladder outlet in epispadiac patients who were incontinent due to bladder outlet incontinence.[97] Young had altered his approach from narrowing the posterior bladder outlet to narrowing the anterior urethral and bladder neck. He excised a full-thickness strip of tissue from the "funnel-like neck" of the bladder and reapproximated the sides with a single row of chromic catgut sutures to create a more normal appearance (Figure 56.10). Ureterosigmoidostomy diversion was the accepted surgical treatment of incontinence due to epispadias and exstrophy prior to Young's procedure.[98] Young was obviously pleased with the results of his procedure and reported, "No fistula, no stricture, perfect urinary control, sexual powers normal." For more than 25 years after Young first presented his method to reconfigure the bladder neck for epispadias, his procedure remained the best surgical treatment for urinary incontinence due to a weak bladder outlet.

In 1949, John Dees improved upon Young's procedure by extending the posterior urethral flap into the bladder and removing the mucosa from the muscle on the lateral aspect of this flap. This posterior strip of urethra and bladder was then closed in two layers, mucosa and muscle, to form a neourethra (Figure 56.11).[99] Whereas Young had been content to narrow the proximal urethra and bladder neck, Dees changed the position of the bladder neck itself. He created a long neourethra from tissue that normally would have been the posterior bladder wall. The result was to move the bladder outlet higher into the pelvis and provide a longer, more muscular, urethra.

In 1964, Guy Leadbetter advanced this concept further by extending the posterior bladder flap even higher into the bladder.[100] This was made possible by moving the ureters from their normal location to a more cranial position further from the urethra and original bladder neck. The position of the ureters had been the limiting factor when Dees created his neourethra and moved the bladder neck above its natural location. Leadbetter moved the ureters out of the way by mobilizing them and reimplanting them transversely across the posterior bladder wall well above the trigone.

By extending the neourethra higher in the bladder, Leadbetter was also presented with a wider strip of bladder to use for his neourethra. A narrow strip of mucosa was left in the central portion of the neourethra. This was tubularized, the entire mucosa lateral to the strip was excised, and the two flaps of muscle lateral to the neourethra were then wrapped over the mucosa in an overlapping fashion, providing additional muscular support to the neourethra and bladder neck (Figure 56.12). With few changes today, the YDL bladder neck repair remains the gold standard of bladder neck reconstruction. Continence has been obtained in 78% of patients with neuropathic bladders and in 80% of exstrophy patients.[101–103] It must

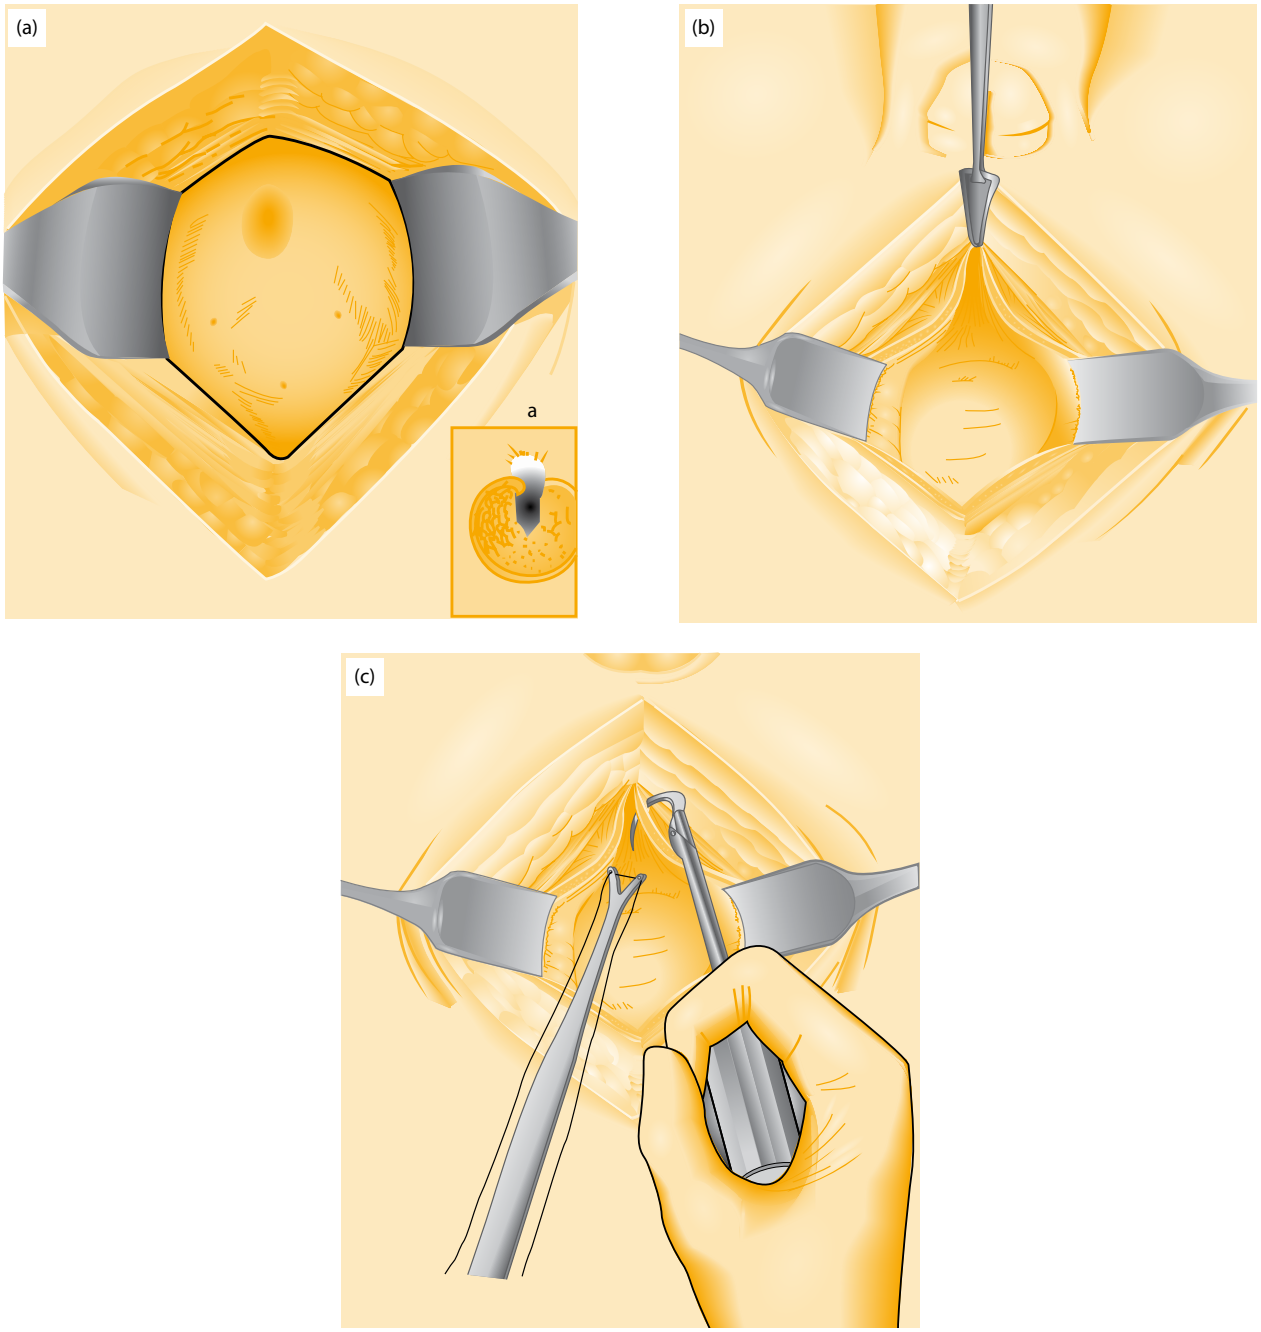

FIGURE 56.10 Young's original bladder neck repair was essentially an excision and narrowing of the outlet. He excised a full-thickness strip of mucosa and muscle from the bladder neck and proximal urethra and closed it with a single row of sutures to create a more normal-appearing bladder neck when viewed from within the bladder. This, in essence, lengthened the urethra and placed the bladder neck higher in the pelvis. (a) Open bladder outlet viewed from above. The inset shows Young's view of epispadias with incontinence. (b) Excision of the strip of mucosa and muscle. (c) Narrowing of the bladder outlet using Young's instrument to pass suture.

be noted that augmentation cystoplasty was necessary to obtain this degree of continence in 90% of the neuropathic bladder children in our series and in 50% of the exstrophy–epispadias patients in the Mayo Clinic series.

Disadvantages of the YDL bladder neck reconstruction include loss of significant bladder capacity that results from the reallocation of bladder wall tissue to the urethral continence mechanism. The neourethra may be tortuous and difficult to catheterize.

Variations of the Young–Dees–Leadbetter Procedure

Of the many variations to the YDL, that of Mollard is closest to the original.[104] He creates a 7 cm long urethral strip that is wide enough to close over a 10 Fr catheter and removes the mucosa from the triangular muscle flaps lateral to the strip. He then incises one of the periurethral muscular flaps vertically parallel to the strip and rotates it horizontally across the midline in order to develop an

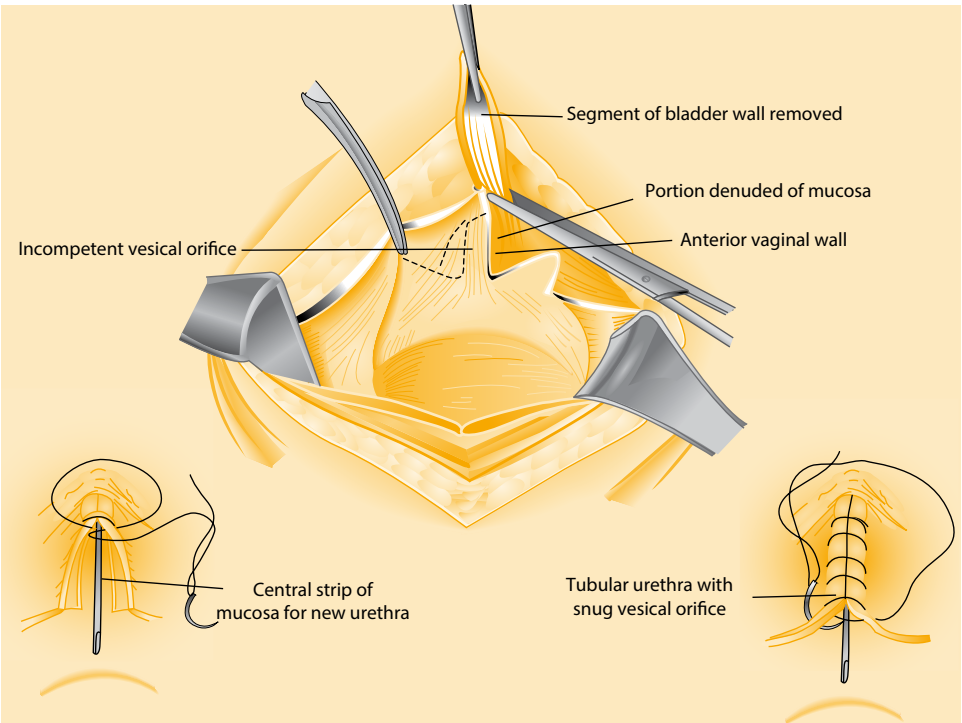

FIGURE 56.11 Dee's revision of Young's procedure extended the posterior urethral flap into the bladder and allowed a longer neourethra. He removed the mucosa from the muscle on the lateral aspect of this flap, and after closing the central flap of mucosa into a tube, he closed the muscle over the mucosa in a second layer. This provided additional muscle around the neourethra.

anterior bladder neck angle (Figure 56.13). Mollard's procedure has been applied mostly in exstrophy patients, and he has achieved a 70% continence rate.

Koff's variation on the YDL also differs from the original in its use of the periurethral muscle flaps.[105]

Koff's initial incision is on the lateral aspect of the bladder neck, rather than the midline, and this produces a single long muscle flap on one side of the bladder. After he moves the ureters cephalad, Koff then strips the mucosa from the long muscle flap, leaving a midline strip of urethra and bladder to tubularize for the neourethra. The long muscle flap is then wrapped around the neourethra, producing what he has termed "the cinch" (Figure 56.14). Koff has achieved 80% continence rates in mostly exstrophy patients. All the patients have had significant difficulties voiding. Forty percent of the children required bladder augmentation and intermittent catheterization. Bladder capacity is lost to a similar degree as in the YDL procedure.

Mitchell returned to Young's original concept of a narrowed neourethra without added muscular support.[106] He noted that overlapping bladder muscle flaps used to create more outlet resistance made the bladder smaller by reducing the bladder itself. Mitchell's procedure is the only bladder neck repair that does not decrease bladder capacity, as the anterior bladder and urethral flap are incorporated into the bladder (Figure 56.15). He mobilized a triangular full-thickness flap of anterior urethra and bladder neck and then narrowed the bladder outlet. The flap was then rotated cephalad and integrated into the bladder. Continence was achieved in 64% of patients, who all voided and were a mixed group of children including neuropathic bladders and exstrophy.

Some other variations of the YDL procedure have been developed, including Koyle's Thiersch–Duplay type tubularization of the posterior bladder wall.[107]

This procedure isolates and rolls a strip of mucosa into a tube in situ and then closes muscle and mucosa over the tube by rolling in the lateral tissue (Figure 56.16). He calls this the reverse Kropp or Ppork repair, and has achieved 82% continence in neuropathic bladder patients. There may be problems with catheterization per urethra, and therefore all of his patients had an alternative access for bladder catheterization. Chrizan et al. reported on a variation of Koyle's procedure that is done using the laparoscope within the bladder and basically forms a mucosal tube of the anterior bladder wall. It was performed on eight patients who had failed previous surgery. Six of eight were improved and four were dry. Operative time and hospital stay were less than with open procedures.[108]

Arap et al. presented the most radical variation of the YDL posterior-tube bladder neck repair for use in the most severe cases of exstrophy with tiny bladder plates.[109]

Their procedure is performed in two stages: the first stage is creation of a colon conduit with antirefluxing ureterocolonic anastomosis; the second procedure creates a tube in the same manner as the YDL procedure, but uses the entire bladder except for the dome, which is left open as a wide funnel (Figure 56.17).

The previously created colon conduit is then reconfigured as a reservoir and attached to the funneled bladder plate. Arap reported a 75% continence rate with patients voiding frequently. Intermittent catheterization has provided continence and allowed a long dry interval in our limited experience with the Arap procedure.

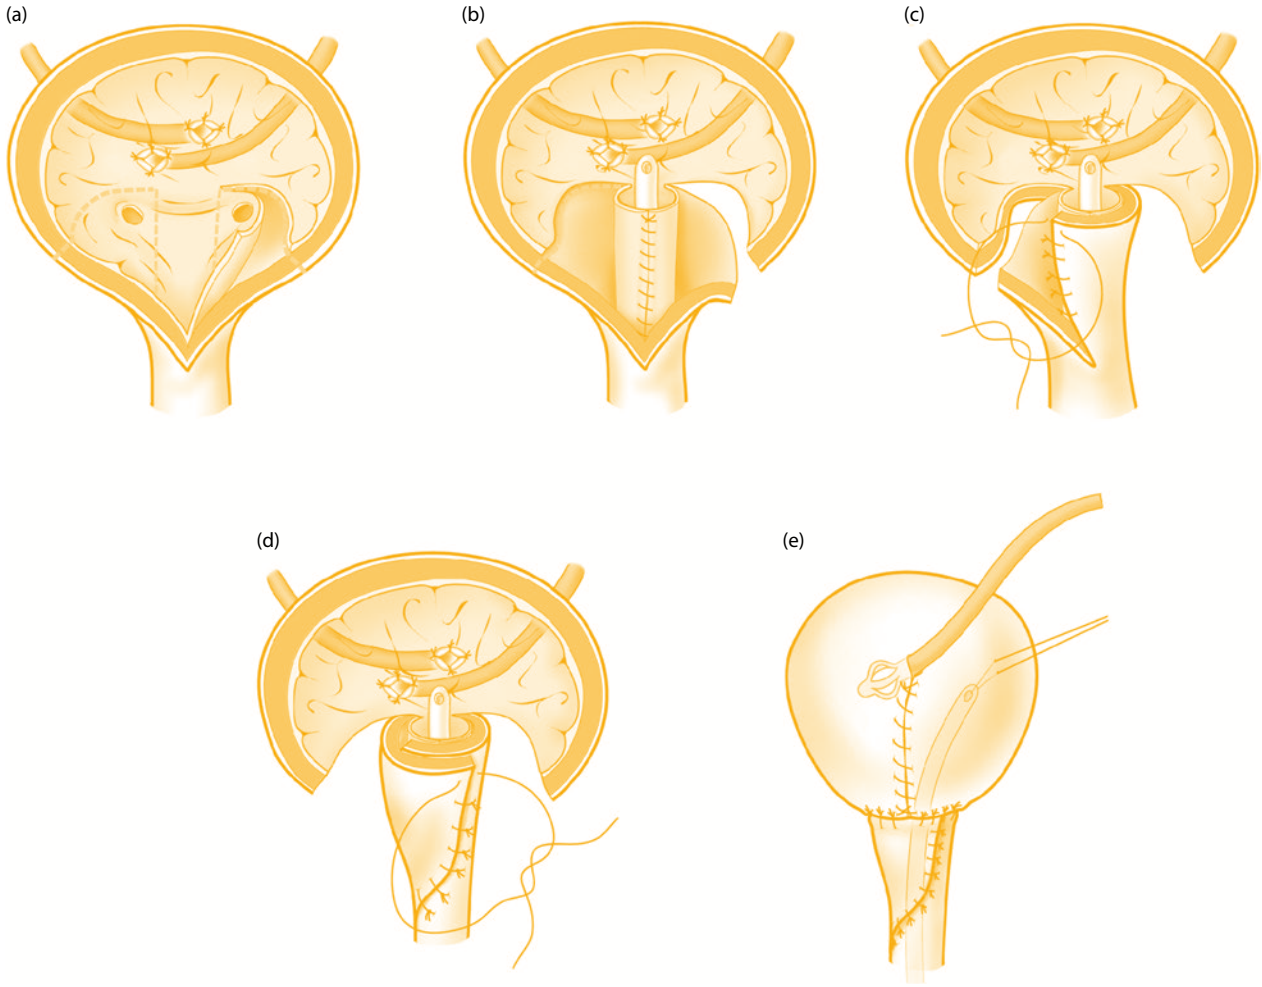

FIGURE 56.12 Leadbetter further improved on the Young–Dees bladder neck repair by moving the ureters to a new location higher along the posterior bladder wall and away from the urethra. This maneuver allowed the posterior bladder strip to be even longer and produce a long neourethra and a much higher bladder neck. (a and b) Leadbetter removed the mucosa from the triangular flaps of bladder muscle on each side of the mucosal strip that was to be used for the neourethra. (c) After rolling the strip into a tube for the neourethra, he closed the lateral muscle flaps over the neourethra in layers to provide even more muscle at the bladder outlet. (d) Muscle is rotated over the neourethra in an overlapping fashion. (e) Dependable bladder drainage is necessary.

Tanagho Bladder Neck Repair

In 1968, Tanagho was studying function and anatomy of bladder muscle when he noticed "a condensation of circle fibers above the internal meatus."[110] He then designed the first anterior bladder tube repair for incontinence and perfected it in dogs.[111] Three years later, he presented his experience in patients, including postprostatectomy adults.[112]

Tanagho intended to capture the muscle fibers of the anterior bladder and incorporate them into the bladder neck. He created a bladder-based flap from the anterior bladder just proximal to the urethra and rolled it into a tube for the neourethra (Figure 56.18). He then divided the urethra from the original bladder neck and anastomosed the neourethra to the native urethra end to end. The effect of this maneuver was to lengthen the urethra and create a new, more cephalad bladder neck.

Tanagho achieved a 72% continence rate and patients voided well. He compared his long-term results in 50 patients with the YDL procedure performed in 25 patients and found a 70% success with the Tanagho anterior bladder tube compared with 52% with the YDL posterior tube.[113] One advantage of Tanagho's bladder-based anterior flap was its applicability to short urethras, as demonstrated by Diamond and Ransley in urogenital sinus patients.[114]

This application remains as the most likely used of the Tanagho repair in children today. Disadvantages include the necessity to divide the bladder from the urethra, possibly resulting in difficult catheterization, and loss of bladder volume.

Kropp Bladder Neck Repair

In 1972, Jack Lapides made a contribution that forever changed our attitude and approach toward incontinence surgery.[115] His introduction of CIC controlled infection decreased bladder pressure and made many patients continent without further surgery.[116] CIC made voiding an option rather than a requirement, and changed the goals and results of incontinence surgery.

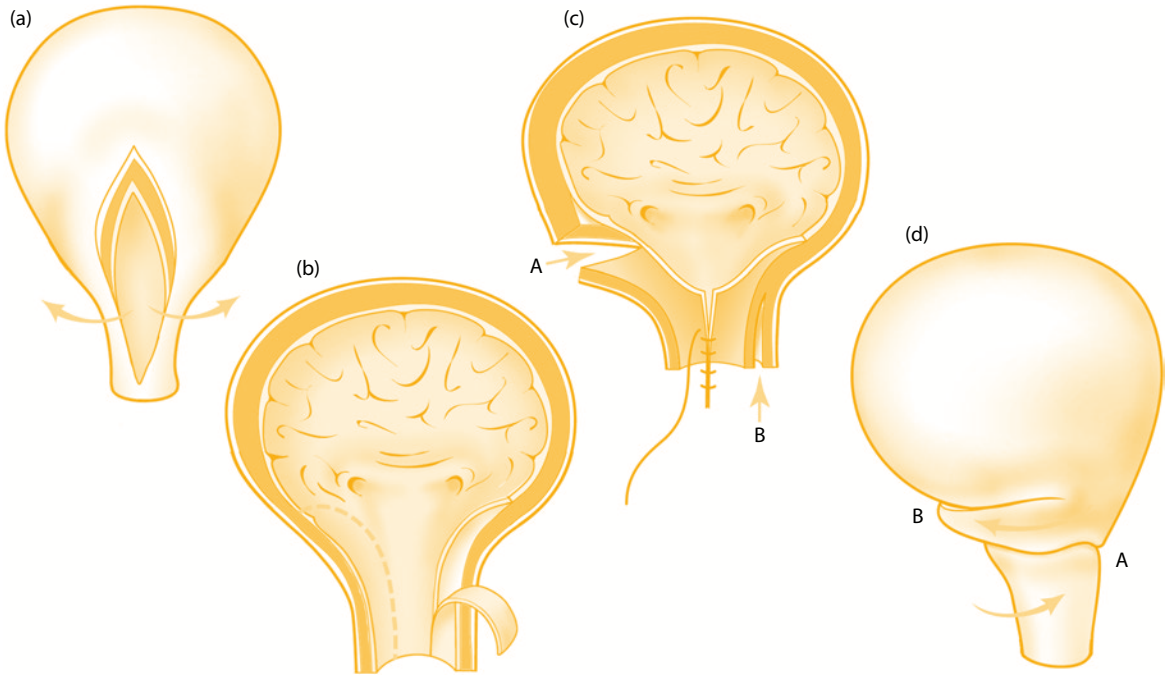

FIGURE 56.13 Mollard's variation of the YDL procedure is similar in its construction of the neourethra from a long posterior strip of urethra and bladder. It differs in that one of the two triangular flaps is incised vertically and parallel to the neourethra. This flap is then rotated horizontally across the midline to create an angle of the anterior bladder neck. (a) The bladder is opened in the midline. (b) The mucosa lateral to the central urethal strip is excised. (c) The two lateral muscle flaps are incised, one vertically and one horizontally. (d) Flap A is wrapped around the neourethra like the YDL operation, while flap B is rotated horizontally across the repair to create an anterior bladder neck.

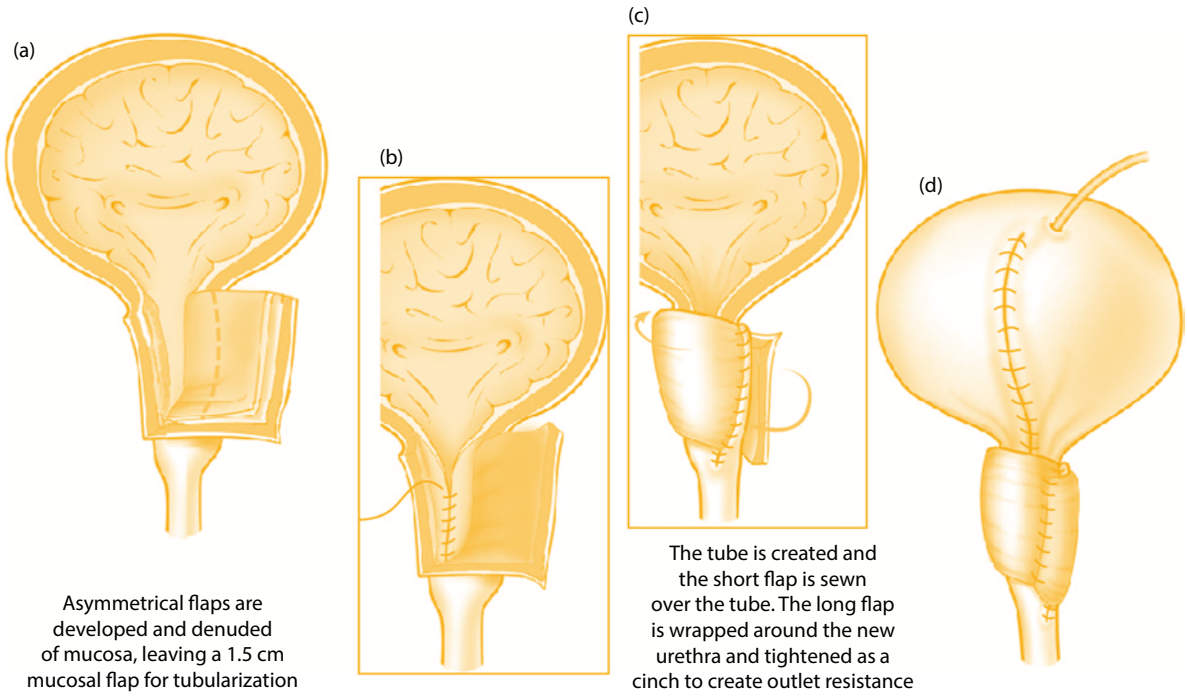

FIGURE 56.14 Koff's variation of the YDL procedure also creates the neourethra from a posterior flap of urethra and bladder and covers it with a flap of demucosalized muscle. The construction of this flap is different from other repairs that rely on two flaps. Koff makes a lateral incision of the bladder neck instead of opening the midline. This creates a single long flap on one side of the neourethra. The flap is then wrapped around the neourethra and sewn to itself with permanent sutures. It acts as a constant compression of the bladder outlet. (a) The bladder outlet is opened on one side. (b) A midline mucosal strip is tubularized, and the mucosa is dissected from the remaining muscle flap. (c and d) The muscle flap is then rotated around the bladder outlet.

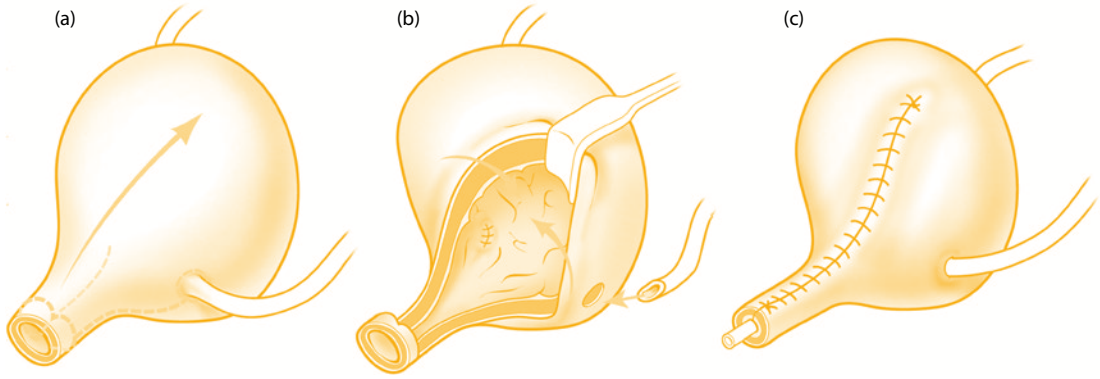

FIGURE 56.15 Mitchell returned to Young's original concept of a narrowed bladder neck that is not reinforced with additional muscle layers. His repair mobilizes a triangular flap of anterior bladder and urethra based on the bladder-side blood supply and then rotates the flap into the bladder. It is the only repair that does not decrease bladder volume. (a) An incision is made across the anterior urethra, extending up along the posterior lateral wall of the bladder outlet on each side. (b) The flap of bladder and urethra is rotated back into the bladder. (c) The incision is closed in the midline.

Kropp was the first surgeon to develop a new bladder neck reconstruction designed to take full advantage of CIC.[117] The goals of the surgery had changed. Dryness was foremost, and voiding was no longer a consideration. CIC had been used in patients with other forms of bladder neck reconstruction before this, but they were all procedures that allowed the patient to void, at least in theory. The Kropp procedure was the first to preclude voiding.

The Kropp procedure uses a full-thickness flap of anterior bladder muscle. This flap is based on the urethra, unlike Tanagho's flap, which is based on the bladder. The full-thickness bladder flap is isolated from the bladder and rolled into a tube of the same diameter as the urethra. The tube is then reimplanted in a submucosal tunnel in the midline of the posterior bladder wall between the ureters (Figure 56.19).

Advantages of Kropp's reconstruction included a very high continence rate of 80%–94%.[118,119] Kropp's strict definition of continence has been complete dryness or rare leakage. The reoperation rate was high in the original series, but most secondary procedures involved the storage function of the bladder, and only 20% of patients required additional surgery to the bladder outlet. To facilitate storage and to compensate for bladder volume lost in construction of the tube, Kropp now suggests that all patients undergo a simultaneous bladder augmentation. There have been problems catheterizing through the repair, but the improvement of leaving lateral attachments at the bladder neck intact and not completely separating the neourethra from the bladder has minimized this difficulty.

In 1997, Snodgrass reported a series of 22 children treated with the modified Kropp procedure described by Belman and Kaplan.[119,120] Snodgrass created a urethral-based flap of anterior bladder wall and rolled it into a tube. He did not divide the bladder neck from the remainder of the bladder. The posterior bladder mucosa is then incised in the midline to create a trough, and the tube is laid in this trough with the mucosa closed over the tube

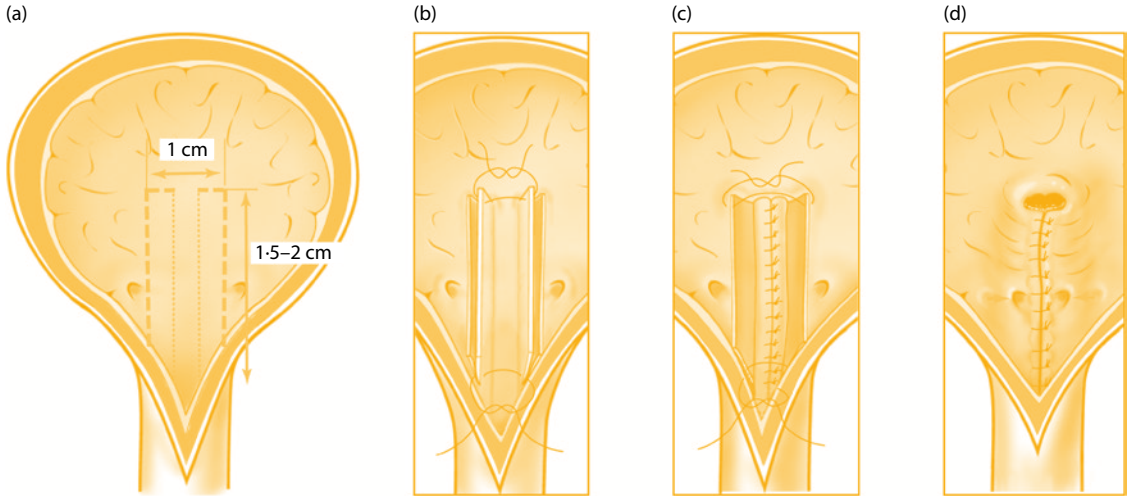

FIGURE 56.16 Koyle presented a bladder neck reconfiguration that isolates a strip of posterior mucosa in the posterior midline of the bladder. This strip is then rolled into a tube, creating a neourethra. Finally, the neourethra is covered with flaps of muscle and mucosa that have been mobilized lateral to the neourethra. (a) A mucosal flap is outlined. (b) The flap is then tubularized. (c) A second layer of muscle is closed. (d) Lateral mucosa is closed over the tube.

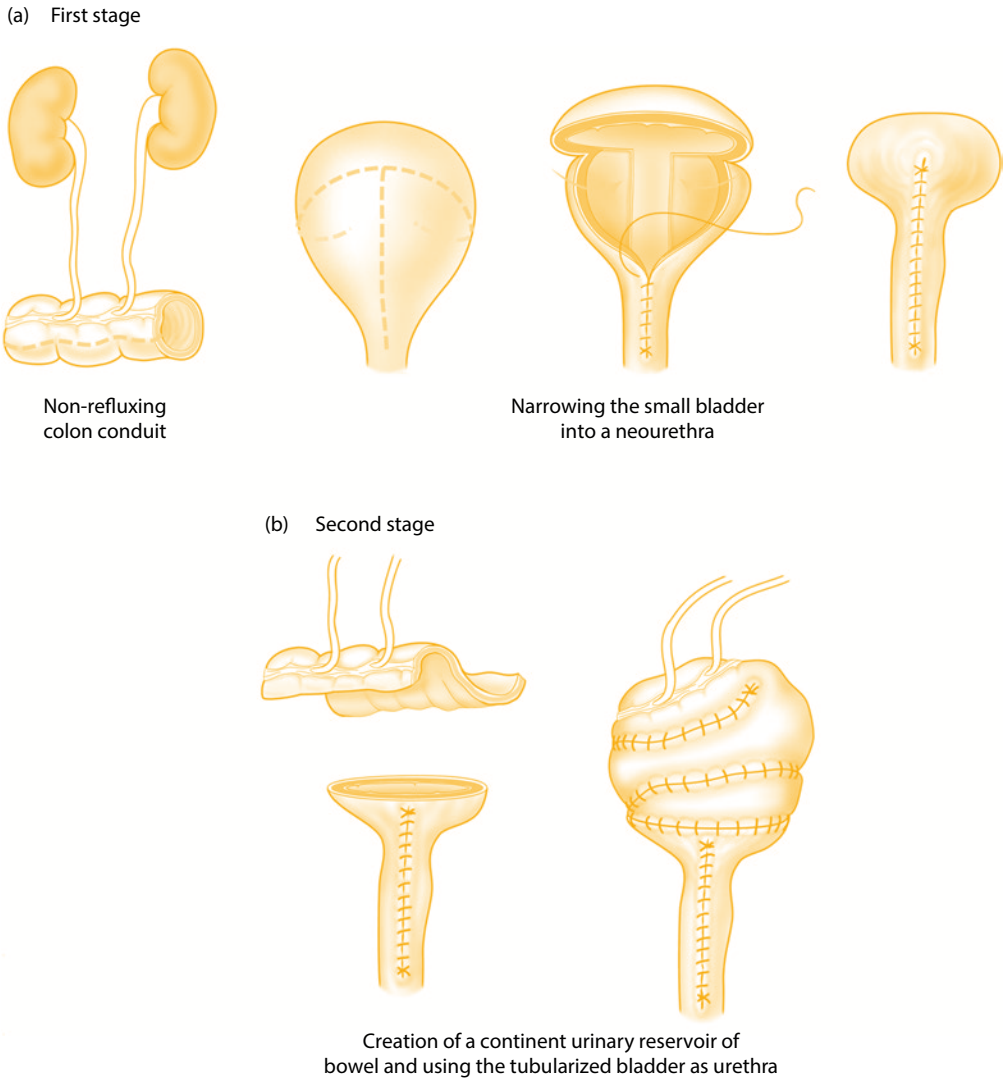

FIGURE 56.17 Arap's staged bladder reconstruction is the most radical reconfiguration of the bladder outlet. In the first stage, the ureters are transplanted from the bladder plate to a nonrefluxing anastomosis into a colon conduit. The second procedure creates a neourethra from the entire bladder except for the dome, which is left open as a wide funnel. The colon conduit is then reconfigured as a reservoir and sewn to the funneled bladder.

(Figure 56.20). No attempt is made to tunnel the tube. He reported a 91% continence rate, defined as dry intervals of 3 hours. Snodgrass notes that these patients are socially continent and will have slight leakage when catheterization is delayed. Bladder augmentation was performed in 91% of his patients at the same time as bladder outlet surgery. Just as in the original Kropp procedure, voiding is impossible.

Pippi Salle Bladder Neck Repair

Pippi Salle developed a bladder outlet repair for incontinence by creating a neourethra composed of both anterior and posterior bladder flaps.[121] This flap valve continence mechanism produces the only neourethra made of two separate flaps. Both anterior and posterior strips of bladder are isolated, and the anterior flap is completely mobilized as a flap based on the urethra. The posterior flap is outlined with two parallel mucosal incisions, and the posterior bladder muscle is left intact. The anterior bladder flap is then flipped down to oppose the posterior flap at the level of the posterior bladder wall. The two flaps are sewn together, creating a neourethra, which extends above the level of the ureters (Figure 56.21). Mucosa on either side of the strip of posterior bladder wall is mobilized, and the muscle from the anterior strip is sewn to the muscle of the posterior bladder. The complete-thickness bladder tube is then covered with the previously mobilized bladder mucosa just lateral to the tube.

The Pippi Salle repair produces continence rates of 80%, and this repair is easy to catheterize primarily because the posterior wall remains intact.[122] Bladder volume is decreased by the use of bladder wall to create the continence mechanism. This repair also requires the patient to catheterize, as voiding is impossible. McLorie and Khoury have warned about the potential danger of damaging the blood supply while isolating the long, thin anterior bladder flap.[123]

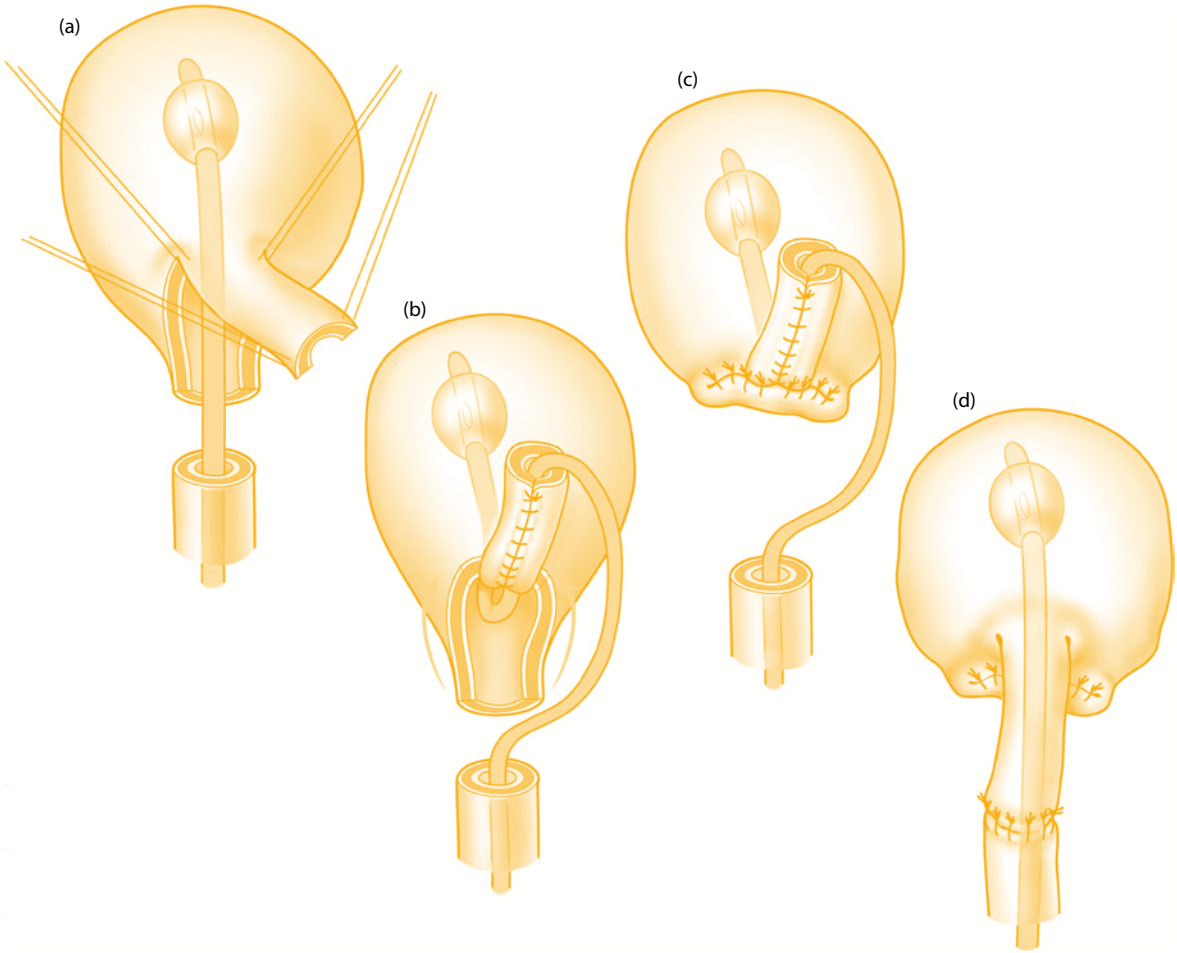

FIGURE 56.18 Tanagho's procedure created a neourethra from a strip of the anterior bladder neck and bladder. This allowed the creation of an angle at the posterior bladder neck. It required complete separation of the bladder from the urethra and a reanastomosis of the neourethra to the native urethra. (a) The bladder outlet is divided from the urethra and an anterior bladder-based tube is formed. (b) The flap is tubularized. (c) The posterior bladder is closed. (d) The tube is sewn to the urethra.

Bladder Neck Closure
